.NET defines a set of standard format specifiers for all numeric types, all date and time types, and all enumeration types. For example, each of these categories supports a "G" standard format specifier, which defines a general string representation of a value of that type.

Standard format strings for enumeration types directly control the string representation of a value. The format strings passed to an enumeration value's `ToString` method determine whether the value is displayed using its string name (the "G" and "F" format specifiers), its underlying integral value (the "D" format specifier), or its hexadecimal value (the "X" format specifier). The following example illustrates the use of standard format strings to format a `DayOfWeek` enumeration value.

C#

```
DayOfWeek thisDay = DayOfWeek.Monday;
string[] formatStrings = {"G", "F", "D", "X"};

foreach (string formatString in formatStrings)
    Console.WriteLine(thisDay.ToString(formatString));
// The example displays the following output:
//      Monday
//      Monday
//      1
//      00000001
```

For information about enumeration format strings, see [Enumeration Format Strings](#).

Standard format strings for numeric types usually define a result string whose precise appearance is controlled by one or more property values. For example, the "C" format specifier formats a number as a currency value. When you call the `ToString` method with the "C" format specifier as the only parameter, the following property values from the current culture's `NumberFormatInfo` object are used to define the string representation of the numeric value:

- The `CurrencySymbol` property, which specifies the current culture's currency symbol.

- The [CurrencyNegativePattern](#) or [CurrencyPositivePattern](#) property, which returns an integer that determines the following:
 - The placement of the currency symbol.
 - Whether negative values are indicated by a leading negative sign, a trailing negative sign, or parentheses.
 - Whether a space appears between the numeric value and the currency symbol.
- The [CurrencyDecimalDigits](#) property, which defines the number of fractional digits in the result string.
- The [CurrencyDecimalSeparator](#) property, which defines the decimal separator symbol in the result string.
- The [CurrencyGroupSeparator](#) property, which defines the group separator symbol.
- The [CurrencyGroupSizes](#) property, which defines the number of digits in each group to the left of the decimal.
- The [NegativeSign](#) property, which determines the negative sign used in the result string if parentheses are not used to indicate negative values.

In addition, numeric format strings may include a precision specifier. The meaning of this specifier depends on the format string with which it is used, but it typically indicates either the total number of digits or the number of fractional digits that should appear in the result string. For example, the following example uses the "X4" standard numeric string and a precision specifier to create a string value that has four hexadecimal digits.

C#

```
byte[] byteValues = { 12, 163, 255 };
foreach (byte byteValue in byteValues)
    Console.WriteLine(byteValue.ToString("X4"));
// The example displays the following output:
//      000C
//      00A3
//      00FF
```

For more information about standard numeric formatting strings, see [Standard Numeric Format Strings](#).

Standard format strings for date and time values are aliases for custom format strings stored by a particular [DateTimeFormatInfo](#) property. For example, calling the `ToString` method of a date and time value with the "D" format specifier displays the date and

time by using the custom format string stored in the current culture's `DateFormatInfo.LongDatePattern` property. (For more information about custom format strings, see the [next section](#).) The following example illustrates this relationship.

C#

```
using System;
using System.Globalization;

public class Example
{
    public static void Main()
    {
        DateTime date1 = new DateTime(2009, 6, 30);
        Console.WriteLine("D Format Specifier: {0:D}", date1);
        string longPattern =
CultureInfo.CurrentCulture.DateTimeFormat.LongDatePattern;
        Console.WriteLine("{0}' custom format string: {1}",
                           longPattern, date1.ToString(longPattern));
    }
}
// The example displays the following output when run on a system whose
// current culture is en-US:
//      D Format Specifier: Tuesday, June 30, 2009
//      'ddd, MMMM dd, yyyy' custom format string: Tuesday, June 30, 2009
```

For more information about standard date and time format strings, see [Standard Date and Time Format Strings](#).

You can also use standard format strings to define the string representation of an application-defined object that is produced by the object's `ToString(String)` method.

You can define the specific standard format specifiers that your object supports, and you can determine whether they are case-sensitive or case-insensitive. Your implementation of the `ToString(String)` method should support the following:

- A "G" format specifier that represents a customary or common format of the object. The parameterless overload of your object's `ToString` method should call its `ToString(String)` overload and pass it the "G" standard format string.
- Support for a format specifier that is equal to a null reference (`Nothing` in Visual Basic). A format specifier that is equal to a null reference should be considered equivalent to the "G" format specifier.

For example, a `Temperature` class can internally store the temperature in degrees Celsius and use format specifiers to represent the value of the `Temperature` object in degrees Celsius, degrees Fahrenheit, and kelvins. The following example provides an illustration.

C#

```
using System;

public class Temperature
{
    private decimal m_Temp;

    public Temperature(decimal temperature)
    {
        this.m_Temp = temperature;
    }

    public decimal Celsius
    {
        get { return this.m_Temp; }
    }

    public decimal Kelvin
    {
        get { return this.m_Temp + 273.15m; }
    }

    public decimal Fahrenheit
    {
        get { return Math.Round(((decimal) (this.m_Temp * 9 / 5 + 32)), 2); }
    }

    public override string ToString()
    {
        return this.ToString("C");
    }

    public string ToString(string format)
    {
        // Handle null or empty string.
        if (String.IsNullOrEmpty(format)) format = "C";
        // Remove spaces and convert to uppercase.
        format = format.Trim().ToUpperInvariant();

        // Convert temperature to Fahrenheit and return string.
        switch (format)
        {
            // Convert temperature to Fahrenheit and return string.
            case "F":
                return this.Fahrenheit.ToString("N2") + " °F";
            // Convert temperature to Kelvin and return string.
            case "K":
                return this.Kelvin.ToString("N2") + " K";
            // return temperature in Celsius.
            case "G":
            case "C":
                return this.Celsius.ToString("N2") + " °C";
            default:
```

```

        throw new FormatException(String.Format("The '{0}' format string
is not supported.", format));
    }
}
}

public class Example1
{
    public static void Main()
    {
        Temperature temp1 = new Temperature(0m);
        Console.WriteLine(temp1.ToString());
        Console.WriteLine(temp1.ToString("G"));
        Console.WriteLine(temp1.ToString("C"));
        Console.WriteLine(temp1.ToString("F"));
        Console.WriteLine(temp1.ToString("K"));

        Temperature temp2 = new Temperature(-40m);
        Console.WriteLine(temp2.ToString());
        Console.WriteLine(temp2.ToString("G"));
        Console.WriteLine(temp2.ToString("C"));
        Console.WriteLine(temp2.ToString("F"));
        Console.WriteLine(temp2.ToString("K"));

        Temperature temp3 = new Temperature(16m);
        Console.WriteLine(temp3.ToString());
        Console.WriteLine(temp3.ToString("G"));
        Console.WriteLine(temp3.ToString("C"));
        Console.WriteLine(temp3.ToString("F"));
        Console.WriteLine(temp3.ToString("K"));

        Console.WriteLine(String.Format("The temperature is now {0:F}.", 
temp3));
    }
}

// The example displays the following output:
//      0.00 °C
//      0.00 °C
//      0.00 °C
//      32.00 °F
//      273.15 K
//      -40.00 °C
//      -40.00 °C
//      -40.00 °F
//      233.15 K
//      16.00 °C
//      16.00 °C
//      16.00 °C
//      60.80 °F
//      289.15 K
//      The temperature is now 16.00 °C.

```

Custom format strings

In addition to the standard format strings, .NET defines custom format strings for both numeric values and date and time values. A custom format string consists of one or more custom format specifiers that define the string representation of a value. For example, the custom date and time format string "yyyy/mm/dd hh:mm:ss.ffff t zzz" converts a date to its string representation in the form "2008/11/15 07:45:00.0000 P -08:00" for the en-US culture. Similarly, the custom format string "0000" converts the integer value 12 to "0012". For a complete list of custom format strings, see [Custom Date and Time Format Strings](#) and [Custom Numeric Format Strings](#).

If a format string consists of a single custom format specifier, the format specifier should be preceded by the percent (%) symbol to avoid confusion with a standard format specifier. The following example uses the "M" custom format specifier to display a one-digit or two-digit number of the month of a particular date.

C#

```
DateTime date1 = new DateTime(2009, 9, 8);
Console.WriteLine(date1.ToString("%M"));           // Displays 9
```

Many standard format strings for date and time values are aliases for custom format strings that are defined by properties of the [DateTimeFormatInfo](#) object. Custom format strings also offer considerable flexibility in providing application-defined formatting for numeric values or date and time values. You can define your own custom result strings for both numeric values and date and time values by combining multiple custom format specifiers into a single custom format string. The following example defines a custom format string that displays the day of the week in parentheses after the month name, day, and year.

C#

```
string customFormat = "MMMM dd, yyyy (dddd)";
DateTime date1 = new DateTime(2009, 8, 28);
Console.WriteLine(date1.ToString(customFormat));
// The example displays the following output if run on a system
// whose language is English:
//     August 28, 2009 (Friday)
```

The following example defines a custom format string that displays an [Int64](#) value as a standard, seven-digit U.S. telephone number along with its area code.

C#

```

using System;

public class Example17
{
    public static void Main()
    {
        long number = 800999999;
        string fmt = "000-000-0000";
        Console.WriteLine(number.ToString(fmt));
    }
}
// The example displays the following output:
//      800-999-9999

```

Although standard format strings can generally handle most of the formatting needs for your application-defined types, you may also define custom format specifiers to format your types.

Format strings and .NET types

All numeric types (that is, the [Byte](#), [Decimal](#), [Double](#), [Int16](#), [Int32](#), [Int64](#), [SByte](#), [Single](#), [UInt16](#), [UInt32](#), [UInt64](#), and [BigInteger](#) types), as well as the [DateTime](#), [DateTimeOffset](#), [TimeSpan](#), [Guid](#), and all enumeration types, support formatting with format strings. For information on the specific format strings supported by each type, see the following topics:

| Title | Definition |
|---|---|
| Standard Numeric Format Strings | Describes standard format strings that create commonly used string representations of numeric values. |
| Custom Numeric Format Strings | Describes custom format strings that create application-specific formats for numeric values. |
| Standard Date and Time Format Strings | Describes standard format strings that create commonly used string representations of DateTime and DateTimeOffset values. |
| Custom Date and Time Format Strings | Describes custom format strings that create application-specific formats for DateTime and DateTimeOffset values. |
| Standard TimeSpan Format Strings | Describes standard format strings that create commonly used string representations of time intervals. |
| Custom TimeSpan Format Strings | Describes custom format strings that create application-specific formats for time intervals. |
| Enumeration Format Strings | Describes standard format strings that are used to create string |

| Title | Definition |
|-----------------------|--|
| | representations of enumeration values. |
| Guid.ToString(String) | Describes standard format strings for Guid values. |

Culture-sensitive formatting with format providers

Although format specifiers let you customize the formatting of objects, producing a meaningful string representation of objects often requires additional formatting information. For example, formatting a number as a currency value by using either the "C" standard format string or a custom format string such as "\$ #,#.00" requires, at a minimum, information about the correct currency symbol, group separator, and decimal separator to be available to include in the formatted string. In .NET, this additional formatting information is made available through the [IFormatProvider](#) interface, which is provided as a parameter to one or more overloads of the `ToString` method of numeric types and date and time types. [IFormatProvider](#) implementations are used in .NET to support culture-specific formatting. The following example illustrates how the string representation of an object changes when it is formatted with three [IFormatProvider](#) objects that represent different cultures.

C#

```
using System;
using System.Globalization;

public class Example18
{
    public static void Main()
    {
        decimal value = 1603.42m;
        Console.WriteLine(value.ToString("C3", new CultureInfo("en-US")));
        Console.WriteLine(value.ToString("C3", new CultureInfo("fr-FR")));
        Console.WriteLine(value.ToString("C3", new CultureInfo("de-DE")));
    }
}
// The example displays the following output:
//      $1,603.420
//      1 603,420 €
//      1.603,420 €
```

The [IFormatProvider](#) interface includes one method, [GetFormat\(Type\)](#), which has a single parameter that specifies the type of object that provides formatting information. If the

method can provide an object of that type, it returns it. Otherwise, it returns a null reference (`Nothing` in Visual Basic).

[IFormatProvider.GetFormat](#) is a callback method. When you call a `ToString` method overload that includes an [IFormatProvider](#) parameter, it calls the [GetFormat](#) method of that [IFormatProvider](#) object. The [GetFormat](#) method is responsible for returning an object that provides the necessary formatting information, as specified by its `formatType` parameter, to the `ToString` method.

A number of formatting or string conversion methods include a parameter of type [IFormatProvider](#), but in many cases the value of the parameter is ignored when the method is called. The following table lists some of the formatting methods that use the parameter and the type of the [Type](#) object that they pass to the [IFormatProvider.GetFormat](#) method.

| Method | Type of <code>formatType</code> parameter |
|---|--|
| <code>ToString</code> method of numeric types | <code>System.Globalization.NumberFormatInfo</code> |
| <code>ToString</code> method of date and time types | <code>System.Globalization.DateTimeFormatInfo</code> |
| <code>String.Format</code> | <code>System.ICustomFormatter</code> |
| <code>StringBuilder.AppendFormat</code> | <code>System.ICustomFormatter</code> |

① Note

The `ToString` methods of the numeric types and date and time types are overloaded, and only some of the overloads include an [IFormatProvider](#) parameter. If a method does not have a parameter of type [IFormatProvider](#), the object that is returned by the [CultureInfo.CurrentCulture](#) property is passed instead. For example, a call to the default [Int32.ToString\(\)](#) method ultimately results in a method call such as the following: `Int32.ToString("G", System.Globalization.CultureInfo.CurrentCulture)`.

.NET provides three classes that implement [IFormatProvider](#):

- [DateTimeFormatInfo](#), a class that provides formatting information for date and time values for a specific culture. Its [IFormatProvider.GetFormat](#) implementation returns an instance of itself.
- [NumberFormatInfo](#), a class that provides numeric formatting information for a specific culture. Its [IFormatProvider.GetFormat](#) implementation returns an instance

of itself.

- **CultureInfo**. Its [IFormatProvider.GetFormat](#) implementation can return either a **NumberFormatInfo** object to provide numeric formatting information or a **DateTimeFormatInfo** object to provide formatting information for date and time values.

You can also implement your own format provider to replace any one of these classes. However, your implementation's [GetFormat](#) method must return an object of the type listed in the previous table if it has to provide formatting information to the [ToString](#) method.

Culture-sensitive formatting of numeric values

By default, the formatting of numeric values is culture-sensitive. If you do not specify a culture when you call a formatting method, the formatting conventions of the current culture are used. This is illustrated in the following example, which changes the current culture four times and then calls the [Decimal.ToString\(String\)](#) method. In each case, the result string reflects the formatting conventions of the current culture. This is because the [ToString](#) and [ToString\(String\)](#) methods wrap calls to each numeric type's [ToString\(String, IFormatProvider\)](#) method.

C#

```
using System.Globalization;

public class Example6
{
    public static void Main()
    {
        string[] cultureNames = { "en-US", "fr-FR", "es-MX", "de-DE" };
        Decimal value = 1043.17m;

        foreach (var cultureName in cultureNames) {
            // Change the current culture.
            CultureInfo.CurrentCulture =
            CultureInfo.CreateSpecificCulture(cultureName);
            Console.WriteLine($"The current culture is
{CultureInfo.CurrentCulture.Name}");
            Console.WriteLine(value.ToString("C2"));
            Console.WriteLine();
        }
    }
} // The example displays the following output:
//      The current culture is en-US
//      $1,043.17
//
```

```
//      The current culture is fr-FR
//      1 043,17 €
//
//      The current culture is es-MX
//      $1,043.17
//
//      The current culture is de-DE
//      1.043,17 €
```

You can also format a numeric value for a specific culture by calling a `ToString` overload that has a `provider` parameter and passing it either of the following:

- A `CultureInfo` object that represents the culture whose formatting conventions are to be used. Its `CultureInfo.GetFormat` method returns the value of the `CultureInfo.NumberFormat` property, which is the `NumberFormatInfo` object that provides culture-specific formatting information for numeric values.
- A `NumberFormatInfo` object that defines the culture-specific formatting conventions to be used. Its `GetFormat` method returns an instance of itself.

The following example uses `NumberFormatInfo` objects that represent the English (United States) and English (United Kingdom) cultures and the French and Russian neutral cultures to format a floating-point number.

C#

```
using System.Globalization;

public class Example7
{
    public static void Main()
    {
        double value = 1043.62957;
        string[] cultureNames = { "en-US", "en-GB", "ru", "fr" };

        foreach (string? name in cultureNames)
        {
            NumberFormatInfo nfi =
CultureInfo.CreateSpecificCulture(name).NumberFormat;
            Console.WriteLine("{0,-6} {1}", name + ":", value.ToString("N3",
nfi));
        }
    }
}
// The example displays the following output:
//      en-US: 1,043.630
//      en-GB: 1,043.630
//      ru:      1 043,630
//      fr:      1 043,630
```

Culture-sensitive formatting of date and time values

By default, the formatting of date and time values is culture-sensitive. If you do not specify a culture when you call a formatting method, the formatting conventions of the current culture are used. This is illustrated in the following example, which changes the current culture four times and then calls the [DateTime.ToString\(String\)](#) method. In each case, the result string reflects the formatting conventions of the current culture. This is because the [DateTime.ToString\(\)](#), [DateTime.ToString\(String\)](#), [DateTimeOffset.ToString\(\)](#), and [DateTimeOffset.ToString\(String\)](#) methods wrap calls to the [DateTime.ToString\(String, IFormatProvider\)](#) and [DateTimeOffset.ToString\(String, IFormatProvider\)](#) methods.

C#

```
using System.Globalization;

public class Example4
{
    public static void Main()
    {
        string[] cultureNames = { "en-US", "fr-FR", "es-MX", "de-DE" };
        DateTime dateToFormat = new DateTime(2012, 5, 28, 11, 30, 0);

        foreach (var cultureName in cultureNames) {
            // Change the current culture.
            CultureInfo.CurrentCulture =
            CultureInfo.CreateSpecificCulture(cultureName);
            Console.WriteLine($"The current culture is
{CultureInfo.CurrentCulture.Name}");
            Console.WriteLine(dateToFormat.ToString("F"));
            Console.WriteLine();
        }
    }
}

// The example displays the following output:
//      The current culture is en-US
//      Monday, May 28, 2012 11:30:00 AM
//
//      The current culture is fr-FR
//      lundi 28 mai 2012 11:30:00
//
//      The current culture is es-MX
//      lunes, 28 de mayo de 2012 11:30:00 a.m.
//
//      The current culture is de-DE
//      Montag, 28. Mai 2012 11:30:00
```

You can also format a date and time value for a specific culture by calling a [DateTime.ToString](#) or [DateTimeOffset.ToString](#) overload that has a `provider` parameter and passing it either of the following:

- A [CultureInfo](#) object that represents the culture whose formatting conventions are to be used. Its [CultureInfo.GetFormat](#) method returns the value of the [CultureInfo.DateTimeFormat](#) property, which is the [DateTimeFormatInfo](#) object that provides culture-specific formatting information for date and time values.
- A [DateTimeFormatInfo](#) object that defines the culture-specific formatting conventions to be used. Its [GetFormat](#) method returns an instance of itself.

The following example uses [DateTimeFormatInfo](#) objects that represent the English (United States) and English (United Kingdom) cultures and the French and Russian neutral cultures to format a date.

C#

```
using System.Globalization;

public class Example5
{
    public static void Main()
    {
        DateTime dat1 = new(2012, 5, 28, 11, 30, 0);
        string[] cultureNames = { "en-US", "en-GB", "ru", "fr" };

        foreach (var name in cultureNames) {
            DateTimeFormatInfo dtfi =
                CultureInfo.CreateSpecificCulture(name).DateTimeFormat;
            Console.WriteLine($"{name}: {dat1.ToString(dtfi)}");
        }
    }
}
// The example displays the following output:
//      en-US: 5/28/2012 11:30:00 AM
//      en-GB: 28/05/2012 11:30:00
//      ru: 28.05.2012 11:30:00
//      fr: 28/05/2012 11:30:00
```

The [IFormattable](#) interface

Typically, types that overload the [ToString](#) method with a format string and an [IFormatProvider](#) parameter also implement the [IFormattable](#) interface. This interface has a single member, [IFormattable.ToString\(String, IFormatProvider\)](#), that includes both a format string and a format provider as parameters.

Implementing the [IFormattable](#) interface for your application-defined class offers two advantages:

- Support for string conversion by the [Convert](#) class. Calls to the [Convert.ToString\(Object\)](#) and [Convert.ToString\(Object, IFormatProvider\)](#) methods call your [IFormattable](#) implementation automatically.
- Support for composite formatting. If a format item that includes a format string is used to format your custom type, the common language runtime automatically calls your [IFormattable](#) implementation and passes it the format string. For more information about composite formatting with methods such as [String.Format](#) or [Console.WriteLine](#), see the [Composite Formatting](#) section.

The following example defines a `Temperature` class that implements the [IFormattable](#) interface. It supports the "C" or "G" format specifiers to display the temperature in Celsius, the "F" format specifier to display the temperature in Fahrenheit, and the "K" format specifier to display the temperature in Kelvin.

C#

```
using System;
using System.Globalization;

namespace HotAndCold
{
    public class Temperature : IFormattable
    {
        private decimal m_Temp;

        public Temperature(decimal temperature)
        {
            this.m_Temp = temperature;
        }

        public decimal Celsius
        {
            get { return this.m_Temp; }
        }

        public decimal Kelvin
        {
            get { return this.m_Temp + 273.15m; }
        }

        public decimal Fahrenheit
        {
            get { return Math.Round((decimal)this.m_Temp * 9 / 5 + 32, 2); }
        }

        public override string ToString()
        {
            return this.ToString("G", null);
        }
    }
}
```

```

    }

    public string ToString(string format)
    {
        return this.ToString(format, null);
    }

    public string ToString(string format, IFormatProvider provider)
    {
        // Handle null or empty arguments.
        if (String.IsNullOrEmpty(format))
            format = "G";
        // Remove any white space and convert to uppercase.
        format = format.Trim().ToUpperInvariant();

        if (provider == null)
            provider = NumberFormatInfo.CurrentInfo;

        switch (format)
        {
            // Convert temperature to Fahrenheit and return string.
            case "F":
                return this.Fahrenheit.ToString("N2", provider) + °F";
            // Convert temperature to Kelvin and return string.
            case "K":
                return this.Kelvin.ToString("N2", provider) + "K";
            // Return temperature in Celsius.
            case "C":
            case "G":
                return this.Celsius.ToString("N2", provider) + °C";
            default:
                throw new FormatException(String.Format("The '{0}'"
format string is not supported.", format));
        }
    }
}

```

The following example instantiates a `Temperature` object. It then calls the `ToString` method and uses several composite format strings to obtain different string representations of a `Temperature` object. Each of these method calls, in turn, calls the `IFormattable` implementation of the `Temperature` class.

C#

```

public class Example11
{
    public static void Main()
    {
        CultureInfo.CurrentCulture = CultureInfo.GetCultureInfo("en-US");
        Temperature temp = new Temperature(22m);
        Console.WriteLine(Convert.ToString(temp, new CultureInfo("ja-JP")));
        Console.WriteLine("Temperature: {0}K", temp);
    }
}

```

```

        Console.WriteLine("Temperature: {0:F}", temp);
        Console.WriteLine(String.Format(new CultureInfo("fr-FR"),
"Temperature: {0:F}", temp));
    }
}
// The example displays the following output:
//      22.00°C
//      Temperature: 295.15K
//      Temperature: 71.60°F
//      Temperature: 71,60°F

```

Composite formatting

Some methods, such as [String.Format](#) and [StringBuilder.AppendFormat](#), support composite formatting. A composite format string is a kind of template that returns a single string that incorporates the string representation of zero, one, or more objects. Each object is represented in the composite format string by an indexed format item. The index of the format item corresponds to the position of the object that it represents in the method's parameter list. Indexes are zero-based. For example, in the following call to the [String.Format](#) method, the first format item, `{0:D}`, is replaced by the string representation of `thatDate`; the second format item, `{1}`, is replaced by the string representation of `item1`; and the third format item, `{2:C2}`, is replaced by the string representation of `item1.Value`.

C#

```

result = String.Format("On {0:d}, the inventory of {1} was worth {2:C2}.",
                      thatDate, item1, item1.Value);
Console.WriteLine(result);
// The example displays output like the following if run on a system
// whose current culture is en-US:
//      On 5/1/2009, the inventory of WidgetA was worth $107.44.

```

In addition to replacing a format item with the string representation of its corresponding object, format items also let you control the following:

- The specific way in which an object is represented as a string, if the object implements the [IFormattable](#) interface and supports format strings. You do this by following the format item's index with a `:` (colon) followed by a valid format string. The previous example did this by formatting a date value with the "d" (short date pattern) format string (for example, `{0:d}`) and by formatting a numeric value with the "C2" format string (for example, `{2:c2}` to represent the number as a currency value with two fractional decimal digits.

- The width of the field that contains the object's string representation, and the alignment of the string representation in that field. You do this by following the format item's index with a `,` (comma) followed the field width. The string is right-aligned in the field if the field width is a positive value, and it is left-aligned if the field width is a negative value. The following example left-aligns date values in a 20-character field, and it right-aligns decimal values with one fractional digit in an 11-character field.

C#

```
DateTime startDate = new DateTime(2015, 8, 28, 6, 0, 0);
decimal[] temps = { 73.452m, 68.98m, 72.6m, 69.24563m,
                    74.1m, 72.156m, 72.228m };
Console.WriteLine("{0,-20} {1,11}\n", "Date", "Temperature");
for (int ctr = 0; ctr < temps.Length; ctr++)
    Console.WriteLine("{0,-20:g} {1,11:N1}", startDate.AddDays(ctr),
                      temps[ctr]);

// The example displays the following output:
//          Date                  Temperature
//
//        8/28/2015 6:00 AM      73.5
//        8/29/2015 6:00 AM      69.0
//        8/30/2015 6:00 AM      72.6
//        8/31/2015 6:00 AM      69.2
//        9/1/2015 6:00 AM       74.1
//        9/2/2015 6:00 AM       72.2
//        9/3/2015 6:00 AM       72.2
```

Note that, if both the alignment string component and the format string component are present, the former precedes the latter (for example, `{0,-20:g}`).

For more information about composite formatting, see [Composite Formatting](#).

Custom formatting with `ICustomFormatter`

Two composite formatting methods, `String.Format(IFormatProvider, String, Object[])` and `StringBuilder.AppendFormat(IFormatProvider, String, Object[])`, include a format provider parameter that supports custom formatting. When either of these formatting methods is called, it passes a `Type` object that represents an `ICustomFormatter` interface to the format provider's `GetFormat` method. The `GetFormat` method is then responsible for returning the `ICustomFormatter` implementation that provides custom formatting.

The `ICustomFormatter` interface has a single method, `Format(String, Object, IFormatProvider)`, that is called automatically by a composite formatting method, once for each format item in a composite format string. The `Format(String, Object,`

`IFormatProvider`) method has three parameters: a format string, which represents the `formatString` argument in a format item, an object to format, and an `IFormatProvider` object that provides formatting services. Typically, the class that implements `ICustomFormatter` also implements `IFormatProvider`, so this last parameter is a reference to the custom formatting class itself. The method returns a custom formatted string representation of the object to be formatted. If the method cannot format the object, it should return a null reference (`Nothing` in Visual Basic).

The following example provides an `ICustomFormatter` implementation named `ByteByByteFormatter` that displays integer values as a sequence of two-digit hexadecimal values followed by a space.

C#

```
public class ByteByByteFormatter : IFormatProvider, ICustomFormatter
{
    public object GetFormat(Type formatType)
    {
        if (formatType == typeof(ICustomFormatter))
            return this;
        else
            return null;
    }

    public string Format(string format, object arg,
                         IFormatProvider formatProvider)
    {
        if (!formatProvider.Equals(this)) return null;

        // Handle only hexadecimal format string.
        if (!format.StartsWith("X")) return null;

        byte[] bytes;
        string output = null;

        // Handle only integral types.
        if (arg is Byte)
            bytes = BitConverter.GetBytes((Byte) arg);
        else if (arg is Int16)
            bytes = BitConverter.GetBytes((Int16) arg);
        else if (arg is Int32)
            bytes = BitConverter.GetBytes((Int32) arg);
        else if (arg is Int64)
            bytes = BitConverter.GetBytes((Int64) arg);
        else if (arg is SByte)
            bytes = BitConverter.GetBytes((SByte) arg);
        else if (arg is UInt16)
            bytes = BitConverter.GetBytes((UInt16) arg);
        else if (arg is UInt32)
            bytes = BitConverter.GetBytes((UInt32) arg);
        else if (arg is UInt64)
```

```

        bytes = BitConverter.GetBytes((UInt64) arg);
    else
        return null;

    for (int ctr = bytes.Length - 1; ctr >= 0; ctr--)
        output += String.Format("{0:X2} ", bytes[ctr]);

    return output.Trim();
}
}

```

The following example uses the `ByteByByteFormatter` class to format integer values. Note that the `ICustomFormatter.Format` method is called more than once in the second `String.Format(IFormatProvider, String, Object[])` method call, and that the default `NumberFormatInfo` provider is used in the third method call because the `.ByteByByteFormatter.Format` method does not recognize the "N0" format string and returns a null reference (`Nothing` in Visual Basic).

C#

```

public class Example10
{
    public static void Main()
    {
        long value = 3210662321;
        byte value1 = 214;
        byte value2 = 19;

        Console.WriteLine(String.Format(new ByteByByteFormatter(), "{0:X}",
value));
        Console.WriteLine(String.Format(new ByteByByteFormatter(), "{0:X} And
{1:X} = {2:X} ({2:000})", value1, value2, value1 & value2));
        Console.WriteLine(String.Format(new ByteByByteFormatter(), "
{0,10:N0}", value));
    }
}

// The example displays the following output:
//      00 00 00 00 BF 5E D1 B1
//      00 D6 And 00 13 = 00 12 (018)
//      3,210,662,321

```

Standard numeric format strings

Article • 04/25/2023

Standard numeric format strings are used to format common numeric types. A standard numeric format string takes the form `[format specifier][precision specifier]`, where:

- *Format specifier* is a single alphabetic character that specifies the type of number format, for example, currency or percent. Any numeric format string that contains more than one alphabetic character, including white space, is interpreted as a custom numeric format string. For more information, see [Custom numeric format strings](#).
- *Precision specifier* is an optional integer that affects the number of digits in the resulting string. In .NET 7 and later versions, the maximum precision value is 999,999,999. In .NET 6, the maximum precision value is `Int32.MaxValue`. In previous .NET versions, the precision can range from 0 to 99. The precision specifier controls the number of digits in the string representation of a number. It does not round the number itself. To perform a rounding operation, use the `Math.Ceiling`, `Math.Floor`, or `Math.Round` method.

When *precision specifier* controls the number of fractional digits in the result string, the result string reflects a number that is rounded to a representable result nearest to the infinitely precise result. If there are two equally near representable results:

- On .NET Framework and .NET Core up to .NET Core 2.0, the runtime selects the result with the greater least significant digit (that is, using `MidpointRounding.AwayFromZero`).
- On .NET Core 2.1 and later, the runtime selects the result with an even least significant digit (that is, using `MidpointRounding.ToEven`).

(!) Note

The precision specifier determines the number of digits in the result string. To pad a result string with leading or trailing spaces, use the [composite formatting](#) feature and define an *alignment component* in the format item.

Standard numeric format strings are supported by:

- Some overloads of the `ToString` method of all numeric types. For example, you can supply a numeric format string to the `Int32.ToString(String)` and `Int32.ToString(String, IFormatProvider)` methods.

- The `TryFormat` method of all numeric types, for example, `Int32.TryParse(Span<Char>, Int32, ReadOnlySpan<Char>, IFormatProvider)` and `Single.TryParse(Span<Char>, Int32, ReadOnlySpan<Char>, IFormatProvider)`.
- The .NET [composite formatting feature](#), which is used by some `Write` and `WriteLine` methods of the `Console` and `StreamWriter` classes, the `String.Format` method, and the `StringBuilder.AppendFormat` method. The composite format feature allows you to include the string representation of multiple data items in a single string, to specify field width, and to align numbers in a field. For more information, see [Composite Formatting](#).
- [Interpolated strings](#) in C# and Visual Basic, which provide a simplified syntax when compared to composite format strings.

Tip

You can download the [Formatting Utility](#), a .NET Core Windows Forms application that lets you apply format strings to either numeric or date and time values and displays the result string. Source code is available for [C#](#) and [Visual Basic](#).

Standard format specifiers

The following table describes the standard numeric format specifiers and displays sample output produced by each format specifier. See the [Notes](#) section for additional information about using standard numeric format strings, and the [Code example](#) section for a comprehensive illustration of their use.

The result of a formatted string for a specific culture might differ from the following examples. Operating system settings, user settings, environment variables, and the .NET version you're using can all affect the format. For example, starting with .NET 5, .NET tries to unify cultural formats across platforms. For more information, see [.NET globalization and ICU](#).

| Format specifier | Name | Description | Examples |
|------------------|--------|--|--|
| "B" or "b" | Binary | <p>Result: A binary string.</p> <p>Supported by: Integral types only (.NET 8+).</p> <p>Precision specifier: Number of digits in the result string.</p> | <p>42 ("B") -> 101010</p> <p>255 ("b16") -> 0000000011111111</p> |

| Format specifier | Name | Description | Examples |
|-------------------------|--------------------------|---|--|
| | | More information: The Binary ("B") Format Specifier . | |
| "C" or "c" | Currency | <p>Result: A currency value.</p> <p>Supported by: All numeric types.</p> <p>Precision specifier: Number of decimal digits.</p> <p>Default precision specifier: Defined by NumberFormatInfo.CurrencyDecimalDigits.</p> <p>More information: The Currency ("C") Format Specifier.</p> | 123.456 ("C", en-US) -> \$123.46 123.456 ("C", fr-FR) -> 123,46 € 123.456 ("C", ja-JP) -> ¥123 -123.456 ("C3", en-US) -> (\$123.456) -123.456 ("C3", fr-FR) -> -123,456 € -123.456 ("C3", ja-JP) -> -¥123.456 |
| "D" or "d" | Decimal | <p>Result: Integer digits with optional negative sign.</p> <p>Supported by: Integral types only.</p> <p>Precision specifier: Minimum number of digits.</p> <p>Default precision specifier: Minimum number of digits required.</p> <p>More information: The Decimal("D") Format Specifier.</p> | 1234 ("D") -> 1234 -1234 ("D6") -> -001234 |
| "E" or "e" | Exponential (scientific) | <p>Result: Exponential notation.</p> <p>Supported by: All numeric types.</p> <p>Precision specifier: Number of decimal digits.</p> <p>Default precision specifier: 6.</p> <p>More information: The Exponential ("E") Format Specifier.</p> | 1052.0329112756 ("E", en-US) -> 1.052033E+003 1052.0329112756 ("e", fr-FR) -> 1,052033e+003 -1052.0329112756 ("e2", en-US) -> -1.05e+003 |

| Format specifier | Name | Description | Examples |
|-------------------------|-------------|---|--|

| "F" or "f" | Fixed-point | <p>Result: Integral and decimal digits with optional negative sign.</p> <p>Supported by: All numeric types.</p> <p>Precision specifier: Number of decimal digits.</p> <p>Default precision specifier: Defined by NumberFormatInfo.NumberDecimalDigits.</p> <p>More information: The Fixed-Point ("F") Format Specifier.</p> | 1234.567 ("F", en-US) -> 1234.57 1234.567 ("F", de-DE) -> 1234,57 1234 ("F1", en-US) -> 1234.0 1234 ("F1", de-DE) -> 1234,0 -1234.56 ("F4", en-US) -> -1234.5600 -1234.56 ("F4", de-DE) -> -1234,5600 |
| "G" or "g" | General | <p>Result: The more compact of either fixed-point or scientific notation.</p> <p>Supported by: All numeric types.</p> <p>Precision specifier: Number of significant digits.</p> <p>Default precision specifier: Depends on numeric type.</p> <p>More information: The General ("G") Format Specifier.</p> | -123.456 ("G", en-US) -> -123.456 -123.456 ("G", sv-SE) -> -123,456 123.4546 ("G4", en-US) -> 123.5 123.4546 ("G4", sv-SE) -> 123,5 -1.234567890e-25 ("G", en-US) -> -1.23456789E-25 -1.234567890e-25 ("G", sv-SE) -> -1,23456789E-25 |
| "N" or "n" | Number | Result: Integral and decimal digits, group separators, and a decimal separator with optional negative sign. | 1234.567 ("N", en-US) -> 1,234.57 1234.567 ("N", ru-RU) |

| Format specifier | Name | Description | Examples |
|------------------|-------------|---|---|
| | | Supported by: All numeric types. | -> 1 234,57 |
| | | Precision specifier: Desired number of decimal places. | 1234 ("N1", en-US) -> 1,234.0 |
| | | Default precision specifier: Defined by NumberFormatInfo.NumberDecimalDigits . | 1234 ("N1", ru-RU) -> 1 234,0 |
| | | More information: The Numeric ("N") Format Specifier . | -1234.56 ("N3", en-US) -> -1,234.560 |
| | | | -1234.56 ("N3", ru-RU) -> -1 234,560 |
| "P" or "p" | Percent | Result: Number multiplied by 100 and displayed with a percent symbol. | 1 ("P", en-US) -> 100.00 % |
| | | Supported by: All numeric types. | 1 ("P", fr-FR) -> 100,00 % |
| | | Precision specifier: Desired number of decimal places. | -0.39678 ("P1", en-US) -> -39.7 % |
| | | Default precision specifier: Defined by NumberFormatInfo.PercentDecimalDigits . | -0.39678 ("P1", fr-FR) -> -39,7 % |
| | | More information: The Percent ("P") Format Specifier . | |
| "R" or "r" | Round-trip | Result: A string that can round-trip to an identical number. Supported by: Single , Double , and BigInteger . Note: Recommended for the BigInteger type only. For Double types, use "G17"; for Single types, use "G9". Precision specifier: Ignored. | 123456789.12345678 ("R") -> 123456789.12345678 -1234567890.12345678 ("R") -> -1234567890.1234567 |
| | | More information: The Round-trip ("R") Format Specifier . | |
| "X" or "x" | Hexadecimal | Result: A hexadecimal string. Supported by: Integral types only. Precision specifier: Number of digits in the | 255 ("X") -> FF -1 ("x") -> ff |

| Format specifier | Name | Description | Examples |
|----------------------------|-------------------|--|---|
| | | <p>result string.</p> <p>More information: The Hexadecimal ("X") Format Specifier.</p> | 255 ("x4") -> 00ff -1 ("X4") -> 00FF |
| Any other single character | Unknown specifier | Result: Throws a FormatException at run time. | |

Use standard numeric format strings

ⓘ Note

The C# examples in this article run in the Try.NET inline code runner and playground. Select the **Run** button to run an example in an interactive window. Once you execute the code, you can modify it and run the modified code by selecting **Run** again. The modified code either runs in the interactive window or, if compilation fails, the interactive window displays all C# compiler error messages.

A standard numeric format string can be used to define the formatting of a numeric value in one of the following ways:

- It can be passed to the `TryFormat` method or an overload of the `ToString` method that has a `format` parameter. The following example formats a numeric value as a currency string in the current culture (in this case, the en-US culture).

C#

```
decimal value = 123.456m;
Console.WriteLine(value.ToString("C2"));
// Displays $123.46
```

- It can be supplied as the `formatString` argument in a format item used with such methods as `String.Format`, `Console.WriteLine`, and `StringBuilder.AppendFormat`. For more information, see [Composite Formatting](#). The following example uses a format item to insert a currency value in a string.

C#

```
decimal value = 123.456m;
Console.WriteLine("Your account balance is {0:C2}.", value);
// Displays "Your account balance is $123.46."
```

Optionally, you can supply an `alignment` argument to specify the width of the numeric field and whether its value is right- or left-aligned. The following example left-aligns a currency value in a 28-character field, and it right-aligns a currency value in a 14-character field.

C#

```
decimal[] amounts = { 16305.32m, 18794.16m };
Console.WriteLine("    Beginning Balance          Ending Balance");
Console.WriteLine("    {0,-28:C2}{1,14:C2}", amounts[0], amounts[1]);
// Displays:
//      Beginning Balance          Ending Balance
//      $16,305.32                $18,794.16
```

- It can be supplied as the `formatString` argument in an interpolated expression item of an interpolated string. For more information, see the [String interpolation](#) article in the C# reference or the [Interpolated strings](#) article in the Visual Basic reference.

The following sections provide detailed information about each of the standard numeric format strings.

Binary format specifier (B)

The binary ("B") format specifier converts a number to a string of binary digits. This format is supported only for integral types and only on .NET 8+.

The precision specifier indicates the minimum number of digits desired in the resulting string. If required, the number is padded with zeros to its left to produce the number of digits given by the precision specifier.

The result string is not affected by the formatting information of the current [NumberFormatInfo](#) object.

Currency format specifier (C)

The "C" (or currency) format specifier converts a number to a string that represents a currency amount. The precision specifier indicates the desired number of decimal places in the result string. If the precision specifier is omitted, the default precision is defined by the [NumberFormatInfo.CurrencyDecimalDigits](#) property.

If the value to be formatted has more than the specified or default number of decimal places, the fractional value is rounded in the result string. If the value to the right of the number of specified decimal places is 5 or greater, the last digit in the result string is rounded away from zero.

The result string is affected by the formatting information of the current [NumberFormatInfo](#) object. The following table lists the [NumberFormatInfo](#) properties that control the formatting of the returned string.

| NumberFormatInfo property | Description |
|--|---|
| CurrencyPositivePattern | Defines the placement of the currency symbol for positive values. |
| CurrencyNegativePattern | Defines the placement of the currency symbol for negative values, and specifies whether the negative sign is represented by parentheses or the NegativeSign property. |
| NegativeSign | Defines the negative sign used if CurrencyNegativePattern indicates that parentheses are not used. |
| CurrencySymbol | Defines the currency symbol. |
| CurrencyDecimalDigits | Defines the default number of decimal digits in a currency value. This value can be overridden by using the precision specifier. |
| CurrencyDecimalSeparator | Defines the string that separates integral and decimal digits. |
| CurrencyGroupSeparator | Defines the string that separates groups of integral numbers. |
| CurrencyGroupSizes | Defines the number of integer digits that appear in a group. |

The following example formats a [Double](#) value with the currency format specifier:

```
C#  
  
double value = 12345.6789;  
Console.WriteLine(value.ToString("C", CultureInfo.CurrentCulture));  
  
Console.WriteLine(value.ToString("C3", CultureInfo.CurrentCulture));  
  
Console.WriteLine(value.ToString("C3",  
        CultureInfo.CreateSpecificCulture("da-DK")));  
// The example displays the following output on a system whose
```

```
// current culture is English (United States):
//      $12,345.68
//      $12,345.679
//      12.345,679 kr
```

Decimal format specifier (D)

The "D" (or decimal) format specifier converts a number to a string of decimal digits (0-9), prefixed by a minus sign if the number is negative. This format is supported only for integral types.

The precision specifier indicates the minimum number of digits desired in the resulting string. If required, the number is padded with zeros to its left to produce the number of digits given by the precision specifier. If no precision specifier is specified, the default is the minimum value required to represent the integer without leading zeros.

The result string is affected by the formatting information of the current [NumberFormatInfo](#) object. As the following table shows, a single property affects the formatting of the result string.

| NumberFormatInfo property | Description |
|------------------------------|--|
| NegativeSign | Defines the string that indicates that a number is negative. |

The following example formats an [Int32](#) value with the decimal format specifier.

```
C#
int value;

value = 12345;
Console.WriteLine(value.ToString("D"));
// Displays 12345
Console.WriteLine(value.ToString("D8"));
// Displays 00012345

value = -12345;
Console.WriteLine(value.ToString("D"));
// Displays -12345
Console.WriteLine(value.ToString("D8"));
// Displays -00012345
```

Exponential format specifier (E)

The exponential ("E") format specifier converts a number to a string of the form "-d.ddd...E+ddd" or "-d.ddd...e+ddd", where each "d" indicates a digit (0-9). The string starts with a minus sign if the number is negative. Exactly one digit always precedes the decimal point.

The precision specifier indicates the desired number of digits after the decimal point. If the precision specifier is omitted, a default of six digits after the decimal point is used.

The case of the format specifier indicates whether to prefix the exponent with an "E" or an "e". The exponent always consists of a plus or minus sign and a minimum of three digits. The exponent is padded with zeros to meet this minimum, if required.

The result string is affected by the formatting information of the current [NumberFormatInfo](#) object. The following table lists the [NumberFormatInfo](#) properties that control the formatting of the returned string.

| NumberFormatInfo property | Description |
|--|--|
| NegativeSign | Defines the string that indicates that a number is negative for both the coefficient and exponent. |
| NumberDecimalSeparator | Defines the string that separates the integral digit from decimal digits in the coefficient. |
| PositiveSign | Defines the string that indicates that an exponent is positive. |

The following example formats a [Double](#) value with the exponential format specifier:

C#

```
double value = 12345.6789;
Console.WriteLine(value.ToString("E", CultureInfo.InvariantCulture));
// Displays 1.234568E+004

Console.WriteLine(value.ToString("E10", CultureInfo.InvariantCulture));
// Displays 1.2345678900E+004

Console.WriteLine(value.ToString("e4", CultureInfo.InvariantCulture));
// Displays 1.2346e+004

Console.WriteLine(value.ToString("E",
    CultureInfo.CreateSpecificCulture("fr-FR")));
// Displays 1,234568E+004
```

Fixed-point format specifier (F)

The fixed-point ("F") format specifier converts a number to a string of the form "-ddd.ddd..." where each "d" indicates a digit (0-9). The string starts with a minus sign if the number is negative.

The precision specifier indicates the desired number of decimal places. If the precision specifier is omitted, the current [NumberFormatInfo.NumberDecimalDigits](#) property supplies the numeric precision.

The result string is affected by the formatting information of the current [NumberFormatInfo](#) object. The following table lists the properties of the [NumberFormatInfo](#) object that control the formatting of the result string.

| NumberFormatInfo property | Description |
|--|--|
| NegativeSign | Defines the string that indicates that a number is negative. |
| NumberDecimalSeparator | Defines the string that separates integral digits from decimal digits. |
| NumberDecimalDigits | Defines the default number of decimal digits. This value can be overridden by using the precision specifier. |

The following example formats a [Double](#) and an [Int32](#) value with the fixed-point format specifier:

C#

```
int integerNumber;
integerNumber = 17843;
Console.WriteLine(integerNumber.ToString("F",
    CultureInfo.InvariantCulture));
// Displays 17843.00

integerNumber = -29541;
Console.WriteLine(integerNumber.ToString("F3",
    CultureInfo.InvariantCulture));
// Displays -29541.000

double doubleNumber;
doubleNumber = 18934.1879;
Console.WriteLine(doubleNumber.ToString("F", CultureInfo.InvariantCulture));
// Displays 18934.19

Console.WriteLine(doubleNumber.ToString("F0",
CultureInfo.InvariantCulture));
// Displays 18934

doubleNumber = -1898300.1987;
Console.WriteLine(doubleNumber.ToString("F1",
```

```

CultureInfo.InvariantCulture));
// Displays -1898300.2

Console.WriteLine(doubleNumber.ToString("F3",
    CultureInfo.CreateSpecificCulture("es-ES")));
// Displays -1898300,199

```

General format specifier (G)

The general ("G") format specifier converts a number to the more compact of either fixed-point or scientific notation, depending on the type of the number and whether a precision specifier is present. The precision specifier defines the maximum number of significant digits that can appear in the result string. If the precision specifier is omitted or zero, the type of the number determines the default precision, as indicated in the following table.

| Numeric type | Default precision |
|-----------------|---|
| Byte or SByte | 3 digits |
| Int16 or UInt16 | 5 digits |
| Int32 or UInt32 | 10 digits |
| Int64 | 19 digits |
| UInt64 | 20 digits |
| BigInteger | Unlimited (same as "R") |
| Half | Smallest round-trippable number of digits to represent the number |
| Single | Smallest round-trippable number of digits to represent the number (in .NET Framework, G7 is the default) |
| Double | Smallest round-trippable number of digits to represent the number (in .NET Framework, G15 is the default) |
| Decimal | Smallest round-trippable number of digits to represent the number |

Fixed-point notation is used if the exponent that would result from expressing the number in scientific notation is greater than -5 and less than the precision specifier; otherwise, scientific notation is used. The result contains a decimal point if required, and trailing zeros after the decimal point are omitted. If the precision specifier is present and

the number of significant digits in the result exceeds the specified precision, the excess trailing digits are removed by rounding.

However, if the number is a [Decimal](#) and the precision specifier is omitted, fixed-point notation is always used and trailing zeros are preserved.

If scientific notation is used, the exponent in the result is prefixed with "E" if the format specifier is "G", or "e" if the format specifier is "g". The exponent contains a minimum of two digits. This differs from the format for scientific notation that is produced by the exponential format specifier, which includes a minimum of three digits in the exponent.

When used with a [Double](#) value, the "G17" format specifier ensures that the original [Double](#) value successfully round-trips. This is because [Double](#) is an IEEE 754-2008-compliant double-precision (`binary64`) floating-point number that gives up to 17 significant digits of precision. On .NET Framework, we recommend its use instead of the "[R](#)" [format specifier](#), since in some cases "R" fails to successfully round-trip double-precision floating point values.

When used with a [Single](#) value, the "G9" format specifier ensures that the original [Single](#) value successfully round-trips. This is because [Single](#) is an IEEE 754-2008-compliant single-precision (`binary32`) floating-point number that gives up to nine significant digits of precision. For performance reasons, we recommend its use instead of the "[R](#)" [format specifier](#).

The result string is affected by the formatting information of the current [NumberFormatInfo](#) object. The following table lists the [NumberFormatInfo](#) properties that control the formatting of the result string.

| NumberFormatInfo property | Description |
|--|--|
| NegativeSign | Defines the string that indicates that a number is negative. |
| NumberDecimalSeparator | Defines the string that separates integral digits from decimal digits. |
| PositiveSign | Defines the string that indicates that an exponent is positive. |

The following example formats assorted floating-point values with the general format specifier:

C#

```
double number;  
  
number = 12345.6789;
```

```

Console.WriteLine(number.ToString("G", CultureInfo.InvariantCulture));
// Displays 12345.6789
Console.WriteLine(number.ToString("G",
                               CultureInfo.CreateSpecificCulture("fr-FR")));
// Displays 12345,6789

Console.WriteLine(number.ToString("G7", CultureInfo.InvariantCulture));
// Displays 12345.68

number = .0000023;
Console.WriteLine(number.ToString("G", CultureInfo.InvariantCulture));
// Displays 2.3E-06
Console.WriteLine(number.ToString("G",
                               CultureInfo.CreateSpecificCulture("fr-FR")));
// Displays 2,3E-06

number = .0023;
Console.WriteLine(number.ToString("G", CultureInfo.InvariantCulture));
// Displays 0.0023

number = 1234;
Console.WriteLine(number.ToString("G2", CultureInfo.InvariantCulture));
// Displays 1.2E+03

number = Math.PI;
Console.WriteLine(number.ToString("G5", CultureInfo.InvariantCulture));
// Displays 3.1416

```

Numeric format specifier (N)

The numeric ("N") format specifier converts a number to a string of the form "-d,ddd,ddd.ddd...", where "-" indicates a negative number symbol if required, "d" indicates a digit (0-9), "," indicates a group separator, and "." indicates a decimal point symbol. The precision specifier indicates the desired number of digits after the decimal point. If the precision specifier is omitted, the number of decimal places is defined by the current [NumberFormatInfo.NumberDecimalDigits](#) property.

The result string is affected by the formatting information of the current [NumberFormatInfo](#) object. The following table lists the [NumberFormatInfo](#) properties that control the formatting of the result string.

| NumberFormatInfo property | Description |
|---------------------------------------|--|
| NegativeSign | Defines the string that indicates that a number is negative. |
| NumberNegativePattern | Defines the format of negative values, and specifies whether the negative sign is represented by parentheses or the NegativeSign |

| NumberFormatInfo property | Description |
|--|--|
| | property. |
| NumberGroupSizes | Defines the number of integral digits that appear between group separators. |
| NumberGroupSeparator | Defines the string that separates groups of integral numbers. |
| NumberDecimalSeparator | Defines the string that separates integral and decimal digits. |
| NumberDecimalDigits | Defines the default number of decimal digits. This value can be overridden by using a precision specifier. |

The following example formats assorted floating-point values with the number format specifier:

C#

```
double dblValue = -12445.6789;
Console.WriteLine(dblValue.ToString("N", CultureInfo.InvariantCulture));
// Displays -12,445.68
Console.WriteLine(dblValue.ToString("N1",
    CultureInfo.CreateSpecificCulture("sv-SE")));
// Displays -12 445,7

int intValue = 123456789;
Console.WriteLine(intValue.ToString("N1", CultureInfo.InvariantCulture));
// Displays 123,456,789.0
```

Percent format specifier (P)

The percent ("P") format specifier multiplies a number by 100 and converts it to a string that represents a percentage. The precision specifier indicates the desired number of decimal places. If the precision specifier is omitted, the default numeric precision supplied by the current [PercentDecimalDigits](#) property is used.

The following table lists the [NumberFormatInfo](#) properties that control the formatting of the returned string.

| NumberFormatInfo property | Description |
|--|--|
| PercentPositivePattern | Defines the placement of the percent symbol for positive values. |
| PercentNegativePattern | Defines the placement of the percent symbol and the negative |

| NumberFormatInfo property | Description |
|--|--|
| | symbol for negative values. |
| NegativeSign | Defines the string that indicates that a number is negative. |
| PercentSymbol | Defines the percent symbol. |
| PercentDecimalDigits | Defines the default number of decimal digits in a percentage value. This value can be overridden by using the precision specifier. |
| PercentDecimalSeparator | Defines the string that separates integral and decimal digits. |
| PercentGroupSeparator | Defines the string that separates groups of integral numbers. |
| PercentGroupSizes | Defines the number of integer digits that appear in a group. |

The following example formats floating-point values with the percent format specifier:

C#

```
double number = .2468013;
Console.WriteLine(number.ToString("P", CultureInfo.InvariantCulture));
// Displays 24.68 %
Console.WriteLine(number.ToString("P",
    CultureInfo.CreateSpecificCulture("hr-HR")));
// Displays 24,68%
Console.WriteLine(number.ToString("P1", CultureInfo.InvariantCulture));
// Displays 24.7 %
```

Round-trip format specifier (R)

The round-trip ("R") format specifier attempts to ensure that a numeric value that is converted to a string is parsed back into the same numeric value. This format is supported only for the [Half](#), [Single](#), [Double](#), and [BigInteger](#) types.

In .NET Framework and in .NET Core versions earlier than 3.0, the "R" format specifier fails to successfully round-trip [Double](#) values in some cases. For both [Double](#) and [Single](#) values, the "R" format specifier offers relatively poor performance. Instead, we recommend that you use the "[G17](#)" format specifier for [Double](#) values and the "[G9](#)" format specifier to successfully round-trip [Single](#) values.

When a [BigInteger](#) value is formatted using this specifier, its string representation contains all the significant digits in the [BigInteger](#) value.

Although you can include a precision specifier, it is ignored. Round trips are given precedence over precision when using this specifier. The result string is affected by the formatting information of the current [NumberFormatInfo](#) object. The following table lists the [NumberFormatInfo](#) properties that control the formatting of the result string.

| NumberFormatInfo property | Description |
|--------------------------------------|--|
| NegativeSign | Defines the string that indicates that a number is negative. |
| NumberDecimalSeparator | Defines the string that separates integral digits from decimal digits. |
| PositiveSign | Defines the string that indicates that an exponent is positive. |

The following example formats a [BigInteger](#) value with the round-trip format specifier.

C#

```
using System;
using System.Numerics;

public class Example
{
    public static void Main()
    {
        var value = BigInteger.Pow(Int64.MaxValue, 2);
        Console.WriteLine(value.ToString("R"));
    }
}
// The example displays the following output:
//      85070591730234615847396907784232501249
```

ⓘ Important

In some cases, [Double](#) values formatted with the "R" standard numeric format string do not successfully round-trip if compiled using the `/platform:x64` or `/platform:anycpu` switches and run on 64-bit systems. See the following paragraph for more information.

To work around the problem of [Double](#) values formatted with the "R" standard numeric format string not successfully round-tripping if compiled using the `/platform:x64` or `/platform:anycpu` switches and run on 64-bit systems, you can format [Double](#) values by using the "G17" standard numeric format string. The following example uses the "R"

format string with a `Double` value that does not round-trip successfully, and also uses the "G17" format string to successfully round-trip the original value:

```
C#  
  
Console.WriteLine("Attempting to round-trip a Double with 'R':");  
double initialValue = 0.6822871999174;  
string valueString = initialValue.ToString("R",  
                                         CultureInfo.InvariantCulture);  
double roundTripped = double.Parse(valueString,  
                                      CultureInfo.InvariantCulture);  
Console.WriteLine("{0:R} = {1:R}: {2}\n",  
                  initialValue, roundTripped,  
                  initialValue.Equals(roundTripped));  
  
Console.WriteLine("Attempting to round-trip a Double with 'G17':");  
string valueString17 = initialValue.ToString("G17",  
                                         CultureInfo.InvariantCulture);  
double roundTripped17 = double.Parse(valueString17,  
                                       CultureInfo.InvariantCulture);  
Console.WriteLine("{0:R} = {1:R}: {2}\n",  
                  initialValue, roundTripped17,  
                  initialValue.Equals(roundTripped17));  
// If compiled to an application that targets anycpu or x64 and run on an  
// x64 system,  
// the example displays the following output:  
//     Attempting to round-trip a Double with 'R':  
//     0.6822871999174 = 0.68228719991740006: False  
//  
//     Attempting to round-trip a Double with 'G17':  
//     0.6822871999174 = 0.6822871999174: True
```

Hexadecimal format specifier (X)

The hexadecimal ("X") format specifier converts a number to a string of hexadecimal digits. The case of the format specifier indicates whether to use uppercase or lowercase characters for hexadecimal digits that are greater than 9. For example, use "X" to produce "ABCDEF", and "x" to produce "abcdef". This format is supported only for integral types.

The precision specifier indicates the minimum number of digits desired in the resulting string. If required, the number is padded with zeros to its left to produce the number of digits given by the precision specifier.

The result string is not affected by the formatting information of the current `NumberFormatInfo` object.

The following example formats `Int32` values with the hexadecimal format specifier.

C#

```
int value;

value = 0x2045e;
Console.WriteLine(value.ToString("x"));
// Displays 2045e
Console.WriteLine(value.ToString("X"));
// Displays 2045E
Console.WriteLine(value.ToString("X8"));
// Displays 0002045E

value = 123456789;
Console.WriteLine(value.ToString("X"));
// Displays 75BCD15
Console.WriteLine(value.ToString("X2"));
// Displays 75BCD15
```

Notes

This section contains additional information about using standard numeric format strings.

Control Panel settings

The settings in the **Regional and Language Options** item in Control Panel influence the result string produced by a formatting operation. Those settings are used to initialize the **NumberFormatInfo** object associated with the current culture, which provides values used to govern formatting. Computers that use different settings generate different result strings.

In addition, if the **CultureInfo(String)** constructor is used to instantiate a new **CultureInfo** object that represents the same culture as the current system culture, any customizations established by the **Regional and Language Options** item in Control Panel will be applied to the new **CultureInfo** object. You can use the **CultureInfo(String, Boolean)** constructor to create a **CultureInfo** object that does not reflect a system's customizations.

NumberFormatInfo properties

Formatting is influenced by the properties of the current **NumberFormatInfo** object, which is provided implicitly by the current culture or explicitly by the **IFormatProvider** parameter of the method that invokes formatting. Specify a **NumberFormatInfo** or **CultureInfo** object for that parameter.

Note

For information about customizing the patterns or strings used in formatting numeric values, see the [NumberFormatInfo](#) class topic.

Integral and floating-point numeric types

Some descriptions of standard numeric format specifiers refer to integral or floating-point numeric types. The integral numeric types are [Byte](#), [SByte](#), [Int16](#), [Int32](#), [Int64](#), [UInt16](#), [UInt32](#), [UInt64](#), and [BigInteger](#). The floating-point numeric types are [Decimal](#), [Half](#), [Single](#), and [Double](#).

Floating-point infinities and NaN

Regardless of the format string, if the value of a [Half](#), [Single](#), or [Double](#) floating-point type is positive infinity, negative infinity, or not a number (NaN), the formatted string is the value of the respective [PositiveInfinitySymbol](#), [NegativeInfinitySymbol](#), or [NaNSymbol](#) property that is specified by the currently applicable [NumberFormatInfo](#) object.

Code example

The following example formats an integral and a floating-point numeric value using the en-US culture and all the standard numeric format specifiers. This example uses two particular numeric types ([Double](#) and [Int32](#)), but would yield similar results for any of the other numeric base types ([Byte](#), [SByte](#), [Int16](#), [Int32](#), [Int64](#), [UInt16](#), [UInt32](#), [UInt64](#), [BigInteger](#), [Decimal](#), [Half](#), and [Single](#)).

C#

```
// Display string representations of numbers for en-us culture
CultureInfo ci = new CultureInfo("en-us");

// Output floating point values
double floating = 10761.937554;
Console.WriteLine("C: {0}",
    floating.ToString("C", ci));           // Displays "C: $10,761.94"
Console.WriteLine("E: {0}",
    floating.ToString("E03", ci));         // Displays "E: 1.076E+004"
Console.WriteLine("F: {0}",
    floating.ToString("F04", ci));         // Displays "F: 10761.9376"
Console.WriteLine("G: {0}",
    floating.ToString("G", ci));          // Displays "G: 10761.937554"
```

```

Console.WriteLine("N: {0}",
    floating.ToString("N03", ci));           // Displays "N: 10,761.938"
Console.WriteLine("P: {0}",
    (floating/10000).ToString("P02", ci)); // Displays "P: 107.62 %"
Console.WriteLine("R: {0}",
    floating.ToString("R", ci));           // Displays "R: 10761.937554"
Console.WriteLine();

// Output integral values
int integral = 8395;
Console.WriteLine("C: {0}",
    integral.ToString("C", ci));           // Displays "C: $8,395.00"
Console.WriteLine("D: {0}",
    integral.ToString("D6", ci));           // Displays "D: 008395"
Console.WriteLine("E: {0}",
    integral.ToString("E03", ci));           // Displays "E: 8.395E+003"
Console.WriteLine("F: {0}",
    integral.ToString("F01", ci));           // Displays "F: 8395.0"
Console.WriteLine("G: {0}",
    integral.ToString("G", ci));            // Displays "G: 8395"
Console.WriteLine("N: {0}",
    integral.ToString("N01", ci));           // Displays "N: 8,395.0"
Console.WriteLine("P: {0}",
    (integral/10000.0).ToString("P02", ci)); // Displays "P: 83.95 %"
Console.WriteLine("X: 0x{0}",
    integral.ToString("X", ci));           // Displays "X: 0x20CB"
Console.WriteLine();

```

Custom numeric format strings

Article • 11/20/2021

You can create a custom numeric format string, which consists of one or more custom numeric specifiers, to define how to format numeric data. A custom numeric format string is any format string that is not a [standard numeric format string](#).

Custom numeric format strings are supported by some overloads of the `ToString` method of all numeric types. For example, you can supply a numeric format string to the `ToString(String)` and `ToString(String, IFormatProvider)` methods of the `Int32` type. Custom numeric format strings are also supported by the .NET [composite formatting feature](#), which is used by some `Write` and `WriteLine` methods of the `Console` and `StreamWriter` classes, the `String.Format` method, and the `StringBuilder.AppendFormat` method. [String interpolation](#) feature also supports custom numeric format strings.

Tip

You can download the [Formatting Utility](#), a .NET Core Windows Forms application that lets you apply format strings to either numeric or date and time values and displays the result string. Source code is available for [C#](#) and [Visual Basic](#).

The following table describes the custom numeric format specifiers and displays sample output produced by each format specifier. See the [Notes](#) section for additional information about using custom numeric format strings, and the [Example](#) section for a comprehensive illustration of their use.

| Format specifier | Name | Description | Examples |
|------------------|-------------------|---|--|
| "0" | Zero placeholder | Replaces the zero with the corresponding digit if one is present; otherwise, zero appears in the result string. More information: The "0" Custom Specifier . | 1234.5678 ("00000") -> 01235 0.45678 ("0.00", en-US) -> 0.46 0.45678 ("0.00", fr-FR) -> 0,46 |
| "#" | Digit placeholder | Replaces the "#" symbol with the corresponding digit if one is present; otherwise, no digit appears in the result string. | 1234.5678 ("#####") -> 1235 |

| Format specifier | Name | Description | Examples |
|-------------------------|------------------------------------|--|---|
| | | <p>Note that no digit appears in the result string if the corresponding digit in the input string is a non-significant 0. For example, 0003 ("#####") -> 3.</p> <p>More information: The "#" Custom Specifier.</p> | 0.45678 ("#.##", en-US) -> .46 0.45678 ("#.##", fr-FR) -> ,46 |
| "." | Decimal point | Determines the location of the decimal separator in the result string. | 0.45678 ("0.00", en-US) -> 0.46 |
| | | <p>More information: The "." Custom Specifier.</p> | 0.45678 ("0.00", fr-FR) -> 0,46 |
| "," | Group separator and number scaling | <p>Serves as both a group separator and a number scaling specifier. As a group separator, it inserts a localized group separator character between each group. As a number scaling specifier, it divides a number by 1000 for each comma specified.</p> <p>More information: The "," Custom Specifier.</p> | Group separator specifier: 2147483647 ("##,#", en-US) -> 2,147,483,647 Scaling specifier: 2147483647 ("#,##,", es-ES) -> 2.147.483.647 2147483647 ("#,##,,", en-US) -> 2,147 2147483647 ("#,##,,", es-ES) -> 2.147 |
| "%" | Percentage placeholder | <p>Multiplies a number by 100 and inserts a localized percentage symbol in the result string.</p> <p>More information: The "%" Custom Specifier.</p> | 0.3697 ("%#0.00", en-US) -> %36.97 0.3697 ("%#0.00", el-GR) -> %36,97 0.3697 ("##.0%", en-US) -> 37.0 % 0.3697 ("##.0") |

| Format specifier | Name | Description | Examples |
|------------------|--------------------------|--|---|
| | | | %", el-GR) -> 37,0 % |
| "%o" | Per mille placeholder | Multiplies a number by 1000 and inserts a localized per mille symbol in the result string. More information: The "%o" Custom Specifier . | 0.03697 ("0.00%", en-US) -> 36.97% |
| | | | 0.03697 ("0.00%", ru-RU) -> 36,97% |
| "E0" | Exponential notation | If followed by at least one 0 (zero), formats the result using exponential notation. The case of "E" or "e" indicates the case of the exponent symbol in the result string. The number of zeros following the "E" or "e" character determines the minimum number of digits in the exponent. A plus sign (+) indicates that a sign character always precedes the exponent. A minus sign (-) indicates that a sign character precedes only negative exponents. | 987654 ("#0.0e0") -> 98.8e4 |
| "E-0" | | | 1503.92311 ("0.0##e+00") -> 1.504e+03 |

| "e-0" | | More information: The "E" and "e" Custom Specifiers . | 1.9e-16 |
| "\" | Escape character | Causes the next character to be interpreted as a literal rather than as a custom format specifier. More information: The "\" Escape Character . | 987654 ("###00\#") -> #987654# |
| 'string' | Literal string delimiter | Indicates that the enclosed characters should be copied to the result string unchanged. | 68 ("# 'degrees'") -> 68 degrees |
| "string" | | More information: Character literals . | 68 ("#' degrees'") -> 68 degrees |
| ; | Section separator | Defines sections with separate format strings for positive, negative, and zero numbers. More information: The ";" Section Separator . | 12.345 ("#0.0#; (#0.0#);-\0-") -> 12.35 0 ("#0.0#; (#0.0#);-\0-") -> -0- |
| | | | -12.345 ("#0.0#; (#0.0#);-\0-") -> (12.35) |

| Format specifier | Name | Description | Examples |
|--|----------------------|---|---|
| | | | 12.345 ("#0.0#; (#0.0#)") -> 12.35 |
| | | | 0 ("#0.0#; (#0.0#)") -> 0.0 |
| | | | -12.345 ("#0.0#; (#0.0#)") -> (12.35) |
| Other | All other characters | The character is copied to the result string unchanged. | 68 ("# °") -> 68° |
| More information: Character literals . | | | |

The following sections provide detailed information about each of the custom numeric format specifiers.

ⓘ Note

Some of the C# examples in this article run in the [Try.NET](#) inline code runner and playground. Select the **Run** button to run an example in an interactive window. Once you execute the code, you can modify it and run the modified code by selecting **Run** again. The modified code either runs in the interactive window or, if compilation fails, the interactive window displays all C# compiler error messages.

The "0" custom specifier

The "0" custom format specifier serves as a zero-placeholder symbol. If the value that is being formatted has a digit in the position where the zero appears in the format string, that digit is copied to the result string; otherwise, a zero appears in the result string. The position of the leftmost zero before the decimal point and the rightmost zero after the decimal point determines the range of digits that are always present in the result string.

The "00" specifier causes the value to be rounded to the nearest digit preceding the decimal, where rounding away from zero is always used. For example, formatting 34.5 with "00" would result in the value 35.

The following example displays several values that are formatted by using custom format strings that include zero placeholders.

C#

```
double value;

value = 123;
Console.WriteLine(value.ToString("00000"));
Console.WriteLine(String.Format("{0:00000}", value));
// Displays 00123

value = 1.2;
Console.WriteLine(value.ToString("0.00", CultureInfo.InvariantCulture));
Console.WriteLine(String.Format(CultureInfo.InvariantCulture,
    "{0:0.00}", value));
// Displays 1.20

Console.WriteLine(value.ToString("00.00", CultureInfo.InvariantCulture));
Console.WriteLine(String.Format(CultureInfo.InvariantCulture,
    "{0:00.00}", value));
// Displays 01.20

CultureInfo daDK = CultureInfo.CreateSpecificCulture("da-DK");
Console.WriteLine(value.ToString("00.00", daDK));
Console.WriteLine(String.Format(daDK, "{0:00.00}", value));
// Displays 01,20

value = .56;
Console.WriteLine(value.ToString("0.0", CultureInfo.InvariantCulture));
Console.WriteLine(String.Format(CultureInfo.InvariantCulture,
    "{0:0.0}", value));
// Displays 0.6

value = 1234567890;
Console.WriteLine(value.ToString("0,0", CultureInfo.InvariantCulture));
Console.WriteLine(String.Format(CultureInfo.InvariantCulture,
    "{0:0,0}", value));
// Displays 1,234,567,890

CultureInfo elGR = CultureInfo.CreateSpecificCulture("el-GR");
Console.WriteLine(value.ToString("0,0", elGR));
Console.WriteLine(String.Format(elGR, "{0:0,0}", value));
// Displays 1.234.567.890

value = 1234567890.123456;
Console.WriteLine(value.ToString("0,0.0", CultureInfo.InvariantCulture));
Console.WriteLine(String.Format(CultureInfo.InvariantCulture,
    "{0:0,0.0}", value));
// Displays 1,234,567,890.1

value = 1234.567890;
Console.WriteLine(value.ToString("0,0.00", CultureInfo.InvariantCulture));
Console.WriteLine(String.Format(CultureInfo.InvariantCulture,
```

```
        "{0:0,0.00}", value));  
// Displays 1,234.57
```

[Back to table](#)

The "#" custom specifier

The "#" custom format specifier serves as a digit-placeholder symbol. If the value that is being formatted has a digit in the position where the "#" symbol appears in the format string, that digit is copied to the result string. Otherwise, nothing is stored in that position in the result string.

Note that this specifier never displays a zero that is not a significant digit, even if zero is the only digit in the string. It will display zero only if it is a significant digit in the number that is being displayed.

The "##" format string causes the value to be rounded to the nearest digit preceding the decimal, where rounding away from zero is always used. For example, formatting 34.5 with "##" would result in the value 35.

The following example displays several values that are formatted by using custom format strings that include digit placeholders.

```
C#  
  
double value;  
  
value = 1.2;  
Console.WriteLine(value.ToString("#.##", CultureInfo.InvariantCulture));  
Console.WriteLine(String.Format(CultureInfo.InvariantCulture,  
        "{0:#.##}", value));  
// Displays 1.2  
  
value = 123;  
Console.WriteLine(value.ToString("#####"));  
Console.WriteLine(String.Format("{0:#####}", value));  
// Displays 123  
  
value = 123456;  
Console.WriteLine(value.ToString("[##-##-##]"));  
Console.WriteLine(String.Format("{0:[##-##-##]}", value));  
// Displays [12-34-56]  
  
value = 1234567890;  
Console.WriteLine(value.ToString("#"));  
Console.WriteLine(String.Format("{0:#}", value));  
// Displays 1234567890
```

```
Console.WriteLine(value.ToString("###) ###-###"));
Console.WriteLine(String.Format("{0:(###) ###-###}", value));
// Displays (123) 456-7890
```

To return a result string in which absent digits or leading zeroes are replaced by spaces, use the [composite formatting feature](#) and specify a field width, as the following example illustrates.

C#

```
using System;

public class SpaceOrDigit
{
    public static void Main()
    {
        Double value = .324;
        Console.WriteLine("The value is: '{0,5:#.###}'", value);
    }
}
// The example displays the following output if the current culture
// is en-US:
//      The value is: '.324'
```

[Back to table](#)

The "." custom specifier

The "." custom format specifier inserts a localized decimal separator into the result string. The first period in the format string determines the location of the decimal separator in the formatted value; any additional periods are ignored. If the format specifier ends with a "." only the significant digits are formatted into the result string.

The character that is used as the decimal separator in the result string is not always a period; it is determined by the [NumberDecimalSeparator](#) property of the [NumberFormatInfo](#) object that controls formatting.

The following example uses the "." format specifier to define the location of the decimal point in several result strings.

C#

```
double value;

value = 1.2;
Console.WriteLine(value.ToString("0.00", CultureInfo.InvariantCulture));
Console.WriteLine(String.Format(CultureInfo.InvariantCulture,
```

```

        "{0:0.00}", value));
// Displays 1.20

Console.WriteLine(value.ToString("00.00", CultureInfo.InvariantCulture));
Console.WriteLine(String.Format(CultureInfo.InvariantCulture,
                               "{0:00.00}", value));
// Displays 01.20

Console.WriteLine(value.ToString("00.00",
                               CultureInfo.CreateSpecificCulture("da-DK")));
Console.WriteLine(String.Format(CultureInfo.CreateSpecificCulture("da-DK"),
                               "{0:00.00}", value));
// Displays 01,20

value = .086;
Console.WriteLine(value.ToString("#0.##%", CultureInfo.InvariantCulture));
Console.WriteLine(String.Format(CultureInfo.InvariantCulture,
                               "{0:#0.##%}", value));
// Displays 8.6%

value = 86000;
Console.WriteLine(value.ToString("0.###E+0", CultureInfo.InvariantCulture));
Console.WriteLine(String.Format(CultureInfo.InvariantCulture,
                               "{0:0.###E+0}", value));
// Displays 8.6E+4

```

[Back to table](#)

The "," custom specifier

The "," character serves as both a group separator and a number scaling specifier.

- Group separator: If one or more commas are specified between two digit placeholders (0 or #) that format the integral digits of a number, a group separator character is inserted between each number group in the integral part of the output.

The [NumberGroupSeparator](#) and [NumberGroupSizes](#) properties of the current [NumberFormatInfo](#) object determine the character used as the number group separator and the size of each number group. For example, if the string "#,#" and the invariant culture are used to format the number 1000, the output is "1,000".

- Number scaling specifier: If one or more commas are specified immediately to the left of the explicit or implicit decimal point, the number to be formatted is divided by 1000 for each comma. For example, if the string "0,," is used to format the number 100 million, the output is "100".

You can use group separator and number scaling specifiers in the same format string. For example, if the string "#,0," and the invariant culture are used to format the number one billion, the output is "1,000".

The following example illustrates the use of the comma as a group separator.

```
C#  
  
double value = 1234567890;  
Console.WriteLine(value.ToString("#,#", CultureInfo.InvariantCulture));  
Console.WriteLine(String.Format(CultureInfo.InvariantCulture,  
        "{0:#,#}", value));  
// Displays 1,234,567,890  
  
Console.WriteLine(value.ToString("#,##0,,", CultureInfo.InvariantCulture));  
Console.WriteLine(String.Format(CultureInfo.InvariantCulture,  
        "{0:#,##0,,}", value));  
// Displays 1,235
```

The following example illustrates the use of the comma as a specifier for number scaling.

```
C#  
  
double value = 1234567890;  
Console.WriteLine(value.ToString("#,,", CultureInfo.InvariantCulture));  
Console.WriteLine(String.Format(CultureInfo.InvariantCulture,  
        "{0:#,,}", value));  
// Displays 1235  
  
Console.WriteLine(value.ToString("#,,,", CultureInfo.InvariantCulture));  
Console.WriteLine(String.Format(CultureInfo.InvariantCulture,  
        "{0:#,,,}", value));  
// Displays 1  
  
Console.WriteLine(value.ToString("#,##0,,", CultureInfo.InvariantCulture));  
Console.WriteLine(String.Format(CultureInfo.InvariantCulture,  
        "{0:#,##0,,}", value));  
// Displays 1,235
```

[Back to table](#)

The "%" custom specifier

A percent sign (%) in a format string causes a number to be multiplied by 100 before it is formatted. The localized percent symbol is inserted in the number at the location

where the % appears in the format string. The percent character used is defined by the [PercentSymbol](#) property of the current [NumberFormatInfo](#) object.

The following example defines several custom format strings that include the "%" custom specifier.

C#

```
double value = .086;
Console.WriteLine(value.ToString("#0.##%", CultureInfo.InvariantCulture));
Console.WriteLine(String.Format(CultureInfo.InvariantCulture,
    "{0:#0.##%}", value));
// Displays 8.6%
```

[Back to table](#)

The "%o" custom specifier

A per mille character (%o or \u2030) in a format string causes a number to be multiplied by 1000 before it is formatted. The appropriate per mille symbol is inserted in the returned string at the location where the %o symbol appears in the format string. The per mille character used is defined by the [NumberFormatInfo.PerMilleSymbol](#) property of the object that provides culture-specific formatting information.

The following example defines a custom format string that includes the "%o" custom specifier.

C#

```
double value = .00354;
string perMilleFmt = "#0.## " + '\u2030';
Console.WriteLine(value.ToString(perMilleFmt,
CultureInfo.InvariantCulture));
Console.WriteLine(String.Format(CultureInfo.InvariantCulture,
    "{0:" + perMilleFmt + "}", value));
// Displays 3.54%
```

[Back to table](#)

The "E" and "e" custom specifiers

If any of the strings "E", "E+", "E-", "e", "e+", or "e-" are present in the format string and are followed immediately by at least one zero, the number is formatted by using scientific notation with an "E" or "e" inserted between the number and the exponent.

The number of zeros following the scientific notation indicator determines the minimum number of digits to output for the exponent. The "E+" and "e+" formats indicate that a plus sign or minus sign should always precede the exponent. The "E", "E-", "e", or "e-" formats indicate that a sign character should precede only negative exponents.

The following example formats several numeric values using the specifiers for scientific notation.

```
C#
```

```
double value = 86000;
Console.WriteLine(value.ToString("0.###E+0", CultureInfo.InvariantCulture));
Console.WriteLine(String.Format(CultureInfo.InvariantCulture,
    "{0:0.###E+0}", value));
// Displays 8.6E+4

Console.WriteLine(value.ToString("0.###E+000",
CultureInfo.InvariantCulture));
Console.WriteLine(String.Format(CultureInfo.InvariantCulture,
    "{0:0.###E+000}", value));
// Displays 8.6E+004

Console.WriteLine(value.ToString("0.###E-000",
CultureInfo.InvariantCulture));
Console.WriteLine(String.Format(CultureInfo.InvariantCulture,
    "{0:0.###E-000}", value));
// Displays 8.6E004
```

[Back to table](#)

The "\ escape character

The "#", "0", ".", ",", "%", and "%o" symbols in a format string are interpreted as format specifiers rather than as literal characters. Depending on their position in a custom format string, the uppercase and lowercase "E" as well as the + and - symbols may also be interpreted as format specifiers.

To prevent a character from being interpreted as a format specifier, you can precede it with a backslash, which is the escape character. The escape character signifies that the following character is a character literal that should be included in the result string unchanged.

To include a backslash in a result string, you must escape it with another backslash (\\\).

 **Note**

Some compilers, such as the C++ and C# compilers, may also interpret a single backslash character as an escape character. To ensure that a string is interpreted correctly when formatting, you can use the verbatim string literal character (the @ character) before the string in C#, or add another backslash character before each backslash in C# and C++. The following C# example illustrates both approaches.

The following example uses the escape character to prevent the formatting operation from interpreting the "#", "0", and "\" characters as either escape characters or format specifiers. The C# examples uses an additional backslash to ensure that a backslash is interpreted as a literal character.

C#

```
int value = 123;
Console.WriteLine(value.ToString("\#\#\#\#\##0 dollars and \0\0 cents
\#\#\#\#"));
Console.WriteLine(String.Format("{0:\#\#\#\#\##0 dollars and \0\0 cents
\#\#\#\#}", value));
// Displays ### 123 dollars and 00 cents ###

Console.WriteLine(value.ToString(@"#\#\#\##0 dollars and \0\0 cents
#\#\#\#"));
Console.WriteLine(String.Format(@"{0:#\#\#\##0 dollars and \0\0 cents
#\#\#\#}", value));
// Displays ### 123 dollars and 00 cents ###

Console.WriteLine(value.ToString("\\\\\\\\\\##0 dollars and \0\0 cents
\\\\\\\\\\\\\\\\"));
Console.WriteLine(String.Format("{0:\\\\\\\\\\##0 dollars and \0\0 cents
\\\\\\\\\\\\\\\\}", value));
// Displays \\ 123 dollars and 00 cents \\

Console.WriteLine(value.ToString(@"\\\\\\##0 dollars and \0\0 cents
\\\\\\"));
Console.WriteLine(String.Format(@"{0:\\\\\\##0 dollars and \0\0 cents
\\\\\\}", value));
// Displays \\ 123 dollars and 00 cents \\
```

[Back to table](#)

The ";" section separator

The semicolon (;) is a conditional format specifier that applies different formatting to a number depending on whether its value is positive, negative, or zero. To produce this behavior, a custom format string can contain up to three sections separated by semicolons. These sections are described in the following table.

| Number of sections | Description |
|--------------------|---|
| One section | The format string applies to all values. |
| Two sections | <p>The first section applies to positive values and zeros, and the second section applies to negative values.</p> <p>If the number to be formatted is negative, but becomes zero after rounding according to the format in the second section, the resulting zero is formatted according to the first section.</p> |
| Three sections | <p>The first section applies to positive values, the second section applies to negative values, and the third section applies to zeros.</p> <p>The second section can be left empty (by having nothing between the semicolons), in which case the first section applies to all nonzero values.</p> <p>If the number to be formatted is nonzero, but becomes zero after rounding according to the format in the first or second section, the resulting zero is formatted according to the third section.</p> |

Section separators ignore any preexisting formatting associated with a number when the final value is formatted. For example, negative values are always displayed without a minus sign when section separators are used. If you want the final formatted value to have a minus sign, you should explicitly include the minus sign as part of the custom format specifier.

The following example uses the ";" format specifier to format positive, negative, and zero numbers differently.

C#

```
double posValue = 1234;
double negValue = -1234;
double zeroValue = 0;

string fmt2 = "##;(#)";
string fmt3 = "##;(#);**Zero**";

Console.WriteLine(posValue.ToString(fmt2));
Console.WriteLine(String.Format("{0:" + fmt2 + "}", posValue));
// Displays 1234
```

```
Console.WriteLine(negValue.ToString(fmt2));
Console.WriteLine(String.Format("{0:" + fmt2 + "}", negValue));
// Displays (1234)

Console.WriteLine(zeroValue.ToString(fmt3));
Console.WriteLine(String.Format("{0:" + fmt3 + "}", zeroValue));
// Displays **Zero**
```

[Back to table](#)

Character literals

Format specifiers that appear in a custom numeric format string are always interpreted as formatting characters and never as literal characters. This includes the following characters:

- 0
- #
- %
- %o
- '
- \
- .
- ,
- E or e, depending on its position in the format string.

All other characters are always interpreted as character literals and, in a formatting operation, are included in the result string unchanged. In a parsing operation, they must match the characters in the input string exactly; the comparison is case-sensitive.

The following example illustrates one common use of literal character units (in this case, thousands):

```
C#
double n = 123.8;
Console.WriteLine($"{n:#,##0.0K}");
// The example displays the following output:
//      123.8K
```

There are two ways to indicate that characters are to be interpreted as literal characters and not as formatting characters, so that they can be included in a result string or successfully parsed in an input string:

- By escaping a formatting character. For more information, see [The "\" escape character](#).
- By enclosing the entire literal string in quotation apostrophes.

The following example uses both approaches to include reserved characters in a custom numeric format string.

```
C#  
  
double n = 9.3;  
Console.WriteLine(${@n:##.0%});  
Console.WriteLine(${@n:\##'}");  
Console.WriteLine(${@n:\\##\\});  
Console.WriteLine();  
Console.WriteLine("${n:##.0%'");  
Console.WriteLine(${@n:'\##'\});  
// The example displays the following output:  
//      9.3%  
//      '9'  
//      \9\  
//  
//      9.3%  
//      \9\
```

Notes

Floating-Point infinities and NaN

Regardless of the format string, if the value of a [Half](#), [Single](#), or [Double](#) floating-point type is positive infinity, negative infinity, or not a number (NaN), the formatted string is the value of the respective [PositiveInfinitySymbol](#), [NegativeInfinitySymbol](#), or [NaNSymbol](#) property specified by the currently applicable [NumberFormatInfo](#) object.

Control Panel settings

The settings in the [Regional and Language Options](#) item in Control Panel influence the result string produced by a formatting operation. Those settings are used to initialize the [NumberFormatInfo](#) object associated with the current culture, and the current culture provides values used to govern formatting. Computers that use different settings generate different result strings.

In addition, if you use the [CultureInfo\(String\)](#) constructor to instantiate a new [CultureInfo](#) object that represents the same culture as the current system culture, any

customizations established by the [Regional and Language Options](#) item in Control Panel will be applied to the new [CultureInfo](#) object. You can use the [CultureInfo\(String, Boolean\)](#) constructor to create a [CultureInfo](#) object that does not reflect a system's customizations.

Rounding and fixed-point format strings

For fixed-point format strings (that is, format strings that do not contain scientific notation format characters), numbers are rounded to as many decimal places as there are digit placeholders to the right of the decimal point. If the format string does not contain a decimal point, the number is rounded to the nearest integer. If the number has more digits than there are digit placeholders to the left of the decimal point, the extra digits are copied to the result string immediately before the first digit placeholder.

[Back to table](#)

Example

The following example demonstrates two custom numeric format strings. In both cases, the digit placeholder (#) displays the numeric data, and all other characters are copied to the result string.

C#

```
double number1 = 1234567890;
string value1 = number1.ToString("(###) ###-####");
Console.WriteLine(value1);

int number2 = 42;
string value2 = number2.ToString("My Number = #");
Console.WriteLine(value2);
// The example displays the following output:
//      (123) 456-7890
//      My Number = 42
```

Standard date and time format strings

Article • 05/02/2023

A standard date and time format string uses a single character as the format specifier to define the text representation of a [DateTime](#) or a [DateTimeOffset](#) value. Any date and time format string that contains more than one character, including white space, is interpreted as a [custom date and time format string](#). A standard or custom format string can be used in two ways:

- To define the string that results from a formatting operation.
- To define the text representation of a date and time value that can be converted to a [DateTime](#) or [DateTimeOffset](#) value by a parsing operation.

Tip

You can download the [Formatting Utility](#), a .NET Windows Forms application that lets you apply format strings to either numeric or date and time values and display the result string. Source code is available for [C#](#) and [Visual Basic](#).

Note

Some of the C# examples in this article run in the [Try.NET](#) inline code runner and playground. Select the **Run** button to run an example in an interactive window. Once you execute the code, you can modify it and run the modified code by selecting **Run** again. The modified code either runs in the interactive window or, if compilation fails, the interactive window displays all C# compiler error messages.

The **local time zone** of the [Try.NET](#) inline code runner and playground is Coordinated Universal Time, or UTC. This may affect the behavior and the output of examples that illustrate the [DateTime](#), [DateTimeOffset](#), and [TimeZoneInfo](#) types and their members.

Table of format specifiers

The following table describes the standard date and time format specifiers. Unless otherwise noted, a particular standard date and time format specifier produces an identical string representation regardless of whether it is used with a [DateTime](#) or a

`DateTimeOffset` value. See [Control Panel Settings](#) and [DateTimeFormatInfo Properties](#) for additional information about using standard date and time format strings.

| Format specifier | Description | Examples |
|------------------|---|---|
| "d" | Short date pattern. More information: The short date ("d") format specifier . | 2009-06-15T13:45:30 -> 6/15/2009 (en-US) 2009-06-15T13:45:30 -> 15/06/2009 (fr-FR) 2009-06-15T13:45:30 -> 2009/06/15 (ja-JP) |
| "D" | Long date pattern. More information: The long date ("D") format specifier . | 2009-06-15T13:45:30 -> Monday, June 15, 2009 (en-US) 2009-06-15T13:45:30 -> понедельник, 15 июня 2009 г. (ru-RU) 2009-06-15T13:45:30 -> Montag, 15. Juni 2009 (de-DE) |
| "f" | Full date/time pattern (short time). More information: The full date short time ("f") format specifier . | 2009-06-15T13:45:30 -> Monday, June 15, 2009 1:45 PM (en-US) 2009-06-15T13:45:30 -> den 15 juni 2009 13:45 (sv-SE) 2009-06-15T13:45:30 -> Δευτέρα, 15 Ιουνίου 2009 1:45 μμ (el-GR) |
| "F" | Full date/time pattern (long time). More information: The full date long time ("F") format specifier . | 2009-06-15T13:45:30 -> Monday, June 15, 2009 1:45:30 PM (en-US) 2009-06-15T13:45:30 -> den 15 juni 2009 13:45:30 (sv-SE) 2009-06-15T13:45:30 -> Δευτέρα, 15 Ιουνίου 2009 1:45:30 μμ (el-GR) |
| "g" | General date/time pattern (short time). More information: The general date short time ("g") format specifier . | 2009-06-15T13:45:30 -> 6/15/2009 1:45 PM (en-US) 2009-06-15T13:45:30 -> 15/06/2009 13:45 (es-ES) 2009-06-15T13:45:30 -> 2009/6/15 13:45 (zh-CN) |
| "G" | General date/time pattern (long time). | 2009-06-15T13:45:30 -> 6/15/2009 1:45:30 PM (en-US) |

| Format specifier | Description | Examples |
|-------------------------|--|---|
| | More information: The general date long time ("G") format specifier. | 2009-06-15T13:45:30 -> 15/06/2009 13:45:30 (es-ES) 2009-06-15T13:45:30 -> 2009/6/15 13:45:30 (zh-CN) |
| "M", "m" | Month/day pattern. More information: The month ("M", "m") format specifier. | 2009-06-15T13:45:30 -> June 15 (en-US) 2009-06-15T13:45:30 -> 15. juni (da-DK) 2009-06-15T13:45:30 -> 15 Juni (id-ID) |
| "O", "o" | round-trip date/time pattern. More information: The round-trip ("O", "o") format specifier. | DateTime values: 2009-06-15T13:45:30 (DateTimeKind.Local) --> 2009-06-15T13:45:30.0000000-07:00 2009-06-15T13:45:30 (DateTimeKind.Utc) --> 2009-06-15T13:45:30.0000000Z 2009-06-15T13:45:30 (DateTimeKind.Unspecified) --> 2009-06-15T13:45:30.0000000 |
| | | DateTimeOffset values: 2009-06-15T13:45:30-07:00 --> 2009-06-15T13:45:30.0000000-07:00 |
| "R", "r" | RFC1123 pattern. More information: The RFC1123 ("R", "r") format specifier. | DateTimeOffset input: 2009-06-15T13:45:30 -> Mon, 15 Jun 2009 20:45:30 GMT DateTime input: 2009-06-15T13:45:30 -> Mon, 15 Jun 2009 13:45:30 GMT |
| "s" | Sortable date/time pattern. More information: The sortable ("s") format specifier. | 2009-06-15T13:45:30 (DateTimeKind.Local) -> 2009-06-15T13:45:30 2009-06-15T13:45:30 (DateTimeKind.Utc) -> 2009-06-15T13:45:30 |
| "t" | Short time pattern. More information: The short time ("t") format specifier. | 2009-06-15T13:45:30 -> 1:45 PM (en-US) 2009-06-15T13:45:30 -> 13:45 (hr-HR) 2009-06-15T13:45:30 -> 01:45 ρ (ar-EG) |

| Format specifier | Description | Examples |
|----------------------------|--|---|
| "T" | <p>Long time pattern.</p> <p>More information: The long time ("T") format specifier.</p> | <p>2009-06-15T13:45:30 -> 1:45:30 PM (en-US)</p> <p>2009-06-15T13:45:30 -> 13:45:30 (hr-HR)</p> <p>2009-06-15T13:45:30 -> 01:45:30 ρ (ar-EG)</p> |
| "u" | <p>Universal sortable date/time pattern.</p> <p>More information: The universal sortable ("u") format specifier.</p> | <p>With a DateTime value: 2009-06-15T13:45:30 -> 2009-06-15 13:45:30Z</p> <p>With a DateTimeOffset value: 2009-06-15T13:45:30 -> 2009-06-15 20:45:30Z</p> |
| "U" | <p>Universal full date/time pattern.</p> <p>More information: The universal full ("U") format specifier.</p> | <p>2009-06-15T13:45:30 -> Monday, June 15, 2009 8:45:30 PM (en-US)</p> <p>2009-06-15T13:45:30 -> den 15 juni 2009 20:45:30 (sv-SE)</p> <p>2009-06-15T13:45:30 -> Δευτέρα, 15 Ιουνίου 2009 8:45:30 μμ (el-GR)</p> |
| "Y", "y" | <p>Year month pattern.</p> <p>More information: The year month ("Y") format specifier.</p> | <p>2009-06-15T13:45:30 -> June 2009 (en-US)</p> <p>2009-06-15T13:45:30 -> juni 2009 (da-DK)</p> <p>2009-06-15T13:45:30 -> Juni 2009 (id-ID)</p> |
| Any other single character | Unknown specifier. | Throws a run-time FormatException . |

How standard format strings work

In a formatting operation, a standard format string is simply an alias for a custom format string. The advantage of using an alias to refer to a custom format string is that, although the alias remains invariant, the custom format string itself can vary. This is important because the string representations of date and time values typically vary by culture. For example, the "d" standard format string indicates that a date and time value is to be displayed using a short date pattern. For the invariant culture, this pattern is "MM/dd/yyyy". For the fr-FR culture, it is "dd/MM/yyyy". For the ja-JP culture, it is "yyyy/MM/dd".

If a standard format string in a formatting operation maps to a particular culture's custom format string, your application can define the specific culture whose custom

format strings are used in one of these ways:

- You can use the default (or current) culture. The following example displays a date using the current culture's short date format. In this case, the current culture is en-US.

C#

```
// Display using current (en-us) culture's short date format
DateTime thisDate = new DateTime(2008, 3, 15);
Console.WriteLine(thisDate.ToString("d"));           // Displays
3/15/2008
```

- You can pass a [CultureInfo](#) object representing the culture whose formatting is to be used to a method that has an [IFormatProvider](#) parameter. The following example displays a date using the short date format of the pt-BR culture.

C#

```
// Display using pt-BR culture's short date format
DateTime thisDate = new DateTime(2008, 3, 15);
CultureInfo culture = new CultureInfo("pt-BR");
Console.WriteLine(thisDate.ToString("d", culture)); // Displays
15/3/2008
```

- You can pass a [DateTimeFormatInfo](#) object that provides formatting information to a method that has an [IFormatProvider](#) parameter. The following example displays a date using the short date format from a [DateTimeFormatInfo](#) object for the hr-HR culture.

C#

```
// Display using date format information from hr-HR culture
DateTime thisDate = new DateTime(2008, 3, 15);
DateTimeFormatInfo fmt = (new CultureInfo("hr-HR")).DateTimeFormat;
Console.WriteLine(thisDate.ToString("d", fmt));      // Displays
15.3.2008
```

ⓘ Note

For information about customizing the patterns or strings used in formatting date and time values, see the [NumberFormatInfo](#) class topic.

In some cases, the standard format string serves as a convenient abbreviation for a longer custom format string that is invariant. Four standard format strings fall into this category: "O" (or "o"), "R" (or "r"), "s", and "u". These strings correspond to custom format strings defined by the invariant culture. They produce string representations of date and time values that are intended to be identical across cultures. The following table provides information on these four standard date and time format strings.

| Standard format string | Defined by DateTimeFormatInfo.InvariantInfo property | Custom format string |
|-------------------------------|--|--|
| "O" or "o" | None | yyyy'-'MM'- 'dd'T'HH':'mm':'ss'.ffffffffffK |
| "R" or "r" | RFC1123Pattern | ddd, dd MMM yyyy HH':'mm':'ss 'GMT' |
| "s" | SortableDateTimePattern | yyyy'-'MM'-'dd'T'HH':'mm':'ss |
| "u" | UniversalSortableDateTimePattern | yyyy'-'MM'-'dd HH':'mm':'ss'Z' |

Standard format strings can also be used in parsing operations with the [DateTime.ParseExact](#) or [DateTimeOffset.ParseExact](#) methods, which require an input string to exactly conform to a particular pattern for the parse operation to succeed. Many standard format strings map to multiple custom format strings, so a date and time value can be represented in a variety of formats and the parse operation will still succeed. You can determine the custom format string or strings that correspond to a standard format string by calling the [DateTimeFormatInfo.GetAllDateTimePatterns\(Char\)](#) method. The following example displays the custom format strings that map to the "d" (short date pattern) standard format string.

C#

```
using System;
using System.Globalization;

public class Example
{
    public static void Main()
    {
        Console.WriteLine("'d' standard format string:");
        foreach (var customString in
DateTimeFormatInfo.CurrentInfo.GetAllDateTimePatterns('d'))
            Console.WriteLine(" {0}", customString);
    }
}
// The example displays the following output:
//      'd' standard format string:
```

```
//      M/d/yyyy  
//      M/d/yy  
//      MM/dd/yy  
//      MM/dd/yyyy  
//      yy/MM/dd  
//      yyyy-MM-dd  
//      dd-MMM-yy
```

The following sections describe the standard format specifiers for [DateTime](#) and [DateTimeOffset](#) values.

Date formats

This group includes the following formats:

- The short date ("d") format specifier
- The long date ("D") format specifier

The short date ("d") format specifier

The "d" standard format specifier represents a custom date and time format string that is defined by a specific culture's [DateTimeFormatInfo.ShortDatePattern](#) property. For example, the custom format string that is returned by the [ShortDatePattern](#) property of the invariant culture is "MM/dd/yyyy".

The following table lists the [DateTimeFormatInfo](#) object properties that control the formatting of the returned string.

| Property | Description |
|----------------------------------|--|
| ShortDatePattern | Defines the overall format of the result string. |
| DateSeparator | Defines the string that separates the year, month, and day components of a date. |

The following example uses the "d" format specifier to display a date and time value.

C#

```
DateTime date1 = new DateTime(2008,4, 10);  
Console.WriteLine(date1.ToString("d", DateTimeFormatInfo.InvariantInfo));  
// Displays 04/10/2008  
Console.WriteLine(date1.ToString("d",  
        CultureInfo.CreateSpecificCulture("en-US")));  
// Displays 4/10/2008  
Console.WriteLine(date1.ToString("d",
```

```

        CultureInfo.CreateSpecificCulture("en-NZ")));
// Displays 10/04/2008
Console.WriteLine(date1.ToString("d",
        CultureInfo.CreateSpecificCulture("de-DE")));
// Displays 10.04.2008

```

[Back to table](#)

The long date ("D") format specifier

The "D" standard format specifier represents a custom date and time format string that is defined by the current [DateTimeFormatInfo.LongDatePattern](#) property. For example, the custom format string for the invariant culture is "dddd, dd MMMM yyyy".

The following table lists the properties of the [DateTimeFormatInfo](#) object that control the formatting of the returned string.

| Property | Description |
|---------------------------------|---|
| LongDatePattern | Defines the overall format of the result string. |
| DayNames | Defines the localized day names that can appear in the result string. |
| MonthNames | Defines the localized month names that can appear in the result string. |

The following example uses the "D" format specifier to display a date and time value.

C#

```

DateTime date1 = new DateTime(2008, 4, 10);
Console.WriteLine(date1.ToString("D",
        CultureInfo.CreateSpecificCulture("en-US")));
// Displays Thursday, April 10, 2008
Console.WriteLine(date1.ToString("D",
        CultureInfo.CreateSpecificCulture("pt-BR")));
// Displays quinta-feira, 10 de abril de 2008
Console.WriteLine(date1.ToString("D",
        CultureInfo.CreateSpecificCulture("es-MX")));
// Displays jueves, 10 de abril de 2008

```

[Back to table](#)

Date and time formats

This group includes the following formats:

- The full date short time ("f") format specifier
- The full date long time ("F") format specifier
- The general date short time ("g") format specifier
- The general date long time ("G") format specifier
- The round-trip ("O", "o") format specifier
- The RFC1123 ("R", "r") format specifier
- The sortable ("s") format specifier
- The universal sortable ("u") format specifier
- The universal full ("U") format specifier

The full date short time ("f") format specifier

The "f" standard format specifier represents a combination of the long date ("D") and short time ("t") patterns, separated by a space.

The result string is affected by the formatting information of a specific [DateTimeFormatInfo](#) object. The following table lists the [DateTimeFormatInfo](#) object properties that may control the formatting of the returned string. The custom format specifier returned by the [DateTimeFormatInfo.LongDatePattern](#) and [DateTimeFormatInfo.ShortTimePattern](#) properties of some cultures may not make use of all properties.

| Property | Description |
|----------------------------------|--|
| LongDatePattern | Defines the format of the date component of the result string. |
| ShortTimePattern | Defines the format of the time component of the result string. |
| DayNames | Defines the localized day names that can appear in the result string. |
| MonthNames | Defines the localized month names that can appear in the result string. |
| TimeSeparator | Defines the string that separates the hour, minute, and second components of a time. |
| AMDesignator | Defines the string that indicates times from midnight to before noon in a 12-hour clock. |
| PMDesignator | Defines the string that indicates times from noon to before midnight in a 12-hour clock. |

The following example uses the "f" format specifier to display a date and time value.

C#

```

DateTime date1 = new DateTime(2008, 4, 10, 6, 30, 0);
Console.WriteLine(date1.ToString("F",
                               CultureInfo.CreateSpecificCulture("en-US")));
// Displays Thursday, April 10, 2008 6:30 AM
Console.WriteLine(date1.ToString("F",
                               CultureInfo.CreateSpecificCulture("fr-FR")));
// Displays jeudi 10 avril 2008 06:30

```

[Back to table](#)

The full date long time ("F") format specifier

The "F" standard format specifier represents a custom date and time format string that is defined by the current [DateTimeFormatInfo.FullDateTimePattern](#) property. For example, the custom format string for the invariant culture is "ddd, dd MMMM yyyy HH:mm:ss".

The following table lists the [DateTimeFormatInfo](#) object properties that may control the formatting of the returned string. The custom format specifier that is returned by the [FullDateTimePattern](#) property of some cultures may not make use of all properties.

| Property | Description |
|-------------------------------------|--|
| FullDateTimePattern | Defines the overall format of the result string. |
| DayNames | Defines the localized day names that can appear in the result string. |
| MonthNames | Defines the localized month names that can appear in the result string. |
| TimeSeparator | Defines the string that separates the hour, minute, and second components of a time. |
| AMDesignator | Defines the string that indicates times from midnight to before noon in a 12-hour clock. |
| PMDesignator | Defines the string that indicates times from noon to before midnight in a 12-hour clock. |

The following example uses the "F" format specifier to display a date and time value.

C#

```

DateTime date1 = new DateTime(2008, 4, 10, 6, 30, 0);
Console.WriteLine(date1.ToString("F",
                               CultureInfo.CreateSpecificCulture("en-US")));
// Displays Thursday, April 10, 2008 6:30:00 AM
Console.WriteLine(date1.ToString("F",

```

```
CultureInfo.CreateSpecificCulture("fr-FR")));
// Displays jeudi 10 avril 2008 06:30:00
```

[Back to table](#)

The general date short time ("g") format specifier

The "g" standard format specifier represents a combination of the short date ("d") and short time ("t") patterns, separated by a space.

The result string is affected by the formatting information of a specific [DateTimeFormatInfo](#) object. The following table lists the [DateTimeFormatInfo](#) object properties that may control the formatting of the returned string. The custom format specifier that is returned by the [DateTimeFormatInfo.ShortDatePattern](#) and [DateTimeFormatInfo.ShortTimePattern](#) properties of some cultures may not make use of all properties.

| Property | Description |
|----------------------------------|--|
| ShortDatePattern | Defines the format of the date component of the result string. |
| ShortTimePattern | Defines the format of the time component of the result string. |
| DateSeparator | Defines the string that separates the year, month, and day components of a date. |
| TimeSeparator | Defines the string that separates the hour, minute, and second components of a time. |
| AMDesignator | Defines the string that indicates times from midnight to before noon in a 12-hour clock. |
| PMDesignator | Defines the string that indicates times from noon to before midnight in a 12-hour clock. |

The following example uses the "g" format specifier to display a date and time value.

C#

```
DateTime date1 = new DateTime(2008, 4, 10, 6, 30, 0);
Console.WriteLine(date1.ToString("g",
    DateTimeFormatInfo.InvariantInfo));
// Displays 04/10/2008 06:30
Console.WriteLine(date1.ToString("g",
    CultureInfo.CreateSpecificCulture("en-us")));
// Displays 4/10/2008 6:30 AM
Console.WriteLine(date1.ToString("g",
```

```
CultureInfo.CreateSpecificCulture("fr-BE")));
// Displays 10/04/2008 6:30
```

[Back to table](#)

The general date long time ("G") format specifier

The "G" standard format specifier represents a combination of the short date ("d") and long time ("T") patterns, separated by a space.

The result string is affected by the formatting information of a specific [DateTimeFormatInfo](#) object. The following table lists the [DateTimeFormatInfo](#) object properties that may control the formatting of the returned string. The custom format specifier that is returned by the [DateTimeFormatInfo.ShortDatePattern](#) and [DateTimeFormatInfo.LongTimePattern](#) properties of some cultures may not make use of all properties.

| Property | Description |
|----------------------------------|--|
| ShortDatePattern | Defines the format of the date component of the result string. |
| LongTimePattern | Defines the format of the time component of the result string. |
| DateSeparator | Defines the string that separates the year, month, and day components of a date. |
| TimeSeparator | Defines the string that separates the hour, minute, and second components of a time. |
| AMDesignator | Defines the string that indicates times from midnight to before noon in a 12-hour clock. |
| PMDesignator | Defines the string that indicates times from noon to before midnight in a 12-hour clock. |

The following example uses the "G" format specifier to display a date and time value.

C#

```
DateTime date1 = new DateTime(2008, 4, 10, 6, 30, 0);
Console.WriteLine(date1.ToString("G",
    DateTimeFormatInfo.InvariantInfo));
// Displays 04/10/2008 06:30:00
Console.WriteLine(date1.ToString("G",
    CultureInfo.CreateSpecificCulture("en-us")));
// Displays 4/10/2008 6:30:00 AM
Console.WriteLine(date1.ToString("G",
```

```
CultureInfo.CreateSpecificCulture("nl-BE")));  
// Displays 10/04/2008 6:30:00
```

[Back to table](#)

The round-trip ("O", "o") format specifier

The "O" or "o" standard format specifier represents a custom date and time format string using a pattern that preserves time zone information and emits a result string that complies with ISO 8601. For [DateTime](#) values, this format specifier is designed to preserve date and time values along with the [DateTime.Kind](#) property in text. The formatted string can be parsed back by using the [DateTime.Parse\(String\)](#), [IFormatProvider](#), [DateTimeStyles](#)) or [DateTime.ParseExact](#) method if the [styles](#) parameter is set to [DateTimeStyles.RoundtripKind](#).

The "O" or "o" standard format specifier corresponds to the "yyyy'-'MM'-'dd'T'HH':'mm':'ss'.fffffffK" custom format string for [DateTime](#) values and to the "yyyy'-'MM'-'dd'T'HH':'mm':'ss'.fffffffzzz" custom format string for [DateTimeOffset](#) values. In this string, the pairs of single quotation marks that delimit individual characters, such as the hyphens, the colons, and the letter "T", indicate that the individual character is a literal that cannot be changed. The apostrophes do not appear in the output string.

The "O" or "o" standard format specifier (and the "yyyy'-'MM'-'dd'T'HH':'mm':'ss'.fffffffK" custom format string) takes advantage of the three ways that ISO 8601 represents time zone information to preserve the [Kind](#) property of [DateTime](#) values:

- The time zone component of [DateTimeKind.Local](#) date and time values is an offset from UTC (for example, +01:00, -07:00). All [DateTimeOffset](#) values are also represented in this format.
- The time zone component of [DateTimeKind.Utc](#) date and time values uses "Z" (which stands for zero offset) to represent UTC.
- [DateTimeKind.Unspecified](#) date and time values have no time zone information.

Because the "O" or "o" standard format specifier conforms to an international standard, the formatting or parsing operation that uses the specifier always uses the invariant culture and the Gregorian calendar.

Strings that are passed to the [Parse](#), [TryParse](#), [ParseExact](#), and [TryParseExact](#) methods of [DateTime](#) and [DateTimeOffset](#) can be parsed by using the "O" or "o" format specifier if they are in one of these formats. In the case of [DateTime](#) objects, the parsing overload that you call should also include a [styles](#) parameter with a value of

[DateTimeStyles.RoundtripKind](#). Note that if you call a parsing method with the custom format string that corresponds to the "O" or "o" format specifier, you won't get the same results as "O" or "o". This is because parsing methods that use a custom format string can't parse the string representation of date and time values that lack a time zone component or use "Z" to indicate UTC.

The following example uses the "o" format specifier to display a series of [DateTime](#) values and a [DateTimeOffset](#) value on a system in the U.S. Pacific Time zone.

C#

```
using System;

public class Example
{
    public static void Main()
    {
        DateTime dat = new DateTime(2009, 6, 15, 13, 45, 30,
                                    DateTimeKind.Unspecified);
        Console.WriteLine("{0} ({1}) --> {0:0}", dat, dat.Kind);

        DateTime uDat = new DateTime(2009, 6, 15, 13, 45, 30,
                                    DateTimeKind.Utc);
        Console.WriteLine("{0} ({1}) --> {0:0}", uDat, uDat.Kind);

        DateTime lDat = new DateTime(2009, 6, 15, 13, 45, 30,
                                    DateTimeKind.Local);
        Console.WriteLine("{0} ({1}) --> {0:0}\n", lDat, lDat.Kind);

        DateTimeOffset dto = new DateTimeOffset(lDat);
        Console.WriteLine("{0} --> {0:0}", dto);
    }
}

// The example displays the following output:
//   6/15/2009 1:45:30 PM (Unspecified) --> 2009-06-15T13:45:30.0000000
//   6/15/2009 1:45:30 PM (Utc) --> 2009-06-15T13:45:30.0000000Z
//   6/15/2009 1:45:30 PM (Local) --> 2009-06-15T13:45:30.0000000-07:00
//
//   6/15/2009 1:45:30 PM -07:00 --> 2009-06-15T13:45:30.0000000-07:00
```

The following example uses the "o" format specifier to create a formatted string, and then restores the original date and time value by calling a date and time [Parse](#) method.

C#

```
// Round-trip DateTime values.
DateTime originalDate, newDate;
string dateString;
// Round-trip a local time.
originalDate = DateTime.SpecifyKind(new DateTime(2008, 4, 10, 6, 30, 0),
```

```

DateTimeKind.Local);
dateString = originalDate.ToString("o");
newDate = DateTime.Parse(dateString, null, DateTimeStyles.RoundtripKind);
Console.WriteLine("Round-tripped {0} {1} to {2} {3}.", originalDate,
originalDate.Kind,
                newDate, newDate.Kind);
// Round-trip a UTC time.
originalDate = DateTime.SpecifyKind(new DateTime(2008, 4, 12, 9, 30, 0),
DateTimeKind.Utc);
dateString = originalDate.ToString("o");
newDate = DateTime.Parse(dateString, null, DateTimeStyles.RoundtripKind);
Console.WriteLine("Round-tripped {0} {1} to {2} {3}.", originalDate,
originalDate.Kind,
                newDate, newDate.Kind);
// Round-trip time in an unspecified time zone.
originalDate = DateTime.SpecifyKind(new DateTime(2008, 4, 13, 12, 30, 0),
DateTimeKind.Unspecified);
dateString = originalDate.ToString("o");
newDate = DateTime.Parse(dateString, null, DateTimeStyles.RoundtripKind);
Console.WriteLine("Round-tripped {0} {1} to {2} {3}.", originalDate,
originalDate.Kind,
                newDate, newDate.Kind);

// Round-trip a DateTimeOffset value.
DateTimeOffset originalDTO = new DateTimeOffset(2008, 4, 12, 9, 30, 0, new
TimeSpan(-8, 0, 0));
dateString = originalDTO.ToString("o");
DateTimeOffset newDTO = DateTimeOffset.Parse(dateString, null,
DateTimeStyles.RoundtripKind);
Console.WriteLine("Round-tripped {0} to {1}.", originalDTO, newDTO);
// The example displays the following output:
//    Round-tripped 4/10/2008 6:30:00 AM Local to 4/10/2008 6:30:00 AM
Local.
//    Round-tripped 4/12/2008 9:30:00 AM Utc to 4/12/2008 9:30:00 AM Utc.
//    Round-tripped 4/13/2008 12:30:00 PM Unspecified to 4/13/2008 12:30:00
PM Unspecified.
//    Round-tripped 4/12/2008 9:30:00 AM -08:00 to 4/12/2008 9:30:00 AM
-08:00.

```

[Back to table](#)

The RFC1123 ("R", "r") format specifier

The "R" or "r" standard format specifier represents a custom date and time format string that's defined by the [DateTimeFormatInfo.RFC1123Pattern](#) property. The pattern reflects a defined standard, and the property is read-only. Therefore, it is always the same, regardless of the culture used or the format provider supplied. The custom format string is "ddd, dd MMM yyyy HH':'mm':'ss 'GMT'". When this standard format specifier is used, the formatting or parsing operation always uses the invariant culture.

The result string is affected by the following properties of the [DateTimeFormatInfo](#) object returned by the [DateTimeFormatInfo.InvariantInfo](#) property that represents the invariant culture.

| Property | Description |
|-----------------------|---|
| RFC1123Pattern | Defines the format of the result string. |
| AbbreviatedDayNames | Defines the abbreviated day names that can appear in the result string. |
| AbbreviatedMonthNames | Defines the abbreviated month names that can appear in the result string. |

Although the RFC 1123 standard expresses a time as Coordinated Universal Time (UTC), the formatting operation does not modify the value of the [DateTime](#) object that's being formatted. Therefore, you must convert the [DateTime](#) value to UTC by calling the [DateTime.ToUniversalTime](#) method before you perform the formatting operation. In contrast, [DateTimeOffset](#) values perform this conversion automatically; there's no need to call the [DateTimeOffset.ToUniversalTime](#) method before the formatting operation.

The following example uses the "r" format specifier to display a [DateTime](#) and a [DateTimeOffset](#) value on a system in the U.S. Pacific Time zone.

C#

```
DateTime date1 = new DateTime(2008, 4, 10, 6, 30, 0);
DateTimeOffset dateOffset = new DateTimeOffset(date1,
    TimeZoneInfo.Local.GetUtcOffset(date1));
Console.WriteLine(date1.ToUniversalTime().ToString("r"));
// Displays Thu, 10 Apr 2008 13:30:00 GMT
Console.WriteLine(dateOffset.ToUniversalTime().ToString("r"));
// Displays Thu, 10 Apr 2008 13:30:00 GMT
```

[Back to table](#)

The sortable ("s") format specifier

The "s" standard format specifier represents a custom date and time format string that is defined by the [DateTimeFormatInfo.SortableDateTimePattern](#) property. The pattern reflects a defined standard (ISO 8601), and the property is read-only. Therefore, it is always the same, regardless of the culture used or the format provider supplied. The custom format string is "yyyy'-'MM'-'dd'T'HH':'mm':'ss".

The purpose of the "s" format specifier is to produce result strings that sort consistently in ascending or descending order based on date and time values. As a result, although the "s" standard format specifier represents a date and time value in a consistent format, the formatting operation does not modify the value of the date and time object that is being formatted to reflect its [DateTime.Kind](#) property or its [DateTimeOffset.Offset](#) value. For example, the result strings produced by formatting the date and time values 2014-11-15T18:32:17+00:00 and 2014-11-15T18:32:17+08:00 are identical.

When this standard format specifier is used, the formatting or parsing operation always uses the invariant culture.

The following example uses the "s" format specifier to display a [DateTime](#) and a [DateTimeOffset](#) value on a system in the U.S. Pacific Time zone.

```
C#
```

```
DateTime date1 = new DateTime(2008, 4, 10, 6, 30, 0);
Console.WriteLine(date1.ToString("s"));
// Displays 2008-04-10T06:30:00
```

[Back to table](#)

The universal sortable ("u") format specifier

The "u" standard format specifier represents a custom date and time format string that is defined by the [DateTimeFormatInfo.UniversalSortableDateTimePattern](#) property. The pattern reflects a defined standard, and the property is read-only. Therefore, it is always the same, regardless of the culture used or the format provider supplied. The custom format string is "yyyy'-'MM'-'dd HH':'mm':'ss'Z"". When this standard format specifier is used, the formatting or parsing operation always uses the invariant culture.

Although the result string should express a time as Coordinated Universal Time (UTC), no conversion of the original [DateTime](#) value is performed during the formatting operation. Therefore, you must convert a [DateTime](#) value to UTC by calling the [DateTime.ToUniversalTime](#) method before formatting it. In contrast, [DateTimeOffset](#) values perform this conversion automatically; there is no need to call the [DateTimeOffset.ToUniversalTime](#) method before the formatting operation.

The following example uses the "u" format specifier to display a date and time value.

```
C#
```

```
DateTime date1 = new DateTime(2008, 4, 10, 6, 30, 0);
Console.WriteLine(date1.ToUniversalTime().ToString("u"));
```

```
// Displays 2008-04-10 13:30:00Z
```

[Back to table](#)

The universal full ("U") format specifier

The "U" standard format specifier represents a custom date and time format string that is defined by a specified culture's [DateTimeFormatInfo.FullDateTimePattern](#) property.

The pattern is the same as the "F" pattern. However, the [DateTime](#) value is automatically converted to UTC before it is formatted.

The following table lists the [DateTimeFormatInfo](#) object properties that may control the formatting of the returned string. The custom format specifier that is returned by the [FullDateTimePattern](#) property of some cultures may not make use of all properties.

| Property | Description |
|-------------------------------------|--|
| FullDateTimePattern | Defines the overall format of the result string. |
| DayNames | Defines the localized day names that can appear in the result string. |
| MonthNames | Defines the localized month names that can appear in the result string. |
| TimeSeparator | Defines the string that separates the hour, minute, and second components of a time. |
| AMDesignator | Defines the string that indicates times from midnight to before noon in a 12-hour clock. |
| PMDesignator | Defines the string that indicates times from noon to before midnight in a 12-hour clock. |

The "U" format specifier is not supported by the [DateTimeOffset](#) type and throws a [FormatException](#) if it is used to format a [DateTimeOffset](#) value.

The following example uses the "U" format specifier to display a date and time value.

C#

```
DateTime date1 = new DateTime(2008, 4, 10, 6, 30, 0);
Console.WriteLine(date1.ToString("U",
                           CultureInfo.CreateSpecificCulture("en-US")));
// Displays Thursday, April 10, 2008 1:30:00 PM
Console.WriteLine(date1.ToString("U",
                           CultureInfo.CreateSpecificCulture("sv-FI")));
// Displays den 10 april 2008 13:30:00
```

Time formats

This group includes the following formats:

- The short time ("t") format specifier
- The long time ("T") format specifier

The short time ("t") format specifier

The "t" standard format specifier represents a custom date and time format string that is defined by the current [DateTimeFormatInfo.ShortTimePattern](#) property. For example, the custom format string for the invariant culture is "HH:mm".

The result string is affected by the formatting information of a specific [DateTimeFormatInfo](#) object. The following table lists the [DateTimeFormatInfo](#) object properties that may control the formatting of the returned string. The custom format specifier that is returned by the [DateTimeFormatInfo.ShortTimePattern](#) property of some cultures may not make use of all properties.

| Property | Description |
|----------------------------------|--|
| ShortTimePattern | Defines the format of the time component of the result string. |
| TimeSeparator | Defines the string that separates the hour, minute, and second components of a time. |
| AMDesignator | Defines the string that indicates times from midnight to before noon in a 12-hour clock. |
| PMDesignator | Defines the string that indicates times from noon to before midnight in a 12-hour clock. |

The following example uses the "t" format specifier to display a date and time value.

C#

```
DateTime date1 = new DateTime(2008, 4, 10, 6, 30, 0);
Console.WriteLine(date1.ToString("t",
    CultureInfo.CreateSpecificCulture("en-us")));
// Displays 6:30 AM
Console.WriteLine(date1.ToString("t",
    CultureInfo.CreateSpecificCulture("es-ES")));
// Displays 6:30
```

[Back to table](#)

The long time ("T") format specifier

The "T" standard format specifier represents a custom date and time format string that is defined by a specific culture's [DateTimeFormatInfo.LongTimePattern](#) property. For example, the custom format string for the invariant culture is "HH:mm:ss".

The following table lists the [DateTimeFormatInfo](#) object properties that may control the formatting of the returned string. The custom format specifier that is returned by the [DateTimeFormatInfo.LongTimePattern](#) property of some cultures may not make use of all properties.

| Property | Description |
|---------------------------------|--|
| LongTimePattern | Defines the format of the time component of the result string. |
| TimeSeparator | Defines the string that separates the hour, minute, and second components of a time. |
| AMDesignator | Defines the string that indicates times from midnight to before noon in a 12-hour clock. |
| PMDesignator | Defines the string that indicates times from noon to before midnight in a 12-hour clock. |

The following example uses the "T" format specifier to display a date and time value.

C#

```
DateTime date1 = new DateTime(2008, 4, 10, 6, 30, 0);
Console.WriteLine(date1.ToString("T",
    CultureInfo.CreateSpecificCulture("en-US")));
// Displays 6:30:00 AM
Console.WriteLine(date1.ToString("T",
    CultureInfo.CreateSpecificCulture("es-ES")));
// Displays 6:30:00
```

[Back to table](#)

Partial date formats

This group includes the following formats:

- [The month \("M", "m"\) format specifier](#)
- [The year month \("Y", "y"\) format specifier](#)

The month ("M", "m") format specifier

The "M" or "m" standard format specifier represents a custom date and time format string that is defined by the current [DateTimeFormatInfo.MonthDayPattern](#) property. For example, the custom format string for the invariant culture is "MMMM dd".

The following table lists the [DateTimeFormatInfo](#) object properties that control the formatting of the returned string.

| Property | Description |
|---------------------------------|---|
| MonthDayPattern | Defines the overall format of the result string. |
| MonthNames | Defines the localized month names that can appear in the result string. |

The following example uses the "m" format specifier to display a date and time value.

C#

```
DateTime date1 = new DateTime(2008, 4, 10, 6, 30, 0);
Console.WriteLine(date1.ToString("m",
    CultureInfo.CreateSpecificCulture("en-us")));
// Displays April 10
Console.WriteLine(date1.ToString("m",
    CultureInfo.CreateSpecificCulture("ms-MY")));
// Displays 10 April
```

[Back to table](#)

The year month ("Y", "y") format specifier

The "Y" or "y" standard format specifier represents a custom date and time format string that is defined by the [DateTimeFormatInfo.YearMonthPattern](#) property of a specified culture. For example, the custom format string for the invariant culture is "yyyy MMMM".

The following table lists the [DateTimeFormatInfo](#) object properties that control the formatting of the returned string.

| Property | Description |
|----------------------------------|---|
| YearMonthPattern | Defines the overall format of the result string. |
| MonthNames | Defines the localized month names that can appear in the result string. |

The following example uses the "y" format specifier to display a date and time value.

C#

```
DateTime date1 = new DateTime(2008, 4, 10, 6, 30, 0);
Console.WriteLine(date1.ToString("Y",
    CultureInfo.CreateSpecificCulture("en-US")));
// Displays April, 2008
Console.WriteLine(date1.ToString("y",
    CultureInfo.CreateSpecificCulture("af-ZA")));
// Displays April 2008
```

[Back to table](#)

Control Panel settings

In Windows, the settings in the **Regional and Language Options** item in Control Panel influence the result string produced by a formatting operation. These settings are used to initialize the [DateTimeFormatInfo](#) object associated with the current culture, which provides values used to govern formatting. Computers that use different settings generate different result strings.

In addition, if you use the [CultureInfo\(String\)](#) constructor to instantiate a new [CultureInfo](#) object that represents the same culture as the current system culture, any customizations established by the **Regional and Language Options** item in Control Panel will be applied to the new [CultureInfo](#) object. You can use the [CultureInfo\(String, Boolean\)](#) constructor to create a [CultureInfo](#) object that does not reflect a system's customizations.

DateTimeFormatInfo properties

Formatting is influenced by properties of the current [DateTimeFormatInfo](#) object, which is provided implicitly by the current culture or explicitly by the [IFormatProvider](#) parameter of the method that invokes formatting. For the [IFormatProvider](#) parameter, your application should specify a [CultureInfo](#) object, which represents a culture, or a [DateTimeFormatInfo](#) object, which represents a particular culture's date and time formatting conventions. Many of the standard date and time format specifiers are aliases for formatting patterns defined by properties of the current [DateTimeFormatInfo](#) object. Your application can change the result produced by some standard date and time format specifiers by changing the corresponding date and time format patterns of the corresponding [DateTimeFormatInfo](#) property.

Custom date and time format strings

Article • 12/04/2022

A date and time format string defines the text representation of a [DateTime](#) or [DateTimeOffset](#) value that results from a formatting operation. It can also define the representation of a date and time value that is required in a parsing operation in order to successfully convert the string to a date and time. A custom format string consists of one or more custom date and time format specifiers. Any string that is not a [standard date and time format string](#) is interpreted as a custom date and time format string.

Tip

You can download the [Formatting Utility](#), a .NET Core Windows Forms application that lets you apply format strings to either numeric or date and time values and displays the result string. Source code is available for [C#](#) and [Visual Basic](#).

Custom date and time format strings can be used with both [DateTime](#) and [DateTimeOffset](#) values.

Note

Some of the C# examples in this article run in the [Try.NET](#) inline code runner and playground. Select the **Run** button to run an example in an interactive window. Once you execute the code, you can modify it and run the modified code by selecting **Run** again. The modified code either runs in the interactive window or, if compilation fails, the interactive window displays all C# compiler error messages.

The **local time zone** of the [Try.NET](#) inline code runner and playground is Coordinated Universal Time, or UTC. This may affect the behavior and the output of examples that illustrate the [DateTime](#), [DateTimeOffset](#), and [TimeZoneInfo](#) types and their members.

In formatting operations, custom date and time format strings can be used either with the `ToString` method of a date and time instance or with a method that supports composite formatting. The following example illustrates both uses.

C#

```
DateTime thisDate1 = new DateTime(2011, 6, 10);
Console.WriteLine("Today is " + thisDate1.ToString("MMMM dd, yyyy") + ".");
```

```

DateTimeOffset thisDate2 = new DateTimeOffset(2011, 6, 10, 15, 24, 16,
                                              TimeSpan.Zero);
Console.WriteLine("The current date and time: {0:MM/dd/yy H:mm:ss zzz}",
                  thisDate2);
// The example displays the following output:
// Today is June 10, 2011.
// The current date and time: 06/10/11 15:24:16 +00:00

```

In parsing operations, custom date and time format strings can be used with the [DateTime.ParseExact](#), [DateTime.TryParseExact](#), [DateTimeOffset.ParseExact](#), and [DateTimeOffset.TryParseExact](#) methods. These methods require that an input string conforms exactly to a particular pattern for the parse operation to succeed. The following example illustrates a call to the [DateTimeOffset.ParseExact\(String, String, IFormatProvider\)](#) method to parse a date that must include a day, a month, and a two-digit year.

C#

```

using System;
using System.Globalization;

public class Example1
{
    public static void Main()
    {
        string[] dateValues = { "30-12-2011", "12-30-2011",
                               "30-12-11", "12-30-11" };
        string pattern = "MM-dd-yy";
        DateTime parsedDate;

        foreach (var dateValue in dateValues)
        {
            if (DateTime.TryParseExact(dateValue, pattern, null,
                                      DateTimeStyles.None, out parsedDate))
                Console.WriteLine("Converted '{0}' to {1:d}.",
                                  dateValue, parsedDate);
            else
                Console.WriteLine("Unable to convert '{0}' to a date and
time.",
                                  dateValue);
        }
    }
}
// The example displays the following output:
// Unable to convert '30-12-2011' to a date and time.
// Unable to convert '12-30-2011' to a date and time.
// Unable to convert '30-12-11' to a date and time.
// Converted '12-30-11' to 12/30/2011.

```

The following table describes the custom date and time format specifiers and displays a result string produced by each format specifier. By default, result strings reflect the formatting conventions of the en-US culture. If a particular format specifier produces a localized result string, the example also notes the culture to which the result string applies. For more information about using custom date and time format strings, see the [Notes](#) section.

| Format specifier | Description | Examples |
|-------------------------|--|---|
| "d" | The day of the month, from 1 to 31. More information: The "d" Custom Format Specifier . | 2009-06-01T13:45:30 -> 1 2009-06-15T13:45:30 -> 15 |
| "dd" | The day of the month, from 01 to 31. More information: The "dd" Custom Format Specifier . | 2009-06-01T13:45:30 -> 01 2009-06-15T13:45:30 -> 15 |
| "ddd" | The abbreviated name of the day of the week. More information: The "ddd" Custom Format Specifier . | 2009-06-15T13:45:30 -> Mon (en-US) 2009-06-15T13:45:30 -> Пн (ru-RU) 2009-06-15T13:45:30 -> lun. (fr-FR) |
| "dddd" | The full name of the day of the week. More information: The "dddd" Custom Format Specifier . | 2009-06-15T13:45:30 -> Monday (en-US) 2009-06-15T13:45:30 -> понедельник (ru-RU) 2009-06-15T13:45:30 -> lundi (fr-FR) |
| "f" | The tenths of a second in a date and time value. More information: The "f" Custom Format Specifier . | 2009-06-15T13:45:30.6170000 -> 6 2009-06-15T13:45:30.05 -> 0 |
| "ff" | The hundredths of a second in a date and time value. More information: The "ff" Custom Format Specifier . | 2009-06-15T13:45:30.6170000 -> 61 2009-06-15T13:45:30.0050000 -> 00 |
| "fff" | The milliseconds in a date and time value. | 6/15/2009 13:45:30.617 -> 617 6/15/2009 13:45:30.0005 -> 000 |

| Format specifier | Description | Examples |
|------------------|---|--|
| | More information: The "fff" Custom Format Specifier . | |
| 'ffff' | <p>The ten thousandths of a second in a date and time value.</p> <p>More information: The "ffff" Custom Format Specifier.</p> | <p>2009-06-15T13:45:30.6175000 -> 6175 2009-06-15T13:45:30.0000500 -> 0000</p> |
| 'fffff' | <p>The hundred thousandths of a second in a date and time value.</p> <p>More information: The "fffff" Custom Format Specifier.</p> | <p>2009-06-15T13:45:30.6175400 -> 61754 6/15/2009 13:45:30.000005 -> 00000</p> |
| 'ffffff' | <p>The millionths of a second in a date and time value.</p> <p>More information: The "ffffff" Custom Format Specifier.</p> | <p>2009-06-15T13:45:30.6175420 -> 617542 2009-06-15T13:45:30.0000005 -> 000000</p> |
| 'fffffff' | <p>The ten millionths of a second in a date and time value.</p> <p>More information: The "fffffff" Custom Format Specifier.</p> | <p>2009-06-15T13:45:30.6175425 -> 6175425 2009-06-15T13:45:30.0001150 -> 0001150</p> |
| 'F' | <p>If non-zero, the tenths of a second in a date and time value.</p> <p>More information: The "F" Custom Format Specifier.</p> | <p>2009-06-15T13:45:30.6170000 -> 6 2009-06-15T13:45:30.0500000 -> (no output)</p> |
| 'FF' | <p>If non-zero, the hundredths of a second in a date and time value.</p> <p>More information: The "FF" Custom Format Specifier.</p> | <p>2009-06-15T13:45:30.6170000 -> 61 2009-06-15T13:45:30.0050000 -> (no output)</p> |
| 'FFF' | <p>If non-zero, the milliseconds in a date and time value.</p> <p>More information: The "FFF" Custom Format Specifier.</p> | <p>2009-06-15T13:45:30.6170000 -> 617 2009-06-15T13:45:30.0005000 -> (no output)</p> |
| 'FFFF' | <p>If non-zero, the ten thousandths of a second in a date and time value.</p> | <p>2009-06-15T13:45:30.5275000 -> 5275</p> |

| Format specifier | Description | Examples |
|-------------------------|--|--|
| | More information: The "FFFF" Custom Format Specifier. | 2009-06-15T13:45:30.0000500 -> (no output) |
| "FFFF" | If non-zero, the hundred thousandths of a second in a date and time value. | 2009-06-15T13:45:30.6175400 -> 61754 |
| | More information: The "FFFF" Custom Format Specifier. | 2009-06-15T13:45:30.0000050 -> (no output) |
| "FFFFFF" | If non-zero, the millionths of a second in a date and time value. | 2009-06-15T13:45:30.6175420 -> 617542 |
| | More information: The "FFFFFF" Custom Format Specifier. | 2009-06-15T13:45:30.0000005 -> (no output) |
| "FFFFFFF" | If non-zero, the ten millionths of a second in a date and time value. | 2009-06-15T13:45:30.6175425 -> 6175425 |
| | More information: The "FFFFFFF" Custom Format Specifier. | 2009-06-15T13:45:30.0001150 -> 000115 |
| "g", "gg" | The period or era. | 2009-06-15T13:45:30.6170000 -> A.D. |
| | More information: The "g" or "gg" Custom Format Specifier. | |
| "h" | The hour, using a 12-hour clock from 1 to 12. | 2009-06-15T01:45:30 -> 1 |
| | More information: The "h" Custom Format Specifier. | 2009-06-15T13:45:30 -> 1 |
| "hh" | The hour, using a 12-hour clock from 01 to 12. | 2009-06-15T01:45:30 -> 01 |
| | More information: The "hh" Custom Format Specifier. | 2009-06-15T13:45:30 -> 01 |
| "H" | The hour, using a 24-hour clock from 0 to 23. | 2009-06-15T01:45:30 -> 1 |
| | More information: The "H" Custom Format Specifier. | 2009-06-15T13:45:30 -> 13 |
| "HH" | The hour, using a 24-hour clock from 00 to 23. | 2009-06-15T01:45:30 -> 01 |
| | | 2009-06-15T13:45:30 -> 13 |

| Format specifier | Description | Examples |
|-------------------------|---|--|
| | More information: The "HH" Custom Format Specifier. | |
| "K" | <p>Time zone information.</p> <p>More information: The "K" Custom Format Specifier.</p> | <p>With DateTime values:</p> <p>2009-06-15T13:45:30, Kind Unspecified -></p> <p>2009-06-15T13:45:30, Kind Utc -> Z</p> <p>2009-06-15T13:45:30, Kind Local -> -07:00 (depends on local computer settings)</p> <p>With DateTimeOffset values:</p> <p>2009-06-15T01:45:30-07:00 --> -07:00</p> <p>2009-06-15T08:45:30+00:00 --> +00:00</p> |
| "m" | <p>The minute, from 0 to 59.</p> <p>More information: The "m" Custom Format Specifier.</p> | 2009-06-15T01:09:30 -> 9 |
| "mm" | <p>The minute, from 00 to 59.</p> <p>More information: The "mm" Custom Format Specifier.</p> | <p>2009-06-15T01:09:30 -> 09</p> <p>2009-06-15T01:45:30 -> 45</p> |

| "MM" | <p>The month, from 01 to 12.</p> <p>More information: The "MM" Custom Format Specifier.</p> | 2009-06-15T13:45:30 -> 06 |
| "MMM" | <p>The abbreviated name of the month.</p> <p>More information: The "MMM" Custom Format Specifier.</p> | <p>2009-06-15T13:45:30 -> Jun (en-US)</p> <p>2009-06-15T13:45:30 -> juin (fr-FR)</p> <p>2009-06-15T13:45:30 -> Jun (zu-ZA)</p> |
| "MMMM" | The full name of the month. | 2009-06-15T13:45:30 -> June (en-US) |

| Format specifier | Description | Examples |
|-------------------------|--|---|
| | More information: The "MMMM" Custom Format Specifier. | 2009-06-15T13:45:30 -> juni (da-DK) 2009-06-15T13:45:30 -> uJuni (zu-ZA) |
| "s" | The second, from 0 to 59. More information: The "s" Custom Format Specifier. | 2009-06-15T13:45:09 -> 9 |
| "ss" | The second, from 00 to 59. More information: The "ss" Custom Format Specifier. | 2009-06-15T13:45:09 -> 09 |
| "t" | The first character of the AM/PM designator. More information: The "t" Custom Format Specifier. | 2009-06-15T13:45:30 -> P (en-US) 2009-06-15T13:45:30 -> 午 (ja-JP) 2009-06-15T13:45:30 -> (fr-FR) |
| "tt" | The AM/PM designator. More information: The "tt" Custom Format Specifier. | 2009-06-15T13:45:30 -> PM (en-US) 2009-06-15T13:45:30 -> 午後 (ja-JP) 2009-06-15T13:45:30 -> (fr-FR) |
| "y" | The year, from 0 to 99. More information: The "y" Custom Format Specifier. | 0001-01-01T00:00:00 -> 1 0900-01-01T00:00:00 -> 0 1900-01-01T00:00:00 -> 0 2009-06-15T13:45:30 -> 9 2019-06-15T13:45:30 -> 19 |
| "yy" | The year, from 00 to 99. More information: The "yy" Custom Format Specifier. | 0001-01-01T00:00:00 -> 01 0900-01-01T00:00:00 -> 00 1900-01-01T00:00:00 -> 00 2019-06-15T13:45:30 -> 19 |
| "yyy" | The year, with a minimum of three digits. | 0001-01-01T00:00:00 -> 001 0900-01-01T00:00:00 -> 900 |

| Format specifier | Description | Examples |
|---|---|--|
| | More information: The "yyy" Custom Format Specifier. | 1900-01-01T00:00:00 -> 1900 2009-06-15T13:45:30 -> 2009 |
| "yyyy" | The year as a four-digit number. More information: The "yyyy" Custom Format Specifier. | 0001-01-01T00:00:00 -> 0001 0900-01-01T00:00:00 -> 0900 1900-01-01T00:00:00 -> 1900 2009-06-15T13:45:30 -> 2009 |
| "yyyyy" | The year as a five-digit number. More information: The "yyyyy" Custom Format Specifier. | 0001-01-01T00:00:00 -> 00001 2009-06-15T13:45:30 -> 02009 |
| "z" | Hours offset from UTC, with no leading zeros. More information: The "z" Custom Format Specifier. | 2009-06-15T13:45:30-07:00 -> -7 |
| "zz" | Hours offset from UTC, with a leading zero for a single-digit value. More information: The "zz" Custom Format Specifier. | 2009-06-15T13:45:30-07:00 -> -07 |
| "zzz" | Hours and minutes offset from UTC. More information: The "zzz" Custom Format Specifier. | 2009-06-15T13:45:30-07:00 -> -07:00 |
| The time separator. More information: The ":" Custom Format Specifier. | 2009-06-15T13:45:30 -> : (en-US) 2009-06-15T13:45:30 -> . (it-IT) 2009-06-15T13:45:30 -> : (ja-JP) | |
| "/" | The date separator. More Information: The "/" Custom Format Specifier. | 2009-06-15T13:45:30 -> / (en-US) 2009-06-15T13:45:30 -> - (ar-DZ) 2009-06-15T13:45:30 -> . (tr-TR) |
| "string" | Literal string delimiter. | 2009-06-15T13:45:30 ("arr:" h:m t) -> arr: 1:45 P |

| Format specifier | Description | Examples |
|---------------------|--|---|
| 'string' | More information: Character literals . | 2009-06-15T13:45:30 ('arr:' h:m t) -> arr: 1:45 P |
| % | Defines the following character as a custom format specifier. More information: Using Single Custom Format Specifiers . | 2009-06-15T13:45:30 (%h) -> 1 |
| \ | The escape character. More information: Character literals and Using the Escape Character . | 2009-06-15T13:45:30 (h \h) -> 1 h |
| Any other character | The character is copied to the result string unchanged. More information: Character literals . | 2009-06-15T01:45:30 (arr hh:mm t) -> arr 01:45 A |

The following sections provide additional information about each custom date and time format specifier. Unless otherwise noted, each specifier produces an identical string representation regardless of whether it's used with a [DateTime](#) value or a [DateTimeOffset](#) value.

Day "d" format specifier

The "d" custom format specifier

The "d" custom format specifier represents the day of the month as a number from 1 to 31. A single-digit day is formatted without a leading zero.

If the "d" format specifier is used without other custom format specifiers, it's interpreted as the "d" standard date and time format specifier. For more information about using a single format specifier, see [Using Single Custom Format Specifiers](#) later in this article.

The following example includes the "d" custom format specifier in several format strings.

C#

```
DateTime date1 = new DateTime(2008, 8, 29, 19, 27, 15);

Console.WriteLine(date1.ToString("d, M",
    CultureInfo.InvariantCulture));
```

```
// Displays 29, 8

Console.WriteLine(date1.ToString("d MMMM",
    CultureInfo.CreateSpecificCulture("en-US")));
// Displays 29 August
Console.WriteLine(date1.ToString("d MMMM",
    CultureInfo.CreateSpecificCulture("es-MX")));
// Displays 29 agosto
```

[Back to table](#)

The "dd" custom format specifier

The "dd" custom format string represents the day of the month as a number from 01 to 31. A single-digit day is formatted with a leading zero.

The following example includes the "dd" custom format specifier in a custom format string.

C#

```
DateTime date1 = new DateTime(2008, 1, 2, 6, 30, 15);

Console.WriteLine(date1.ToString("dd, MM",
    CultureInfo.InvariantCulture));
// 02, 01
```

[Back to table](#)

The "ddd" custom format specifier

The "ddd" custom format specifier represents the abbreviated name of the day of the week. The localized abbreviated name of the day of the week is retrieved from the [DateTimeFormatInfo.AbbreviatedDayNames](#) property of the current or specified culture.

The following example includes the "ddd" custom format specifier in a custom format string.

C#

```
DateTime date1 = new DateTime(2008, 8, 29, 19, 27, 15);

Console.WriteLine(date1.ToString("ddd d MMM",
    CultureInfo.CreateSpecificCulture("en-US")));
// Displays Fri 29 Aug
Console.WriteLine(date1.ToString("ddd d MMM",
```

```
CultureInfo.CreateSpecificCulture("fr-FR")));
// Displays ven. 29 août
```

[Back to table](#)

The "dddd" custom format specifier

The "dddd" custom format specifier (plus any number of additional "d" specifiers) represents the full name of the day of the week. The localized name of the day of the week is retrieved from the [DateTimeFormatInfo.DayNames](#) property of the current or specified culture.

The following example includes the "dddd" custom format specifier in a custom format string.

C#

```
DateTime date1 = new DateTime(2008, 8, 29, 19, 27, 15);

Console.WriteLine(date1.ToString("dddd dd MMMM",
                               CultureInfo.CreateSpecificCulture("en-US")));
// Displays Friday 29 August
Console.WriteLine(date1.ToString("dddd dd MMMM",
                               CultureInfo.CreateSpecificCulture("it-IT")));
// Displays venerdì 29 agosto
```

[Back to table](#)

Lowercase seconds "f" fraction specifier

The "f" custom format specifier

The "f" custom format specifier represents the most significant digit of the seconds fraction; that is, it represents the tenths of a second in a date and time value.

If the "f" format specifier is used without other format specifiers, it's interpreted as the "f" standard date and time format specifier. For more information about using a single format specifier, see [Using Single Custom Format Specifiers](#) later in this article.

When you use "f" format specifiers as part of a format string supplied to the [ParseExact](#), [TryParseExact](#), [ParseExact](#), or [TryParseExact](#) method, the number of "f" format specifiers indicates the number of most significant digits of the seconds fraction that must be present to successfully parse the string.

The following example includes the "f" custom format specifier in a custom format string.

C#

```
DateTime date1 = new DateTime(2008, 8, 29, 19, 27, 15, 18);
CultureInfo ci = CultureInfo.InvariantCulture;

Console.WriteLine(date1.ToString("hh:mm:ss.f", ci));
// Displays 07:27:15.0
Console.WriteLine(date1.ToString("hh:mm:ss.F", ci));
// Displays 07:27:15
Console.WriteLine(date1.ToString("hh:mm:ss.ff", ci));
// Displays 07:27:15.01
Console.WriteLine(date1.ToString("hh:mm:ss.FF", ci));
// Displays 07:27:15.01
Console.WriteLine(date1.ToString("hh:mm:ss.fff", ci));
// Displays 07:27:15.018
Console.WriteLine(date1.ToString("hh:mm:ss.FFF", ci));
// Displays 07:27:15.018
```

[Back to table](#)

The "ff" custom format specifier

The "ff" custom format specifier represents the two most significant digits of the seconds fraction; that is, it represents the hundredths of a second in a date and time value.

following example includes the "ff" custom format specifier in a custom format string.

C#

```
DateTime date1 = new DateTime(2008, 8, 29, 19, 27, 15, 18);
CultureInfo ci = CultureInfo.InvariantCulture;

Console.WriteLine(date1.ToString("hh:mm:ss.f", ci));
// Displays 07:27:15.0
Console.WriteLine(date1.ToString("hh:mm:ss.F", ci));
// Displays 07:27:15
Console.WriteLine(date1.ToString("hh:mm:ss.ff", ci));
// Displays 07:27:15.01
Console.WriteLine(date1.ToString("hh:mm:ss.FF", ci));
// Displays 07:27:15.01
Console.WriteLine(date1.ToString("hh:mm:ss.fff", ci));
// Displays 07:27:15.018
Console.WriteLine(date1.ToString("hh:mm:ss.FFF", ci));
// Displays 07:27:15.018
```

[Back to table](#)

The "fff" custom format specifier

The "fff" custom format specifier represents the three most significant digits of the seconds fraction; that is, it represents the milliseconds in a date and time value.

The following example includes the "fff" custom format specifier in a custom format string.

C#

```
DateTime date1 = new DateTime(2008, 8, 29, 19, 27, 15, 18);
CultureInfo ci = CultureInfo.InvariantCulture;

Console.WriteLine(date1.ToString("hh:mm:ss.f", ci));
// Displays 07:27:15.0
Console.WriteLine(date1.ToString("hh:mm:ss.F", ci));
// Displays 07:27:15
Console.WriteLine(date1.ToString("hh:mm:ss.ff", ci));
// Displays 07:27:15.01
Console.WriteLine(date1.ToString("hh:mm:ss.FF", ci));
// Displays 07:27:15.01
Console.WriteLine(date1.ToString("hh:mm:ss.fff", ci));
// Displays 07:27:15.018
Console.WriteLine(date1.ToString("hh:mm:ss.FFF", ci));
// Displays 07:27:15.018
```

[Back to table](#)

The "ffff" custom format specifier

The "ffff" custom format specifier represents the four most significant digits of the seconds fraction; that is, it represents the ten thousandths of a second in a date and time value.

Although it's possible to display the ten thousandths of a second component of a time value, that value may not be meaningful. The precision of date and time values depends on the resolution of the system clock. On the Windows NT version 3.5 (and later) and Windows Vista operating systems, the clock's resolution is approximately 10-15 milliseconds.

[Back to table](#)

The "fffff" custom format specifier

The "fffff" custom format specifier represents the five most significant digits of the seconds fraction; that is, it represents the hundred thousandths of a second in a date and time value.

Although it's possible to display the hundred thousandths of a second component of a time value, that value may not be meaningful. The precision of date and time values depends on the resolution of the system clock. On the Windows NT 3.5 (and later) and Windows Vista operating systems, the clock's resolution is approximately 10-15 milliseconds.

[Back to table](#)

The "ffffff" custom format specifier

The "ffffff" custom format specifier represents the six most significant digits of the seconds fraction; that is, it represents the millionths of a second in a date and time value.

Although it's possible to display the millionths of a second component of a time value, that value may not be meaningful. The precision of date and time values depends on the resolution of the system clock. On the Windows NT 3.5 (and later) and Windows Vista operating systems, the clock's resolution is approximately 10-15 milliseconds.

[Back to table](#)

The "fffffff" custom format specifier

The "fffffff" custom format specifier represents the seven most significant digits of the seconds fraction; that is, it represents the ten millionths of a second in a date and time value.

Although it's possible to display the ten millionths of a second component of a time value, that value may not be meaningful. The precision of date and time values depends on the resolution of the system clock. On the Windows NT 3.5 (and later) and Windows Vista operating systems, the clock's resolution is approximately 10-15 milliseconds.

[Back to table](#)

Uppercase seconds "F" fraction specifier

The "F" custom format specifier

The "F" custom format specifier represents the most significant digit of the seconds fraction; that is, it represents the tenths of a second in a date and time value. Nothing is displayed if the digit is zero, and the decimal point that follows the number of seconds is also not displayed.

If the "F" format specifier is used without other format specifiers, it's interpreted as the "F" standard date and time format specifier. For more information about using a single format specifier, see [Using Single Custom Format Specifiers](#) later in this article.

The number of "F" format specifiers used with the [ParseExact](#), [TryParseExact](#), [ParseExact](#), or [TryParseExact](#) method indicates the maximum number of most significant digits of the seconds fraction that can be present to successfully parse the string.

The following example includes the "F" custom format specifier in a custom format string.

C#

```
DateTime date1 = new DateTime(2008, 8, 29, 19, 27, 15, 18);
CultureInfo ci = CultureInfo.InvariantCulture;

Console.WriteLine(date1.ToString("hh:mm:ss.f", ci));
// Displays 07:27:15.0
Console.WriteLine(date1.ToString("hh:mm:ss.F", ci));
// Displays 07:27:15
Console.WriteLine(date1.ToString("hh:mm:ss.fff", ci));
// Displays 07:27:15.01
Console.WriteLine(date1.ToString("hh:mm:ss.FFF", ci));
// Displays 07:27:15.018
Console.WriteLine(date1.ToString("hh:mm:ss.FFF", ci));
// Displays 07:27:15.018
```

[Back to table](#)

The "FF" custom format specifier

The "FF" custom format specifier represents the two most significant digits of the seconds fraction; that is, it represents the hundredths of a second in a date and time value. Trailing zeros aren't displayed. Nothing is displayed if the two significant digits are zero, and in that case the decimal point that follows the number of seconds is also not displayed.

The following example includes the "FF" custom format specifier in a custom format string.

C#

```
DateTime date1 = new DateTime(2008, 8, 29, 19, 27, 15, 18);
CultureInfo ci = CultureInfo.InvariantCulture;

Console.WriteLine(date1.ToString("hh:mm:ss.f", ci));
// Displays 07:27:15.0
Console.WriteLine(date1.ToString("hh:mm:ss.F", ci));
// Displays 07:27:15
Console.WriteLine(date1.ToString("hh:mm:ss.ff", ci));
// Displays 07:27:15.01
Console.WriteLine(date1.ToString("hh:mm:ss.FF", ci));
// Displays 07:27:15.01
Console.WriteLine(date1.ToString("hh:mm:ss.fff", ci));
// Displays 07:27:15.018
Console.WriteLine(date1.ToString("hh:mm:ss.FFF", ci));
// Displays 07:27:15.018
```

[Back to table](#)

The "FFF" custom format specifier

The "FFF" custom format specifier represents the three most significant digits of the seconds fraction; that is, it represents the milliseconds in a date and time value. Trailing zeros aren't displayed. Nothing is displayed if the three significant digits are zero, and in that case the decimal point that follows the number of seconds is also not displayed.

The following example includes the "FFF" custom format specifier in a custom format string.

C#

```
DateTime date1 = new DateTime(2008, 8, 29, 19, 27, 15, 18);
CultureInfo ci = CultureInfo.InvariantCulture;

Console.WriteLine(date1.ToString("hh:mm:ss.f", ci));
// Displays 07:27:15.0
Console.WriteLine(date1.ToString("hh:mm:ss.F", ci));
// Displays 07:27:15
Console.WriteLine(date1.ToString("hh:mm:ss.ff", ci));
// Displays 07:27:15.01
Console.WriteLine(date1.ToString("hh:mm:ss.FF", ci));
// Displays 07:27:15.01
Console.WriteLine(date1.ToString("hh:mm:ss.fff", ci));
// Displays 07:27:15.018
Console.WriteLine(date1.ToString("hh:mm:ss.FFF", ci));
// Displays 07:27:15.018
```

[Back to table](#)

The "FFFF" custom format specifier

The "FFFF" custom format specifier represents the four most significant digits of the seconds fraction; that is, it represents the ten thousandths of a second in a date and time value. Trailing zeros aren't displayed. Nothing is displayed if the four significant digits are zero, and in that case the decimal point that follows the number of seconds is also not displayed.

Although it's possible to display the ten thousandths of a second component of a time value, that value may not be meaningful. The precision of date and time values depends on the resolution of the system clock. On the Windows NT 3.5 (and later) and Windows Vista operating systems, the clock's resolution is approximately 10-15 milliseconds.

[Back to table](#)

The "FFFFFF" custom format specifier

The "FFFFFF" custom format specifier represents the five most significant digits of the seconds fraction; that is, it represents the hundred thousandths of a second in a date and time value. Trailing zeros aren't displayed. Nothing is displayed if the five significant digits are zero, and in that case the decimal point that follows the number of seconds is also not displayed.

Although it's possible to display the hundred thousandths of a second component of a time value, that value may not be meaningful. The precision of date and time values depends on the resolution of the system clock. On the Windows NT 3.5 (and later) and Windows Vista operating systems, the clock's resolution is approximately 10-15 milliseconds.

[Back to table](#)

The "FFFFFFF" custom format specifier

The "FFFFFFF" custom format specifier represents the six most significant digits of the seconds fraction; that is, it represents the millionths of a second in a date and time value. Trailing zeros aren't displayed. Nothing is displayed if the six significant digits are zero, and in that case the decimal point that follows the number of seconds is also not displayed.

Although it's possible to display the millionths of a second component of a time value, that value may not be meaningful. The precision of date and time values depends on the resolution of the system clock. On the Windows NT 3.5 (and later) and Windows Vista operating systems, the clock's resolution is approximately 10-15 milliseconds.

[Back to table](#)

The "FFFFFF" custom format specifier

The "FFFFFF" custom format specifier represents the seven most significant digits of the seconds fraction; that is, it represents the ten millionths of a second in a date and time value. Trailing zeros aren't displayed. Nothing is displayed if the seven significant digits are zero, and in that case the decimal point that follows the number of seconds is also not displayed.

Although it's possible to display the ten millionths of a second component of a time value, that value may not be meaningful. The precision of date and time values depends on the resolution of the system clock. On the Windows NT 3.5 (and later) and Windows Vista operating systems, the clock's resolution is approximately 10-15 milliseconds.

[Back to table](#)

Era "g" format specifier

The "g" or "gg" custom format specifier

The "g" or "gg" custom format specifiers (plus any number of additional "g" specifiers) represents the period or era, such as A.D. The formatting operation ignores this specifier if the date to be formatted doesn't have an associated period or era string.

If the "g" format specifier is used without other custom format specifiers, it's interpreted as the "g" standard date and time format specifier. For more information about using a single format specifier, see [Using Single Custom Format Specifiers](#) later in this article.

The following example includes the "g" custom format specifier in a custom format string.

C#

```
DateTime date1 = new DateTime(70, 08, 04);

Console.WriteLine(date1.ToString("MM/dd/yyyy g",
    CultureInfo.InvariantCulture));
```

```
// Displays 08/04/0070 A.D.  
Console.WriteLine(date1.ToString("MM/dd/yyyy g",  
    CultureInfo.CreateSpecificCulture("fr-FR")));  
// Displays 08/04/0070 ap. J.-C.
```

[Back to table](#)

Lowercase hour "h" format specifier

The "h" custom format specifier

The "h" custom format specifier represents the hour as a number from 1 to 12; that is, the hour is represented by a 12-hour clock that counts the whole hours since midnight or noon. A particular hour after midnight is indistinguishable from the same hour after noon. The hour is not rounded, and a single-digit hour is formatted without a leading zero. For example, given a time of 5:43 in the morning or afternoon, this custom format specifier displays "5".

If the "h" format specifier is used without other custom format specifiers, it's interpreted as a standard date and time format specifier and throws a [FormatException](#). For more information about using a single format specifier, see [Using Single Custom Format Specifiers](#) later in this article.

The following example includes the "h" custom format specifier in a custom format string.

C#

```
DateTime date1;  
date1 = new DateTime(2008, 1, 1, 18, 9, 1);  
Console.WriteLine(date1.ToString("h:m:s.F t",  
    CultureInfo.InvariantCulture));  
// Displays 6:9:1 P  
Console.WriteLine(date1.ToString("h:m:s.F t",  
    CultureInfo.CreateSpecificCulture("el-GR")));  
// Displays 6:9:1 μ  
date1 = new DateTime(2008, 1, 1, 18, 9, 1, 500);  
Console.WriteLine(date1.ToString("h:m:s.F t",  
    CultureInfo.InvariantCulture));  
// Displays 6:9:1.5 P  
Console.WriteLine(date1.ToString("h:m:s.F t",  
    CultureInfo.CreateSpecificCulture("el-GR")));  
// Displays 6:9:1.5 μ
```

[Back to table](#)

The "hh" custom format specifier

The "hh" custom format specifier (plus any number of additional "h" specifiers) represents the hour as a number from 01 to 12; that is, the hour is represented by a 12-hour clock that counts the whole hours since midnight or noon. A particular hour after midnight is indistinguishable from the same hour after noon. The hour is not rounded, and a single-digit hour is formatted with a leading zero. For example, given a time of 5:43 in the morning or afternoon, this format specifier displays "05".

The following example includes the "hh" custom format specifier in a custom format string.

C#

```
DateTime date1;
date1 = new DateTime(2008, 1, 1, 18, 9, 1);
Console.WriteLine(date1.ToString("hh:mm:ss tt",
                               CultureInfo.InvariantCulture));
// Displays 06:09:01 PM
Console.WriteLine(date1.ToString("hh:mm:ss tt",
                               CultureInfo.CreateSpecificCulture("hu-HU")));
// Displays 06:09:01 du.
date1 = new DateTime(2008, 1, 1, 18, 9, 1, 500);
Console.WriteLine(date1.ToString("hh:mm:ss.ff tt",
                               CultureInfo.InvariantCulture));
// Displays 06:09:01.50 PM
Console.WriteLine(date1.ToString("hh:mm:ss.ff tt",
                               CultureInfo.CreateSpecificCulture("hu-HU")));
// Displays 06:09:01.50 du.
```

[Back to table](#)

Uppercase hour "H" format specifier

The "H" custom format specifier

The "H" custom format specifier represents the hour as a number from 0 to 23; that is, the hour is represented by a zero-based 24-hour clock that counts the hours since midnight. A single-digit hour is formatted without a leading zero.

If the "H" format specifier is used without other custom format specifiers, it's interpreted as a standard date and time format specifier and throws a [FormatException](#). For more information about using a single format specifier, see [Using Single Custom Format Specifiers](#) later in this article.

The following example includes the "H" custom format specifier in a custom format string.

```
C#
```

```
DateTime date1 = new DateTime(2008, 1, 1, 6, 9, 1);
Console.WriteLine(date1.ToString("H:mm:ss",
    CultureInfo.InvariantCulture));
// Displays 6:09:01
```

[Back to table](#)

The "HH" custom format specifier

The "HH" custom format specifier (plus any number of additional "H" specifiers) represents the hour as a number from 00 to 23; that is, the hour is represented by a zero-based 24-hour clock that counts the hours since midnight. A single-digit hour is formatted with a leading zero.

The following example includes the "HH" custom format specifier in a custom format string.

```
C#
```

```
DateTime date1 = new DateTime(2008, 1, 1, 6, 9, 1);
Console.WriteLine(date1.ToString("HH:mm:ss",
    CultureInfo.InvariantCulture));
// Displays 06:09:01
```

[Back to table](#)

Time zone "K" format specifier

The "K" custom format specifier

The "K" custom format specifier represents the time zone information of a date and time value. When this format specifier is used with [DateTime](#) values, the result string is defined by the value of the [DateTime.Kind](#) property:

- For the local time zone (a [DateTime.Kind](#) property value of [DateTimeKind.Local](#)), this specifier produces a result string containing the local offset from Coordinated Universal Time (UTC); for example, "-07:00".

- For a UTC time (a `DateTime.Kind` property value of `DateTimeKind.Utc`), the result string includes a "Z" character to represent a UTC date.
- For a time from an unspecified time zone (a time whose `DateTime.Kind` property equals `DateTimeKind.Unspecified`), the result is equivalent to `String.Empty`.

For `DateTimeOffset` values, the "K" format specifier is equivalent to the "zzz" format specifier, and produces a result string containing the `DateTimeOffset` value's offset from UTC.

If the "K" format specifier is used without other custom format specifiers, it's interpreted as a standard date and time format specifier and throws a `FormatException`. For more information about using a single format specifier, see [Using Single Custom Format Specifiers](#) later in this article.

The following example displays the string that results from using the "K" custom format specifier with various `DateTime` and `DateTimeOffset` values on a system in the U.S. Pacific Time zone.

C#

```
Console.WriteLine(DateTime.Now.ToString("%K"));
// Displays -07:00
Console.WriteLine(DateTime.UtcNow.ToString("%K"));
// Displays Z
Console.WriteLine("'{0}'",
    DateTime.SpecifyKind(DateTime.Now,
        DateTimeKind.Unspecified).ToString("%K"));
// Displays ''
Console.WriteLine(DateTimeOffset.Now.ToString("%K"));
// Displays -07:00
Console.WriteLine(DateTimeOffset.UtcNow.ToString("%K"));
// Displays +00:00
Console.WriteLine(new DateTimeOffset(2008, 5, 1, 6, 30, 0,
    new TimeSpan(5, 0, 0)).ToString("%K"));
// Displays +05:00
```

[Back to table](#)

Minute "m" format specifier

The "m" custom format specifier

The "m" custom format specifier represents the minute as a number from 0 to 59. The minute represents whole minutes that have passed since the last hour. A single-digit

minute is formatted without a leading zero.

If the "m" format specifier is used without other custom format specifiers, it's interpreted as the "m" standard date and time format specifier. For more information about using a single format specifier, see [Using Single Custom Format Specifiers](#) later in this article.

The following example includes the "m" custom format specifier in a custom format string.

C#

```
DateTime date1;
date1 = new DateTime(2008, 1, 1, 18, 9, 1);
Console.WriteLine(date1.ToString("h:m:s.F t",
                               CultureInfo.InvariantCulture));
// Displays 6:9:1 P
Console.WriteLine(date1.ToString("h:m:s.F t",
                               CultureInfo.CreateSpecificCulture("el-GR")));
// Displays 6:9:1 μ
date1 = new DateTime(2008, 1, 1, 18, 9, 1, 500);
Console.WriteLine(date1.ToString("h:m:s.F t",
                               CultureInfo.InvariantCulture));
// Displays 6:9:1.5 P
Console.WriteLine(date1.ToString("h:m:s.F t",
                               CultureInfo.CreateSpecificCulture("el-GR")));
// Displays 6:9:1.5 μ
```

[Back to table](#)

The "mm" custom format specifier

The "mm" custom format specifier (plus any number of additional "m" specifiers) represents the minute as a number from 00 to 59. The minute represents whole minutes that have passed since the last hour. A single-digit minute is formatted with a leading zero.

The following example includes the "mm" custom format specifier in a custom format string.

C#

```
DateTime date1;
date1 = new DateTime(2008, 1, 1, 18, 9, 1);
Console.WriteLine(date1.ToString("hh:mm:ss tt",
                               CultureInfo.InvariantCulture));
// Displays 06:09:01 PM
Console.WriteLine(date1.ToString("hh:mm:ss tt",
                               CultureInfo.CreateSpecificCulture("hu-HU")));
```

```
// Displays 06:09:01 du.
date1 = new DateTime(2008, 1, 1, 18, 9, 1, 500);
Console.WriteLine(date1.ToString("hh:mm:ss.ff tt",
    CultureInfo.InvariantCulture));
// Displays 06:09:01.50 PM
Console.WriteLine(date1.ToString("hh:mm:ss.ff tt",
    CultureInfo.CreateSpecificCulture("hu-HU")));
// Displays 06:09:01.50 du.
```

[Back to table](#)

Month "M" format specifier

The "M" custom format specifier

The "M" custom format specifier represents the month as a number from 1 to 12 (or from 1 to 13 for calendars that have 13 months). A single-digit month is formatted without a leading zero.

If the "M" format specifier is used without other custom format specifiers, it's interpreted as the "M" standard date and time format specifier. For more information about using a single format specifier, see [Using Single Custom Format Specifiers](#) later in this article.

The following example includes the "M" custom format specifier in a custom format string.

C#

```
DateTime date1 = new DateTime(2008, 8, 18);
Console.WriteLine(date1.ToString("(M) MMM, MMMMM",
    CultureInfo.CreateSpecificCulture("en-US")));
// Displays (8) Aug, August
Console.WriteLine(date1.ToString("(M) MMM, MMMMM",
    CultureInfo.CreateSpecificCulture("nl-NL")));
// Displays (8) aug, augustus
Console.WriteLine(date1.ToString("(M) MMM, MMMMM",
    CultureInfo.CreateSpecificCulture("lv-LV")));
// Displays (8) Aug, augusts
```

[Back to table](#)

The "MM" custom format specifier

The "MM" custom format specifier represents the month as a number from 01 to 12 (or from 1 to 13 for calendars that have 13 months). A single-digit month is formatted with a leading zero.

The following example includes the "MM" custom format specifier in a custom format string.

```
C#
```

```
DateTime date1 = new DateTime(2008, 1, 2, 6, 30, 15);

Console.WriteLine(date1.ToString("dd, MM",
    CultureInfo.InvariantCulture));
// 02, 01
```

[Back to table](#)

The "MMM" custom format specifier

The "MMM" custom format specifier represents the abbreviated name of the month.

The localized abbreviated name of the month is retrieved from the [DateTimeFormatInfo.AbbreviatedMonthNames](#) property of the current or specified culture.

The following example includes the "MMM" custom format specifier in a custom format string.

```
C#
```

```
DateTime date1 = new DateTime(2008, 8, 29, 19, 27, 15);

Console.WriteLine(date1.ToString("ddd d MMM",
    CultureInfo.CreateSpecificCulture("en-US")));
// Displays Fri 29 Aug
Console.WriteLine(date1.ToString("ddd d MMM",
    CultureInfo.CreateSpecificCulture("fr-FR")));
// Displays ven. 29 août
```

[Back to table](#)

The "MMMM" custom format specifier

The "MMMM" custom format specifier represents the full name of the month. The localized name of the month is retrieved from the [DateTimeFormatInfo.MonthNames](#) property of the current or specified culture.

The following example includes the "MMMM" custom format specifier in a custom format string.

C#

```
DateTime date1 = new DateTime(2008, 8, 29, 19, 27, 15);

Console.WriteLine(date1.ToString("ddd dd MMMM",
                               CultureInfo.CreateSpecificCulture("en-US")));
// Displays Friday 29 August
Console.WriteLine(date1.ToString("ddd dd MMMM",
                               CultureInfo.CreateSpecificCulture("it-IT")));
// Displays venerdì 29 agosto
```

[Back to table](#)

Seconds "s" format specifier

The "s" custom format specifier

The "s" custom format specifier represents the seconds as a number from 0 to 59. The result represents whole seconds that have passed since the last minute. A single-digit second is formatted without a leading zero.

If the "s" format specifier is used without other custom format specifiers, it's interpreted as the "s" standard date and time format specifier. For more information about using a single format specifier, see [Using Single Custom Format Specifiers](#) later in this article.

The following example includes the "s" custom format specifier in a custom format string.

C#

```
DateTime date1;
date1 = new DateTime(2008, 1, 1, 18, 9, 1);
Console.WriteLine(date1.ToString("h:m:s.F t",
                               CultureInfo.InvariantCulture));
// Displays 6:9:1 P
Console.WriteLine(date1.ToString("h:m:s.F t",
                               CultureInfo.CreateSpecificCulture("el-GR")));
// Displays 6:9:1 μ
date1 = new DateTime(2008, 1, 1, 18, 9, 1, 500);
Console.WriteLine(date1.ToString("h:m:s.F t",
                               CultureInfo.InvariantCulture));
// Displays 6:9:1.5 P
Console.WriteLine(date1.ToString("h:m:s.F t",
```

```
CultureInfo.CreateSpecificCulture("el-GR")));  
// Displays 6:9:1.5 μ
```

[Back to table](#)

The "ss" custom format specifier

The "ss" custom format specifier (plus any number of additional "s" specifiers) represents the seconds as a number from 00 to 59. The result represents whole seconds that have passed since the last minute. A single-digit second is formatted with a leading zero.

The following example includes the "ss" custom format specifier in a custom format string.

C#

```
DateTime date1;  
date1 = new DateTime(2008, 1, 1, 18, 9, 1);  
Console.WriteLine(date1.ToString("hh:mm:ss tt",  
                                CultureInfo.InvariantCulture));  
// Displays 06:09:01 PM  
Console.WriteLine(date1.ToString("hh:mm:ss tt",  
                                CultureInfo.CreateSpecificCulture("hu-HU")));  
// Displays 06:09:01 du.  
date1 = new DateTime(2008, 1, 1, 18, 9, 1, 500);  
Console.WriteLine(date1.ToString("hh:mm:ss.fff tt",  
                                CultureInfo.InvariantCulture));  
// Displays 06:09:01.50 PM  
Console.WriteLine(date1.ToString("hh:mm:ss.fff tt",  
                                CultureInfo.CreateSpecificCulture("hu-HU")));  
// Displays 06:09:01.50 du.
```

[Back to table](#)

Meridiem "t" format specifier

The "t" custom format specifier

The "t" custom format specifier represents the first character of the AM/PM designator. The appropriate localized designator is retrieved from the [DateTimeFormatInfo.AMDesignator](#) or [DateTimeFormatInfo.PMDesignator](#) property of the current or specific culture. The AM designator is used for all times from 0:00:00

(midnight) to 11:59:59.999. The PM designator is used for all times from 12:00:00 (noon) to 23:59:59.999.

If the "t" format specifier is used without other custom format specifiers, it's interpreted as the "t" standard date and time format specifier. For more information about using a single format specifier, see [Using Single Custom Format Specifiers](#) later in this article.

The following example includes the "t" custom format specifier in a custom format string.

C#

```
DateTime date1;
date1 = new DateTime(2008, 1, 1, 18, 9, 1);
Console.WriteLine(date1.ToString("h:m:s.F t",
                               CultureInfo.InvariantCulture));
// Displays 6:9:1 P
Console.WriteLine(date1.ToString("h:m:s.F t",
                               CultureInfo.CreateSpecificCulture("el-GR")));
// Displays 6:9:1 μ
date1 = new DateTime(2008, 1, 1, 18, 9, 1, 500);
Console.WriteLine(date1.ToString("h:m:s.F t",
                               CultureInfo.InvariantCulture));
// Displays 6:9:1.5 P
Console.WriteLine(date1.ToString("h:m:s.F t",
                               CultureInfo.CreateSpecificCulture("el-GR")));
// Displays 6:9:1.5 μ
```

[Back to table](#)

The "tt" custom format specifier

The "tt" custom format specifier (plus any number of additional "t" specifiers) represents the entire AM/PM designator. The appropriate localized designator is retrieved from the [DateTimeFormatInfo.AMDesignator](#) or [DateTimeFormatInfo.PMDesignator](#) property of the current or specific culture. The AM designator is used for all times from 0:00:00 (midnight) to 11:59:59.999. The PM designator is used for all times from 12:00:00 (noon) to 23:59:59.999.

Make sure to use the "tt" specifier for languages for which it's necessary to maintain the distinction between AM and PM. An example is Japanese, for which the AM and PM designators differ in the second character instead of the first character.

The following example includes the "tt" custom format specifier in a custom format string.

C#

```
DateTime date1;
date1 = new DateTime(2008, 1, 1, 18, 9, 1);
Console.WriteLine(date1.ToString("hh:mm:ss tt",
                               CultureInfo.InvariantCulture));
// Displays 06:09:01 PM
Console.WriteLine(date1.ToString("hh:mm:ss tt",
                               CultureInfo.CreateSpecificCulture("hu-HU")));
// Displays 06:09:01 du.
date1 = new DateTime(2008, 1, 1, 18, 9, 1, 500);
Console.WriteLine(date1.ToString("hh:mm:ss.ff tt",
                               CultureInfo.InvariantCulture));
// Displays 06:09:01.50 PM
Console.WriteLine(date1.ToString("hh:mm:ss.ff tt",
                               CultureInfo.CreateSpecificCulture("hu-HU")));
// Displays 06:09:01.50 du.
```

[Back to table](#)

Year "y" format specifier

The "y" custom format specifier

The "y" custom format specifier represents the year as a one-digit or two-digit number. If the year has more than two digits, only the two low-order digits appear in the result. If the first digit of a two-digit year begins with a zero (for example, 2008), the number is formatted without a leading zero.

If the "y" format specifier is used without other custom format specifiers, it's interpreted as the "y" standard date and time format specifier. For more information about using a single format specifier, see [Using Single Custom Format Specifiers](#) later in this article.

The following example includes the "y" custom format specifier in a custom format string.

C#

```
DateTime date1 = new DateTime(1, 12, 1);
DateTime date2 = new DateTime(2010, 1, 1);
Console.WriteLine(date1.ToString("%y"));
// Displays 1
Console.WriteLine(date1.ToString("yy"));
// Displays 01
Console.WriteLine(date1.ToString("yyy"));
// Displays 001
Console.WriteLine(date1.ToString("yyyy"));
```

```

// Displays 0001
Console.WriteLine(date1.ToString("yyyy"));
// Displays 0001
Console.WriteLine(date2.ToString("%y"));
// Displays 10
Console.WriteLine(date2.ToString("yy"));
// Displays 10
Console.WriteLine(date2.ToString("yyy"));
// Displays 2010
Console.WriteLine(date2.ToString("yyyy"));
// Displays 2010
Console.WriteLine(date2.ToString("yyyyy"));
// Displays 02010

```

[Back to table](#)

The "yy" custom format specifier

The "yy" custom format specifier represents the year as a two-digit number. If the year has more than two digits, only the two low-order digits appear in the result. If the two-digit year has fewer than two significant digits, the number is padded with leading zeros to produce two digits.

In a parsing operation, a two-digit year that is parsed using the "yy" custom format specifier is interpreted based on the [Calendar.TwoDigitYearMax](#) property of the format provider's current calendar. The following example parses the string representation of a date that has a two-digit year by using the default Gregorian calendar of the en-US culture, which, in this case, is the current culture. It then changes the current culture's [CultureInfo](#) object to use a [GregorianCalendar](#) object whose [TwoDigitYearMax](#) property has been modified.

C#

```

using System;
using System.Globalization;
using System.Threading;

public class Example7
{
    public static void Main()
    {
        string fmt = "dd-MMM-yy";
        string value = "24-Jan-49";

        Calendar cal =
(Calendar)CultureInfo.CurrentCulture.Calendar.Clone();
        Console.WriteLine("Two Digit Year Range: {0} - {1}",
                           cal.TwoDigitYearMax - 99, cal.TwoDigitYearMax);
    }
}

```

```

        Console.WriteLine("{0:d}", DateTime.ParseExact(value, fmt, null));
        Console.WriteLine();

        cal.TwoDigitYearMax = 2099;
        CultureInfo culture =
(CultureInfo)CultureInfo.CurrentCulture.Clone();
        culture.DateTimeFormat.Calendar = cal;
        Thread.CurrentThread.CurrentCulture = culture;

        Console.WriteLine("Two Digit Year Range: {0} - {1}",
                           cal.TwoDigitYearMax - 99, cal.TwoDigitYearMax);
        Console.WriteLine("{0:d}", DateTime.ParseExact(value, fmt, null));
    }
}

// The example displays the following output:
//      Two Digit Year Range: 1930 - 2029
//      1/24/1949
//
//      Two Digit Year Range: 2000 - 2099
//      1/24/2049

```

The following example includes the "yy" custom format specifier in a custom format string.

C#

```

DateTime date1 = new DateTime(1, 12, 1);
DateTime date2 = new DateTime(2010, 1, 1);
Console.WriteLine(date1.ToString("%y"));
// Displays 1
Console.WriteLine(date1.ToString("yy"));
// Displays 01
Console.WriteLine(date1.ToString("yyy"));
// Displays 001
Console.WriteLine(date1.ToString("yyyy"));
// Displays 0001
Console.WriteLine(date1.ToString("yyyyy"));
// Displays 00001
Console.WriteLine(date2.ToString("%y"));
// Displays 10
Console.WriteLine(date2.ToString("yy"));
// Displays 10
Console.WriteLine(date2.ToString("yyy"));
// Displays 2010
Console.WriteLine(date2.ToString("yyyy"));
// Displays 2010
Console.WriteLine(date2.ToString("yyyyy"));
// Displays 02010

```

[Back to table](#)

The "yyy" custom format specifier

The "yyy" custom format specifier represents the year with a minimum of three digits. If the year has more than three significant digits, they are included in the result string. If the year has fewer than three digits, the number is padded with leading zeros to produce three digits.

ⓘ Note

For the Thai Buddhist calendar, which can have five-digit years, this format specifier displays all significant digits.

The following example includes the "yyy" custom format specifier in a custom format string.

C#

```
DateTime date1 = new DateTime(1, 12, 1);
DateTime date2 = new DateTime(2010, 1, 1);
Console.WriteLine(date1.ToString("%y"));
// Displays 1
Console.WriteLine(date1.ToString("yy"));
// Displays 01
Console.WriteLine(date1.ToString("yyy"));
// Displays 001
Console.WriteLine(date1.ToString("yyyy"));
// Displays 0001
Console.WriteLine(date1.ToString("yyyyy"));
// Displays 00001
Console.WriteLine(date2.ToString("%y"));
// Displays 10
Console.WriteLine(date2.ToString("yy"));
// Displays 10
Console.WriteLine(date2.ToString("yyy"));
// Displays 2010
Console.WriteLine(date2.ToString("yyyy"));
// Displays 2010
Console.WriteLine(date2.ToString("yyyyy"));
// Displays 02010
```

[Back to table](#)

The "yyyy" custom format specifier

The "yyyy" custom format specifier represents the year with a minimum of four digits. If the year has more than four significant digits, they are included in the result string. If the

year has fewer than four digits, the number is padded with leading zeros to produce four digits.

ⓘ Note

For the Thai Buddhist calendar, which can have five-digit years, this format specifier displays a minimum of four digits.

The following example includes the "yyyy" custom format specifier in a custom format string.

C#

```
DateTime date1 = new DateTime(1, 12, 1);
DateTime date2 = new DateTime(2010, 1, 1);
Console.WriteLine(date1.ToString("%y"));
// Displays 1
Console.WriteLine(date1.ToString("yy"));
// Displays 01
Console.WriteLine(date1.ToString("yyy"));
// Displays 001
Console.WriteLine(date1.ToString("yyyy"));
// Displays 0001
Console.WriteLine(date1.ToString("yyyyy"));
// Displays 00001
Console.WriteLine(date2.ToString("%y"));
// Displays 10
Console.WriteLine(date2.ToString("yy"));
// Displays 10
Console.WriteLine(date2.ToString("yyy"));
// Displays 2010
Console.WriteLine(date2.ToString("yyyy"));
// Displays 2010
Console.WriteLine(date2.ToString("yyyyy"));
// Displays 02010
```

[Back to table](#)

The "yyyyy" custom format specifier

The "yyyyy" custom format specifier (plus any number of additional "y" specifiers) represents the year with a minimum of five digits. If the year has more than five significant digits, they are included in the result string. If the year has fewer than five digits, the number is padded with leading zeros to produce five digits.

If there are additional "y" specifiers, the number is padded with as many leading zeros as necessary to produce the number of "y" specifiers.

The following example includes the "yyyyy" custom format specifier in a custom format string.

C#

```
DateTime date1 = new DateTime(1, 12, 1);
DateTime date2 = new DateTime(2010, 1, 1);
Console.WriteLine(date1.ToString("%y"));
// Displays 1
Console.WriteLine(date1.ToString("yy"));
// Displays 01
Console.WriteLine(date1.ToString("yyy"));
// Displays 001
Console.WriteLine(date1.ToString("yyyy"));
// Displays 0001
Console.WriteLine(date1.ToString("yyyyy"));
// Displays 00001
Console.WriteLine(date2.ToString("%y"));
// Displays 10
Console.WriteLine(date2.ToString("yy"));
// Displays 10
Console.WriteLine(date2.ToString("yyy"));
// Displays 2010
Console.WriteLine(date2.ToString("yyyy"));
// Displays 2010
Console.WriteLine(date2.ToString("yyyyy"));
// Displays 02010
```

[Back to table](#)

Offset "z" format specifier

The "z" custom format specifier

With [DateTime](#) values, the "z" custom format specifier represents the signed offset of the specified time zone from Coordinated Universal Time (UTC), measured in hours. The offset is always displayed with a leading sign. A plus sign (+) indicates hours ahead of UTC, and a minus sign (-) indicates hours behind UTC. A single-digit offset is formatted *without* a leading zero.

The following table shows how the offset value changes depending on [DateTimeKind](#).

| DateTimeKind | Offset value |
|---------------------|--|
| Local | The signed offset of the local operating system's time zone from UTC. |
| Unspecified | The signed offset of the local operating system's time zone from UTC. |
| Utc | +0 on .NET Core and .NET 5+. On .NET Framework, the signed offset of the local operating system's time zone from UTC. |

With [DateTimeOffset](#) values, this format specifier represents the [DateTimeOffset](#) value's offset from UTC in hours.

If the "z" format specifier is used without other custom format specifiers, it's interpreted as a standard date and time format specifier and throws a [FormatException](#). For more information about using a single format specifier, see [Using Single Custom Format Specifiers](#) later in this article.

The following example includes the "z" custom format specifier in a custom format string.

C#

```
DateTime date1 = DateTime.UtcNow;
Console.WriteLine(String.Format("{0:%z}, {0:zz}, {0:zzz}",
    date1));
// Displays -7, -07, -07:00 on .NET Framework
// Displays +0, +00, +00:00 on .NET Core and .NET 5+

DateTimeOffset date2 = new DateTimeOffset(2008, 8, 1, 0, 0, 0,
    new TimeSpan(6, 0, 0));
Console.WriteLine(String.Format("{0:%z}, {0:zz}, {0:zzz}",
    date2));
// Displays +6, +06, +06:00
```

[Back to table](#)

The "zz" custom format specifier

With [DateTime](#) values, the "zz" custom format specifier represents the signed offset of the specified time zone from UTC, measured in hours. The offset is always displayed with a leading sign. A plus sign (+) indicates hours ahead of UTC, and a minus sign (-) indicates hours behind UTC. A single-digit offset is formatted *with* a leading zero.

The following table shows how the offset value changes depending on [DateTimeKind](#).

| DateTimeKind | Offset value |
|---------------------|---|
| Local | The signed offset of the local operating system's time zone from UTC. |
| Unspecified | The signed offset of the local operating system's time zone from UTC. |
| Utc | +00 on .NET Core and .NET 5+. On .NET Framework, the signed offset of the local operating system's time zone from UTC. |

With [DateTimeOffset](#) values, this format specifier represents the [DateTimeOffset](#) value's offset from UTC in hours.

The following example includes the "zz" custom format specifier in a custom format string.

C#

```
DateTime date1 = DateTime.UtcNow;
Console.WriteLine(String.Format("{0:%z}, {0:zz}, {0:zzz}",
                               date1));
// Displays -7, -07, -07:00 on .NET Framework
// Displays +0, +00, +00:00 on .NET Core and .NET 5+

DateTimeOffset date2 = new DateTimeOffset(2008, 8, 1, 0, 0, 0,
                                         new TimeSpan(6, 0, 0));
Console.WriteLine(String.Format("{0:%z}, {0:zz}, {0:zzz}",
                               date2));
// Displays +6, +06, +06:00
```

[Back to table](#)

The "zzz" custom format specifier

With [DateTime](#) values, the "zzz" custom format specifier represents the signed offset of the specified time zone from UTC, measured in hours and minutes. The offset is always displayed with a leading sign. A plus sign (+) indicates hours ahead of UTC, and a minus sign (-) indicates hours behind UTC. A single-digit offset is formatted with a leading zero.

The following table shows how the offset value changes depending on [DateTimeKind](#).

| DateTimeKind | Offset value |
|---------------------|--|
| Local | The signed offset of the local operating system's time zone from UTC. |
| Unspecified | The signed offset of the local operating system's time zone from UTC. |
| Utc | +00:00 on .NET Core and .NET 5+. On .NET Framework, the signed offset of the local operating system's time zone from UTC. |

With [DateTimeOffset](#) values, this format specifier represents the [DateTimeOffset](#) value's offset from UTC in hours and minutes.

The following example includes the "zzz" custom format specifier in a custom format string.

C#

```
DateTime date1 = DateTime.UtcNow;
Console.WriteLine(String.Format("{0:%z}, {0:zz}, {0:zzz}",
                               date1));
// Displays -7, -07, -07:00 on .NET Framework
// Displays +0, +00, +00:00 on .NET Core and .NET 5+

DateTimeOffset date2 = new DateTimeOffset(2008, 8, 1, 0, 0, 0,
                                         new TimeSpan(6, 0, 0));
Console.WriteLine(String.Format("{0:%z}, {0:zz}, {0:zzz}",
                               date2));
// Displays +6, +06, +06:00
```

[Back to table](#)

Date and time separator specifiers

The ":" custom format specifier

The ":" custom format specifier represents the time separator, which is used to differentiate hours, minutes, and seconds. The appropriate localized time separator is retrieved from the [DateTimeFormatInfo.TimeSeparator](#) property of the current or specified culture.

 **Note**

To change the time separator for a particular date and time string, specify the separator character within a literal string delimiter. For example, the custom format string `hh'_'dd'_'ss` produces a result string in which "_" (an underscore) is always used as the time separator. To change the time separator for all dates for a culture, either change the value of the `DateTimeFormatInfo.TimeSeparator` property of the current culture, or instantiate a `DateTimeFormatInfo` object, assign the character to its `TimeSeparator` property, and call an overload of the formatting method that includes an `IFormatProvider` parameter.

If the ":" format specifier is used without other custom format specifiers, it's interpreted as a standard date and time format specifier and throws a `FormatException`. For more information about using a single format specifier, see [Using Single Custom Format Specifiers](#) later in this article.

[Back to table](#)

The "/" custom format specifier

The "/" custom format specifier represents the date separator, which is used to differentiate years, months, and days. The appropriate localized date separator is retrieved from the `DateTimeFormatInfo.DateSeparator` property of the current or specified culture.

ⓘ Note

To change the date separator for a particular date and time string, specify the separator character within a literal string delimiter. For example, the custom format string `mm'/'dd'/'yyyy` produces a result string in which "/" is always used as the date separator. To change the date separator for all dates for a culture, either change the value of the `DateTimeFormatInfo.DateSeparator` property of the current culture, or instantiate a `DateTimeFormatInfo` object, assign the character to its `DateSeparator` property, and call an overload of the formatting method that includes an `IFormatProvider` parameter.

If the "/" format specifier is used without other custom format specifiers, it's interpreted as a standard date and time format specifier and throws a `FormatException`. For more information about using a single format specifier, see [Using Single Custom Format Specifiers](#) later in this article.

[Back to table](#)

Character literals

The following characters in a custom date and time format string are reserved and are always interpreted as formatting characters or, in the case of `"`, `'`, `/`, and `\`, as special characters.

- `F`
- `H`
- `K`
- `M`
- `d`
- `f`
- `g`
- `h`
- `m`
- `s`
- `t`
- `y`
- `z`
- `%`
- `:`
- `/`
- `"`
- `'`
- `\`

All other characters are always interpreted as character literals and, in a formatting operation, are included in the result string unchanged. In a parsing operation, they must match the characters in the input string exactly; the comparison is case-sensitive.

The following example includes the literal characters "PST" (for Pacific Standard Time) and "PDT" (for Pacific Daylight Time) to represent the local time zone in a format string. Note that the string is included in the result string, and that a string that includes the local time zone string also parses successfully.

C#

```
using System;
using System.Globalization;

public class Example5
{
```

```

public static void Main()
{
    String[] formats = { "dd MMM yyyy hh:mm tt PST",
                        "dd MMM yyyy hh:mm tt PDT" };
    var dat = new DateTime(2016, 8, 18, 16, 50, 0);
    // Display the result string.
    Console.WriteLine(dat.ToString(formats[1]));

    // Parse a string.
    String value = "25 Dec 2016 12:00 pm PST";
    DateTime newDate;
    if (DateTime.TryParseExact(value, formats, null,
                               DateTimeStyles.None, out newDate))
        Console.WriteLine(newDate);
    else
        Console.WriteLine("Unable to parse '{0}'", value);
}
// The example displays the following output:
//      18 Aug 2016 04:50 PM PDT
//      12/25/2016 12:00:00 PM

```

There are two ways to indicate that characters are to be interpreted as literal characters and not as reserve characters, so that they can be included in a result string or successfully parsed in an input string:

- By escaping each reserved character. For more information, see [Using the Escape Character](#).

The following example includes the literal characters "pst" (for Pacific Standard time) to represent the local time zone in a format string. Because both "s" and "t" are custom format strings, both characters must be escaped to be interpreted as character literals.

C#

```

using System;
using System.Globalization;

public class Example3
{
    public static void Main()
    {
        String format = "dd MMM yyyy hh:mm tt p\\s\\t";
        var dat = new DateTime(2016, 8, 18, 16, 50, 0);
        // Display the result string.
        Console.WriteLine(dat.ToString(format));

        // Parse a string.
        String value = "25 Dec 2016 12:00 pm pst";
        DateTime newDate;
        if (DateTime.TryParseExact(value, format, null,

```

```

                DateTimeStyles.None, out newDate))
        Console.WriteLine(newDate);
    else
        Console.WriteLine("Unable to parse '{0}'", value);
}
// The example displays the following output:
//      18 Aug 2016 04:50 PM pst
//      12/25/2016 12:00:00 PM

```

- By enclosing the entire literal string in quotation marks or apostrophes. The following example is like the previous one, except that "pst" is enclosed in quotation marks to indicate that the entire delimited string should be interpreted as character literals.

C#

```

using System;
using System.Globalization;

public class Example6
{
    public static void Main()
    {
        String format = "dd MMM yyyy hh:mm tt \"pst\"";
        var dat = new DateTime(2016, 8, 18, 16, 50, 0);
        // Display the result string.
        Console.WriteLine(dat.ToString(format));

        // Parse a string.
        String value = "25 Dec 2016 12:00 pm pst";
        DateTime newDate;
        if (DateTime.TryParseExact(value, format, null,
            DateTimeStyles.None, out newDate))
            Console.WriteLine(newDate);
        else
            Console.WriteLine("Unable to parse '{0}'", value);
    }
}
// The example displays the following output:
//      18 Aug 2016 04:50 PM pst
//      12/25/2016 12:00:00 PM

```

Notes

Using single custom format specifiers

A custom date and time format string consists of two or more characters. Date and time formatting methods interpret any single-character string as a standard date and time format string. If they don't recognize the character as a valid format specifier, they throw a [FormatException](#). For example, a format string that consists only of the specifier "h" is interpreted as a standard date and time format string. However, in this particular case, an exception is thrown because there is no "h" standard date and time format specifier.

To use any of the custom date and time format specifiers as the only specifier in a format string (that is, to use the "d", "f", "F", "g", "h", "H", "K", "m", "M", "s", "t", "y", "z", ":", or "/" custom format specifier by itself), include a space before or after the specifier, or include a percent ("%") format specifier before the single custom date and time specifier.

For example, "%h" is interpreted as a custom date and time format string that displays the hour represented by the current date and time value. You can also use the " h" or "h" format string, although this includes a space in the result string along with the hour. The following example illustrates these three format strings.

C#

```
DateTime dat1 = new DateTime(2009, 6, 15, 13, 45, 0);

Console.WriteLine("{0:%h}", dat1);
Console.WriteLine("{0: h}", dat1);
Console.WriteLine("{0:h }", dat1);
// The example displays the following output:
//      '1'
//      ' 1'
//      '1 '
```

Using the Escape character

The "d", "f", "F", "g", "h", "H", "K", "m", "M", "s", "t", "y", "z", ":", or "/" characters in a format string are interpreted as custom format specifiers rather than as literal characters. To prevent a character from being interpreted as a format specifier, you can precede it with a backslash (\), which is the escape character. The escape character signifies that the following character is a character literal that should be included in the result string unchanged.

To include a backslash in a result string, you must escape it with another backslash (\\\).

 **Note**

Some compilers, such as the C++ and C# compilers, may also interpret a single backslash character as an escape character. To ensure that a string is interpreted correctly when formatting, you can use the verbatim string literal character (the @ character) before the string in C#, or add another backslash character before each backslash in C# and C++. The following C# example illustrates both approaches.

The following example uses the escape character to prevent the formatting operation from interpreting the "h" and "m" characters as format specifiers.

C#

```
DateTime date = new DateTime(2009, 06, 15, 13, 45, 30, 90);
string fmt1 = "h \\h m \\m";
string fmt2 = @"h \h m \m";

Console.WriteLine("{0} ({1}) -> {2}", date, fmt1, date.ToString(fmt1));
Console.WriteLine("{0} ({1}) -> {2}", date, fmt2, date.ToString(fmt2));
// The example displays the following output:
//      6/15/2009 1:45:30 PM (h \h m \m) -> 1 h 45 m
//      6/15/2009 1:45:30 PM (h \h m \m) -> 1 h 45 m
```

Control Panel settings

The **Regional and Language Options** settings in Control Panel influence the result string produced by a formatting operation that includes many of the custom date and time format specifiers. These settings are used to initialize the [DateTimeFormatInfo](#) object associated with the current culture, which provides values used to govern formatting. Computers that use different settings generate different result strings.

In addition, if you use the [CultureInfo\(String\)](#) constructor to instantiate a new [CultureInfo](#) object that represents the same culture as the current system culture, any customizations established by the **Regional and Language Options** item in Control Panel will be applied to the new [CultureInfo](#) object. You can use the [CultureInfo\(String, Boolean\)](#) constructor to create a [CultureInfo](#) object that doesn't reflect a system's customizations.

DateTimeFormatInfo properties

Formatting is influenced by properties of the current [DateTimeFormatInfo](#) object, which is provided implicitly by the current culture or explicitly by the [IFormatProvider](#) parameter of the method that invokes formatting. For the [IFormatProvider](#) parameter,

you should specify a [CultureInfo](#) object, which represents a culture, or a [DateTimeFormatInfo](#) object.

The result string produced by many of the custom date and time format specifiers also depends on properties of the current [DateTimeFormatInfo](#) object. Your application can change the result produced by some custom date and time format specifiers by changing the corresponding [DateTimeFormatInfo](#) property. For example, the "ddd" format specifier adds an abbreviated weekday name found in the [AbbreviatedDayNames](#) string array to the result string. Similarly, the "MMMM" format specifier adds a full month name found in the [MonthNames](#) string array to the result string.

Standard TimeSpan format strings

Article • 07/20/2022

A standard [TimeSpan](#) format string uses a single format specifier to define the text representation of a [TimeSpan](#) value that results from a formatting operation. Any format string that contains more than one character, including white space, is interpreted as a custom [TimeSpan](#) format string. For more information, see [Custom TimeSpan format strings](#).

The string representations of [TimeSpan](#) values are produced by calls to the overloads of the [TimeSpan.ToString](#) method, as well as by methods that support composite formatting, such as [String.Format](#). For more information, see [Formatting Types](#) and [Composite Formatting](#). The following example illustrates the use of standard format strings in formatting operations.

C#

```
using System;

public class Example
{
    public static void Main()
    {
        TimeSpan duration = new TimeSpan(1, 12, 23, 62);
        string output = "Time of Travel: " + duration.ToString("c");
        Console.WriteLine(output);

        Console.WriteLine("Time of Travel: {0:c}", duration);
    }
}
// The example displays the following output:
//      Time of Travel: 1.12:24:02
//      Time of Travel: 1.12:24:02
```

Standard [TimeSpan](#) format strings are also used by the [TimeSpan.ParseExact](#) and [TimeSpan.TryParseExact](#) methods to define the required format of input strings for parsing operations. (Parsing converts the string representation of a value to that value.) The following example illustrates the use of standard format strings in parsing operations.

C#

```
using System;

public class Example
{
```

```

public static void Main()
{
    string value = "1.03:14:56.1667";
    TimeSpan interval;
    try {
        interval = TimeSpan.ParseExact(value, "c", null);
        Console.WriteLine("Converted '{0}' to {1}", value, interval);
    }
    catch (FormatException) {
        Console.WriteLine("{0}: Bad Format", value);
    }
    catch (OverflowException) {
        Console.WriteLine("{0}: Out of Range", value);
    }

    if (TimeSpan.TryParseExact(value, "c", null, out interval))
        Console.WriteLine("Converted '{0}' to {1}", value, interval);
    else
        Console.WriteLine("Unable to convert {0} to a time interval.",
                          value);
}
// The example displays the following output:
//      Converted '1.03:14:56.1667' to 1.03:14:56.1667000
//      Converted '1.03:14:56.1667' to 1.03:14:56.1667000

```

The following table lists the standard time interval format specifiers.

| Format specifier | Name | Description | Examples |
|------------------|-----------------------------|--|--|
| "c" | Constant (invariant) format | This specifier is not culture-sensitive. It takes the form [-] [d'.']hh'':'mm'':'ss['.'fffffff]. (The "t" and "T" format strings produce the same results.) More information: The Constant ("c") Format Specifier . | TimeSpan.Zero -> 00:00:00 New TimeSpan(0, 0, 30, 0) -> 00:30:00 New TimeSpan(3, 17, 25, 30, 500) -> 3.17:25:30.5000000 |
| "g" | General short format | This specifier outputs only what is needed. It is culture-sensitive and takes the form [-] [d' ':']h' ':'mm' ':'ss[.FFFFFF]. More information: The General Short ("g") Format Specifier . | New TimeSpan(1, 3, 16, 50, 500) -> 1:3:16:50.5 (en-US) New TimeSpan(1, 3, 16, 50, 500) -> 1:3:16:50,5 (fr-FR) New TimeSpan(1, 3, 16, 50, 599) -> |

| Format specifier | Name | Description | Examples |
|------------------|---------------------|---|--|
| | | | 1:3:16:50.599 (en-US) |
| "G" | General long format | This specifier always outputs days and seven fractional digits. It is culture-sensitive and takes the form <code>[-]d':'hh':'mm':'ss.fffffff.</code> | New TimeSpan(1, 3, 16, 50, 599) -> 1:3:16:50,599 (fr-FR) More information: The General Long ("G") Format Specifier . |

The Constant ("c") Format Specifier

The "c" format specifier returns the string representation of a [TimeSpan](#) value in the following form:

`[-][d.]hh:mm:ss[.fffffff]`

Elements in square brackets ([and]) are optional. The period (.) and colon (:) are literal symbols. The following table describes the remaining elements.

| Element | Description |
|---------|--|
| - | An optional negative sign, which indicates a negative time interval. |
| d | The optional number of days, with no leading zeros. |
| hh | The number of hours, which ranges from "00" to "23". |
| mm | The number of minutes, which ranges from "00" to "59". |
| ss | The number of seconds, which ranges from "0" to "59". |
| fffffff | The optional fractional portion of a second. Its value can range from "0000001" (one tick, or one ten-millionth of a second) to "9999999" (9,999,999 ten-millionths of a second, or one second less one tick). |

Unlike the "g" and "G" format specifiers, the "c" format specifier is not culture-sensitive. It produces the string representation of a [TimeSpan](#) value that is invariant and that's

common to versions prior to .NET Framework 4. "c" is the default [TimeSpan](#) format string; the [TimeSpan.ToString\(\)](#) method formats a time interval value by using the "c" format string.

ⓘ Note

[TimeSpan](#) also supports the "t" and "T" standard format strings, which are identical in behavior to the "c" standard format string.

The following example instantiates two [TimeSpan](#) objects, uses them to perform arithmetic operations, and displays the result. In each case, it uses composite formatting to display the [TimeSpan](#) value by using the "c" format specifier.

C#

```
using System;

public class Example
{
    public static void Main()
    {
        TimeSpan interval1, interval2;
        interval1 = new TimeSpan(7, 45, 16);
        interval2 = new TimeSpan(18, 12, 38);

        Console.WriteLine("{0:c} - {1:c} = {2:c}", interval1,
                          interval2, interval1 - interval2);
        Console.WriteLine("{0:c} + {1:c} = {2:c}", interval1,
                          interval2, interval1 + interval2);

        interval1 = new TimeSpan(0, 0, 1, 14, 365);
        interval2 = TimeSpan.FromTicks(2143756);
        Console.WriteLine("{0:c} + {1:c} = {2:c}", interval1,
                          interval2, interval1 + interval2);
    }
}

// The example displays the following output:
//      07:45:16 - 18:12:38 = -10:27:22
//      07:45:16 + 18:12:38 = 1.01:57:54
//      00:01:14.3650000 + 00:00:00.2143756 = 00:01:14.5793756
```

The General Short ("g") Format Specifier

The "g" [TimeSpan](#) format specifier returns the string representation of a [TimeSpan](#) value in a compact form by including only the elements that are necessary. It has the following form:

[-][d:]h:mm:ss[.FFFFFF]

Elements in square brackets ([and]) are optional. The colon (:) is a literal symbol. The following table describes the remaining elements.

| Element | Description |
|---------|---|
| - | An optional negative sign, which indicates a negative time interval. |
| d | The optional number of days, with no leading zeros. |
| h | The number of hours, which ranges from "0" to "23", with no leading zeros. |
| mm | The number of minutes, which ranges from "00" to "59". |
| ss | The number of seconds, which ranges from "00" to "59". |
| . | The fractional seconds separator. It is equivalent to the specified culture's NumberDecimalSeparator property without user overrides. |
| FFFFFFF | The fractional seconds. As few digits as possible are displayed. |

Like the "G" format specifier, the "g" format specifier is localized. Its fractional seconds separator is based on either the current culture or a specified culture's [NumberDecimalSeparator](#) property.

The following example instantiates two `TimeSpan` objects, uses them to perform arithmetic operations, and displays the result. In each case, it uses composite formatting to display the `TimeSpan` value by using the "g" format specifier. In addition, it formats the `TimeSpan` value by using the formatting conventions of the current system culture (which, in this case, is English - United States or en-US) and the French - France (fr-FR) culture.

C#

```

        interval2, interval1 + interval2));

interval1 = new TimeSpan(0, 0, 1, 14, 36);
interval2 = TimeSpan.FromTicks(2143756);
Console.WriteLine("{0:g} + {1:g} = {2:g}", interval1,
                  interval2, interval1 + interval2);
}
}
// The example displays the following output:
//      7:45:16 - 18:12:38 = -10:27:22
//      7:45:16 + 18:12:38 = 1:1:57:54
//      0:01:14.036 + 0:00:00.2143756 = 0:01:14.2503756

```

The General Long ("G") Format Specifier

The "G" [TimeSpan](#) format specifier returns the string representation of a [TimeSpan](#) value in a long form that always includes both days and fractional seconds. The string that results from the "G" standard format specifier has the following form:

`[-]d:hh:mm:ss.fffffff`

Elements in square brackets ([and]) are optional. The colon (:) is a literal symbol. The following table describes the remaining elements.

| Element | Description |
|---------|---|
| - | An optional negative sign, which indicates a negative time interval. |
| d | The number of days, with no leading zeros. |
| hh | The number of hours, which ranges from "00" to "23". |
| mm | The number of minutes, which ranges from "00" to "59". |
| ss | The number of seconds, which ranges from "00" to "59". |
| . | The fractional seconds separator. It is equivalent to the specified culture's NumberDecimalSeparator property without user overrides. |
| fffffff | The fractional seconds. |

Like the "G" format specifier, the "g" format specifier is localized. Its fractional seconds separator is based on either the current culture or a specified culture's [NumberDecimalSeparator](#) property.

The following example instantiates two [TimeSpan](#) objects, uses them to perform arithmetic operations, and displays the result. In each case, it uses composite formatting to display the [TimeSpan](#) value by using the "G" format specifier. In addition, it formats

the `TimeSpan` value by using the formatting conventions of the current system culture (which, in this case, is English - United States or en-US) and the French - France (fr-FR) culture.

C#

```
using System;
using System.Globalization;

public class Example
{
    public static void Main()
    {
        TimeSpan interval1, interval2;
        interval1 = new TimeSpan(7, 45, 16);
        interval2 = new TimeSpan(18, 12, 38);

        Console.WriteLine("{0:G} - {1:G} = {2:G}", interval1,
                           interval2, interval1 - interval2);
        Console.WriteLine(String.Format(new CultureInfo("fr-FR"),
                                         "{0:G} + {1:G} = {2:G}", interval1,
                                         interval2, interval1 + interval2));

        interval1 = new TimeSpan(0, 0, 1, 14, 36);
        interval2 = TimeSpan.FromTicks(2143756);
        Console.WriteLine("{0:G} + {1:G} = {2:G}", interval1,
                           interval2, interval1 + interval2);
    }
}
// The example displays the following output:
//      0:07:45:16.0000000 - 0:18:12:38.0000000 = -0:10:27:22.0000000
//      0:07:45:16,0000000 + 0:18:12:38,0000000 = 1:01:57:54,0000000
//      0:00:01:14.0360000 + 0:00:00:00.2143756 = 0:00:01:14.2503756
```

Custom TimeSpan format strings

Article • 09/15/2021

A [TimeSpan](#) format string defines the string representation of a [TimeSpan](#) value that results from a formatting operation. A custom format string consists of one or more custom [TimeSpan](#) format specifiers along with any number of literal characters. Any string that isn't a [Standard TimeSpan format string](#) is interpreted as a custom [TimeSpan](#) format string.

ⓘ Important

The custom [TimeSpan](#) format specifiers don't include placeholder separator symbols, such as the symbols that separate days from hours, hours from minutes, or seconds from fractional seconds. Instead, these symbols must be included in the custom format string as string literals. For example, "dd\.hh\:mm" defines a period (.) as the separator between days and hours, and a colon (:) as the separator between hours and minutes.

Custom [TimeSpan](#) format specifiers also don't include a sign symbol that enables you to differentiate between negative and positive time intervals. To include a sign symbol, you have to construct a format string by using conditional logic. The [Other characters](#) section includes an example.

The string representations of [TimeSpan](#) values are produced by calls to the overloads of the [TimeSpan.ToString](#) method, and by methods that support composite formatting, such as [String.Format](#). For more information, see [Formatting Types](#) and [Composite Formatting](#). The following example illustrates the use of custom format strings in formatting operations.

C#

```
using System;

public class Example
{
    public static void Main()
    {
        TimeSpan duration = new TimeSpan(1, 12, 23, 62);

        string output = null;
        output = "Time of Travel: " + duration.ToString("%d") + " days";
        Console.WriteLine(output);
        output = "Time of Travel: " + duration.ToString(@"dd\.hh\:mm\:ss"));
    }
}
```

```

        Console.WriteLine(output);

        Console.WriteLine("Time of Travel: {0:%d} day(s)", duration);
        Console.WriteLine("Time of Travel: {0:dd\\.hh\\:mm\\:ss} days",
duration);
    }
}
// The example displays the following output:
//      Time of Travel: 1 days
//      Time of Travel: 01.12:24:02
//      Time of Travel: 1 day(s)
//      Time of Travel: 01.12:24:02 days

```

Custom [TimeSpan](#) format strings are also used by the [TimeSpan.ParseExact](#) and [TimeSpan.TryParseExact](#) methods to define the required format of input strings for parsing operations. (Parsing converts the string representation of a value to that value.) The following example illustrates the use of standard format strings in parsing operations.

C#

```

using System;

public class Example
{
    public static void Main()
    {
        string value = null;
        TimeSpan interval;

        value = "6";
        if (TimeSpan.TryParseExact(value, "%d", null, out interval))
            Console.WriteLine("{0} --> {1}", value, interval.ToString("c"));
        else
            Console.WriteLine("Unable to parse '{0}'", value);

        value = "16:32.05";
        if (TimeSpan.TryParseExact(value, @"mm\:ss\.\ff", null, out interval))
            Console.WriteLine("{0} --> {1}", value, interval.ToString("c"));
        else
            Console.WriteLine("Unable to parse '{0}'", value);

        value= "12.035";
        if (TimeSpan.TryParseExact(value, "ss\.\fff", null, out interval))
            Console.WriteLine("{0} --> {1}", value, interval.ToString("c"));
        else
            Console.WriteLine("Unable to parse '{0}'", value);
    }
}
// The example displays the following output:
//      6 --> 6.00:00:00

```

```
//      16:32.05 --> 00:16:32.0500000
//      12.035 --> 00:00:12.0350000
```

The following table describes the custom date and time format specifiers.

| Format specifier | Description | Example |
|----------------------|--|---|
| "d", "%d" | The number of whole days in the time interval. More information: The "d" custom format specifier . | <code>new TimeSpan(6, 14, 32, 17, 685): %d --> "6"</code> <code>d\.\hh\:\mm --> "6.14:32"</code> |
| "dd"- "ddddddddd" | The number of whole days in the time interval, padded with leading zeros as needed. More information: The "dd"- "ddddddddd" custom format specifiers . | <code>new TimeSpan(6, 14, 32, 17, 685): ddd --> "006"</code> <code>dd\.\hh\:\mm --> "06.14:32"</code> |
| "h", "%h" | The number of whole hours in the time interval that aren't counted as part of days. Single-digit hours don't have a leading zero. More information: The "h" custom format specifier . | <code>new TimeSpan(6, 14, 32, 17, 685): %h --> "14"</code> <code>hh\:\mm --> "14:32"</code> |
| "hh" | The number of whole hours in the time interval that aren't counted as part of days. Single-digit hours have a leading zero. More information: The "hh" custom format specifier . | <code>new TimeSpan(6, 14, 32, 17, 685): hh --> "14"</code> <code>new TimeSpan(6, 8, 32, 17, 685): hh --> 08</code> |
| "m", "%m" | The number of whole minutes in the time interval that aren't included as part of hours or days. Single-digit minutes don't have a leading zero. More information: The "m" custom format specifier . | <code>new TimeSpan(6, 14, 8, 17, 685): %m --> "8"</code> <code>h\:\m --> "14:8"</code> |
| "mm" | The number of whole minutes in the time interval that aren't included as part of hours or days. Single-digit minutes have a leading zero. | <code>new TimeSpan(6, 14, 8, 17, 685): mm --> "08"</code> |

| Format specifier | Description | Example |
|------------------|--|---|
| | <p>More information: The "mm" custom format specifier.</p> | <pre>new TimeSpan(6, 8, 5, 17, 685):</pre> <pre>d\.\hh\:\mm\:\ss --> 6.08:05:17</pre> |
| 's', "%s" | <p>The number of whole seconds in the time interval that aren't included as part of hours, days, or minutes. Single-digit seconds don't have a leading zero.</p> <p>More information: The "s" custom format specifier.</p> | <pre>TimeSpan.FromSeconds(12.965):</pre> <pre>%s --> 12</pre> <pre>s\.\fff --> 12.965</pre> |
| 'ss' | <p>The number of whole seconds in the time interval that aren't included as part of hours, days, or minutes. Single-digit seconds have a leading zero.</p> <p>More information: The "ss" custom format specifier.</p> | <pre>TimeSpan.FromSeconds(6.965):</pre> <pre>ss --> 06</pre> <pre>ss\.\fff --> 06.965</pre> |
| 'f', "%f" | <p>The tenths of a second in a time interval.</p> <p>More information: The "f" custom format specifier.</p> | <pre>TimeSpan.FromSeconds(6.895):</pre> <pre>f --> 8</pre> <pre>ss\.\f --> 06.8</pre> |
| 'ff' | <p>The hundredths of a second in a time interval.</p> <p>More information: The "ff" custom format specifier.</p> | <pre>TimeSpan.FromSeconds(6.895):</pre> <pre>ff --> 89</pre> <pre>ss\.\ff --> 06.89</pre> |
| 'fff' | <p>The milliseconds in a time interval.</p> <p>More information: The "fff" custom format specifier.</p> | <pre>TimeSpan.FromSeconds(6.895):</pre> <pre>fff --> 895</pre> <pre>ss\.\fff --> 06.895</pre> |
| 'ffff' | <p>The ten-thousandths of a second in a time interval.</p> <p>More information: The "ffff" custom format specifier.</p> | <pre>TimeSpan.Parse("0:0:6.8954321"):</pre> <pre>ffff --> 8954</pre> <pre>ss\.\ffff --> 06.8954</pre> |
| 'ffffff' | <p>The hundred-thousandths of a second in a time interval.</p> | <pre>TimeSpan.Parse("0:0:6.8954321"):</pre> <pre>ffffff --> 89543</pre> |

| Format specifier | Description | Example |
|------------------|--|--|
| | More information: The "fffff" custom format specifier . | <code>ss\.\fffff</code> --> 06.89543 |
| 'fffff' | The millionths of a second in a time interval. More information: The "fffff" custom format specifier . | <code>TimeSpan.Parse("0:0:6.8954321"):</code> <code>fffff</code> --> 895432 <code>ss\.\fffff</code> --> 06.895432 |
| 'fffffff' | The ten-millionths of a second (or the fractional ticks) in a time interval. More information: The "fffffff" custom format specifier . | <code>TimeSpan.Parse("0:0:6.8954321"):</code> <code>fffffff</code> --> 8954321 <code>ss\.\fffffff</code> --> 06.8954321 |
| 'F', "%F" | The tenths of a second in a time interval. Nothing is displayed if the digit is zero. More information: The "F" custom format specifier . | <code>TimeSpan.Parse("00:00:06.32"):</code> <code>%F</code> : 3 <code>TimeSpan.Parse("0:0:3.091"):</code> <code>ss\.\F</code> : 03. |
| 'FF' | The hundredths of a second in a time interval. Any fractional trailing zeros or two zero digits aren't included. More information: The "FF" custom format specifier . | <code>TimeSpan.Parse("00:00:06.329"):</code> <code>FF</code> : 32 <code>TimeSpan.Parse("0:0:3.101"):</code> <code>ss\.\FF</code> : 03.1 |
| 'FFF' | The milliseconds in a time interval. Any fractional trailing zeros aren't included. More information: | <code>TimeSpan.Parse("00:00:06.3291"):</code> <code>FFF</code> : 329 <code>TimeSpan.Parse("0:0:3.1009"):</code> <code>ss\.\FFF</code> : 03.1 |
| 'FFFF' | The ten-thousandths of a second in a time interval. Any fractional trailing zeros aren't included. More information: The "FFFF" custom format specifier . | <code>TimeSpan.Parse("00:00:06.32917"):</code> <code>FFFF</code> : 3291 <code>TimeSpan.Parse("0:0:3.10009"):</code> <code>ss\.\FFFF</code> : 03.1 |

| Format specifier | Description | Example |
|---------------------|--|--|
| "FFFFF" | The hundred-thousandths of a second in a time interval. Any fractional trailing zeros aren't included. More information: The "FFFFF" custom format specifier . | <code>TimeSpan.Parse("00:00:06.329179"):</code> <code>FFFFF : 32917</code> <code>TimeSpan.Parse("0:0:3.100009"):</code> <code>ss\.\FFFFF : 03.1</code> |
| "FFFFFF" | The millionths of a second in a time interval. Any fractional trailing zeros aren't displayed. More information: The "FFFFFF" custom format specifier . | <code>TimeSpan.Parse("00:00:06.3291791"):</code> <code>FFFFFF : 329179</code> <code>TimeSpan.Parse("0:0:3.1000009"):</code> <code>ss\.\FFFFFF : 03.1</code> |
| "FFFFFFF" | The ten-millionths of a second in a time interval. Any fractional trailing zeros or seven zeros aren't displayed. More information: The "FFFFFFF" custom format specifier . | <code>TimeSpan.Parse("00:00:06.3291791"):</code> <code>FFFFFFF : 3291791</code> <code>TimeSpan.Parse("0:0:3.1900000"):</code> <code>ss\.\FFFFFFF : 03.19</code> |
| 'string' | Literal string delimiter. More information: Other characters . | <code>new TimeSpan(14, 32, 17):</code> <code>hh' : 'mm' : 'ss --> "14:32:17"</code> |
| \ | The escape character. More information: Other characters . | <code>new TimeSpan(14, 32, 17):</code> <code>hh\ :mm\ :ss --> "14:32:17"</code> |
| Any other character | Any other unescaped character is interpreted as a custom format specifier. More Information: Other characters . | <code>new TimeSpan(14, 32, 17):</code> <code>hh\ :mm\ :ss --> "14:32:17"</code> |

The "d" custom format specifier

The "d" custom format specifier outputs the value of the `TimeSpan.Days` property, which represents the number of whole days in the time interval. It outputs the full number of days in a `TimeSpan` value, even if the value has more than one digit. If the value of the `TimeSpan.Days` property is zero, the specifier outputs "0".

If the "d" custom format specifier is used alone, specify "%d" so that it isn't misinterpreted as a standard format string. The following example provides an illustration.

```
C#
```

```
TimeSpan ts1 = new TimeSpan(16, 4, 3, 17, 250);
Console.WriteLine(ts1.ToString("%d"));
// Displays 16
```

The following example illustrates the use of the "d" custom format specifier.

```
C#
```

```
TimeSpan ts2 = new TimeSpan(4, 3, 17);
Console.WriteLine(ts2.ToString(@"d\.\hh\:mm\:ss"));

TimeSpan ts3 = new TimeSpan(3, 4, 3, 17);
Console.WriteLine(ts3.ToString(@"d\.\hh\:mm\:ss"));
// The example displays the following output:
//      0.04:03:17
//      3.04:03:17
```

[Back to table](#)

The "dd"- "dddddd" custom format specifiers

The "dd", "ddd", "dddd", "ddddd", "ddyyyy", "ddyyyyy", and "ddyyyyyy" custom format specifiers output the value of the [TimeSpan.Days](#) property, which represents the number of whole days in the time interval.

The output string includes a minimum number of digits specified by the number of "d" characters in the format specifier, and it's padded with leading zeros as needed. If the digits in the number of days exceed the number of "d" characters in the format specifier, the full number of days is output in the result string.

The following example uses these format specifiers to display the string representation of two [TimeSpan](#) values. The value of the days component of the first time interval is zero; the value of the days component of the second is 365.

```
C#
```

```
TimeSpan ts1 = new TimeSpan(0, 23, 17, 47);
TimeSpan ts2 = new TimeSpan(365, 21, 19, 45);
```

```

for (int ctr = 2; ctr <= 8; ctr++)
{
    string fmt = new String('d', ctr) + @"\.\hh\:\mm\:\ss";
    Console.WriteLine("{0} --> {1:" + fmt + "}", fmt, ts1);
    Console.WriteLine("{0} --> {1:" + fmt + "}", fmt, ts2);
    Console.WriteLine();
}
// The example displays the following output:
//      dd\.hh\:mm\:ss --> 00.23:17:47
//      dd\.hh\:mm\:ss --> 365.21:19:45
//
//      ddd\.hh\:mm\:ss --> 000.23:17:47
//      ddd\.hh\:mm\:ss --> 365.21:19:45
//
//      dddd\.hh\:mm\:ss --> 0000.23:17:47
//      dddd\.hh\:mm\:ss --> 00365.21:19:45
//
//      dddddd\.hh\:mm\:ss --> 000000.23:17:47
//      dddddd\.hh\:mm\:ss --> 000365.21:19:45
//
//      ddddddd\.hh\:mm\:ss --> 0000000.23:17:47
//      ddddddd\.hh\:mm\:ss --> 0000365.21:19:45

```

[Back to table](#)

The "h" custom format specifier

The "h" custom format specifier outputs the value of the `TimeSpan.Hours` property, which represents the number of whole hours in the time interval that isn't counted as part of its day component. It returns a one-digit string value if the value of the `TimeSpan.Hours` property is 0 through 9, and it returns a two-digit string value if the value of the `TimeSpan.Hours` property ranges from 10 to 23.

If the "h" custom format specifier is used alone, specify "%h" so that it isn't misinterpreted as a standard format string. The following example provides an illustration.

C#

```

TimeSpan ts = new TimeSpan(3, 42, 0);
Console.WriteLine("{0:%h} hours {0:%m} minutes", ts);

```

```
// The example displays the following output:  
//      3 hours 42 minutes
```

Ordinarily, in a parsing operation, an input string that includes only a single number is interpreted as the number of days. You can use the "%h" custom format specifier instead to interpret the numeric string as the number of hours. The following example provides an illustration.

C#

```
string value = "8";  
TimeSpan interval;  
if (TimeSpan.TryParseExact(value, "%h", null, out interval))  
    Console.WriteLine(interval.ToString("c"));  
else  
    Console.WriteLine("Unable to convert '{0}' to a time interval",  
                      value);  
// The example displays the following output:  
//      08:00:00
```

The following example illustrates the use of the "h" custom format specifier.

C#

```
TimeSpan ts1 = new TimeSpan(14, 3, 17);  
Console.WriteLine(ts1.ToString(@"d\.h\:mm\:ss"));  
  
TimeSpan ts2 = new TimeSpan(3, 4, 3, 17);  
Console.WriteLine(ts2.ToString(@"d\.h\:mm\:ss"));  
// The example displays the following output:  
//      0.14:03:17  
//      3.4:03:17
```

[Back to table](#)

The "hh" custom format specifier

The "hh" custom format specifier outputs the value of the [TimeSpan.Hours](#) property, which represents the number of whole hours in the time interval that isn't counted as part of its day component. For values from 0 through 9, the output string includes a leading zero.

Ordinarily, in a parsing operation, an input string that includes only a single number is interpreted as the number of days. You can use the "hh" custom format specifier instead

to interpret the numeric string as the number of hours. The following example provides an illustration.

```
C#
```

```
string value = "08";
TimeSpan interval;
if (TimeSpan.TryParseExact(value, "hh", null, out interval))
    Console.WriteLine(interval.ToString("c"));
else
    Console.WriteLine("Unable to convert '{0}' to a time interval",
                     value);
// The example displays the following output:
//      08:00:00
```

The following example illustrates the use of the "hh" custom format specifier.

```
C#
```

```
TimeSpan ts1 = new TimeSpan(14, 3, 17);
Console.WriteLine(ts1.ToString(@"d\.\hh\:mm\:ss"));

TimeSpan ts2 = new TimeSpan(3, 4, 3, 17);
Console.WriteLine(ts2.ToString(@"d\.\hh\:mm\:ss"));
// The example displays the following output:
//      0.14:03:17
//      3.04:03:17
```

[Back to table](#)

The "m" custom format specifier

The "m" custom format specifier outputs the value of the [TimeSpan.Minutes](#) property, which represents the number of whole minutes in the time interval that isn't counted as part of its day component. It returns a one-digit string value if the value of the [TimeSpan.Minutes](#) property is 0 through 9, and it returns a two-digit string value if the value of the [TimeSpan.Minutes](#) property ranges from 10 to 59.

If the "m" custom format specifier is used alone, specify "%m" so that it isn't misinterpreted as a standard format string. The following example provides an illustration.

```
C#
```

```
TimeSpan ts = new TimeSpan(3, 42, 0);
Console.WriteLine("{0:%h} hours {0:%m} minutes", ts);
```

```
// The example displays the following output:  
//      3 hours 42 minutes
```

Ordinarily, in a parsing operation, an input string that includes only a single number is interpreted as the number of days. You can use the "%m" custom format specifier instead to interpret the numeric string as the number of minutes. The following example provides an illustration.

C#

```
string value = "3";  
TimeSpan interval;  
if (TimeSpan.TryParseExact(value, "%m", null, out interval))  
    Console.WriteLine(interval.ToString("c"));  
else  
    Console.WriteLine("Unable to convert '{0}' to a time interval",  
                      value);  
// The example displays the following output:  
//      00:03:00
```

The following example illustrates the use of the "m" custom format specifier.

C#

```
TimeSpan ts1 = new TimeSpan(0, 6, 32);  
Console.WriteLine("{0:m\\:ss} minutes", ts1);  
  
TimeSpan ts2 = new TimeSpan(3, 4, 3, 17);  
Console.WriteLine("Elapsed time: {0:m\\:ss}", ts2);  
// The example displays the following output:  
//      6:32 minutes  
//      Elapsed time: 18:44
```

[Back to table](#)

The "mm" custom format specifier

The "mm" custom format specifier outputs the value of the [TimeSpan.Minutes](#) property, which represents the number of whole minutes in the time interval that isn't included as part of its hours or days component. For values from 0 through 9, the output string includes a leading zero.

Ordinarily, in a parsing operation, an input string that includes only a single number is interpreted as the number of days. You can use the "mm" custom format specifier

instead to interpret the numeric string as the number of minutes. The following example provides an illustration.

C#

```
string value = "07";
TimeSpan interval;
if (TimeSpan.TryParseExact(value, "mm", null, out interval))
    Console.WriteLine(interval.ToString("c"));
else
    Console.WriteLine("Unable to convert '{0}' to a time interval",
                      value);
// The example displays the following output:
//      00:07:00
```

The following example illustrates the use of the "mm" custom format specifier.

C#

```
TimeSpan departTime = new TimeSpan(11, 12, 00);
TimeSpan arriveTime = new TimeSpan(16, 28, 00);
Console.WriteLine("Travel time: {0:hh\\:\\mm}",
                  arriveTime - departTime);
// The example displays the following output:
//      Travel time: 05:16
```

[Back to table](#)

The "s" custom format specifier

The "s" custom format specifier outputs the value of the `TimeSpan.Seconds` property, which represents the number of whole seconds in the time interval that isn't included as part of its hours, days, or minutes component. It returns a one-digit string value if the value of the `TimeSpan.Seconds` property is 0 through 9, and it returns a two-digit string value if the value of the `TimeSpan.Seconds` property ranges from 10 to 59.

If the "s" custom format specifier is used alone, specify "%s" so that it isn't misinterpreted as a standard format string. The following example provides an illustration.

C#

```
TimeSpan ts = TimeSpan.FromSeconds(12.465);
Console.WriteLine(ts.ToString("%s"));
```

```
// The example displays the following output:  
//      12
```

Ordinarily, in a parsing operation, an input string that includes only a single number is interpreted as the number of days. You can use the "%s" custom format specifier instead to interpret the numeric string as the number of seconds. The following example provides an illustration.

C#

```
string value = "9";  
TimeSpan interval;  
if (TimeSpan.TryParseExact(value, "%s", null, out interval))  
    Console.WriteLine(interval.ToString("c"));  
else  
    Console.WriteLine("Unable to convert '{0}' to a time interval",  
                      value);  
// The example displays the following output:  
//      00:00:09
```

The following example illustrates the use of the "s" custom format specifier.

C#

```
TimeSpan startTime = new TimeSpan(0, 12, 30, 15, 0);  
TimeSpan endTime = new TimeSpan(0, 12, 30, 21, 3);  
Console.WriteLine(@"Elapsed Time: {0:s\:fff} seconds",  
                 endTime - startTime);  
// The example displays the following output:  
//      Elapsed Time: 6:003 seconds
```

[Back to table](#)

The "ss" custom format specifier

The "ss" custom format specifier outputs the value of the [TimeSpan.Seconds](#) property, which represents the number of whole seconds in the time interval that isn't included as part of its hours, days, or minutes component. For values from 0 through 9, the output string includes a leading zero.

Ordinarily, in a parsing operation, an input string that includes only a single number is interpreted as the number of days. You can use the "ss" custom format specifier instead to interpret the numeric string as the number of seconds. The following example provides an illustration.

C#

```
string[] values = { "49", "9", "06" };
TimeSpan interval;
foreach (string value in values)
{
    if (TimeSpan.TryParseExact(value, "ss", null, out interval))
        Console.WriteLine(interval.ToString("c"));
    else
        Console.WriteLine("Unable to convert '{0}' to a time interval",
                         value);
}
// The example displays the following output:
//      00:00:49
//      Unable to convert '9' to a time interval
//      00:00:06
```

The following example illustrates the use of the "ss" custom format specifier.

C#

```
TimeSpan interval1 = TimeSpan.FromSeconds(12.60);
Console.WriteLine(interval1.ToString(@"ss\.\fff"));

TimeSpan interval2 = TimeSpan.FromSeconds(6.485);
Console.WriteLine(interval2.ToString(@"ss\.\fff"));
// The example displays the following output:
//      12.600
//      06.485
```

[Back to table](#)

The "f" custom format specifier

The "f" custom format specifier outputs the tenths of a second in a time interval. In a formatting operation, any remaining fractional digits are truncated. In a parsing operation that calls the [TimeSpan.ParseExact](#) or [TimeSpan.TryParseExact](#) method, the input string must contain exactly one fractional digit.

If the "f" custom format specifier is used alone, specify "%f" so that it isn't misinterpreted as a standard format string.

The following example uses the "f" custom format specifier to display the tenths of a second in a [TimeSpan](#) value. "f" is used first as the only format specifier, and then combined with the "s" specifier in a custom format string.

C#

```

TimeSpan ts = new TimeSpan(1003498765432);
string fmt;
Console.WriteLine(ts.ToString("c"));
Console.WriteLine();

for (int ctr = 1; ctr <= 7; ctr++) {
    fmt = new String('f', ctr);
    if (fmt.Length == 1) fmt = "%" + fmt;
    Console.WriteLine("{0,10}: {1:" + fmt + "}", fmt, ts);
}
Console.WriteLine();

for (int ctr = 1; ctr <= 7; ctr++) {
    fmt = new String('f', ctr);
    Console.WriteLine("{0,10}: {1:s\\.{" + fmt + "}}", "s\\.{" + fmt, ts);
}
// The example displays the following output:
//          %f: 8
//          ff: 87
//          fff: 876
//          ffff: 8765
//          fffff: 87654
//          ffffff: 876543
//          ffffffff: 8765432
//
//          s\.f: 29.8
//          s\.ff: 29.87
//          s\.fff: 29.876
//          s\.ffff: 29.8765
//          s\.fffff: 29.87654
//          s\.fffffff: 29.876543
//          s\.fffffff: 29.8765432

```

[Back to table](#)

The "ff" custom format specifier

The "ff" custom format specifier outputs the hundredths of a second in a time interval. In a formatting operation, any remaining fractional digits are truncated. In a parsing operation that calls the [TimeSpan.ParseExact](#) or [TimeSpan.TryParseExact](#) method, the input string must contain exactly two fractional digits.

The following example uses the "ff" custom format specifier to display the hundredths of a second in a [TimeSpan](#) value. "ff" is used first as the only format specifier, and then combined with the "s" specifier in a custom format string.

C#

```

TimeSpan ts = new TimeSpan(1003498765432);
string fmt;
Console.WriteLine(ts.ToString("c"));
Console.WriteLine();

for (int ctr = 1; ctr <= 7; ctr++) {
    fmt = new String('f', ctr);
    if (fmt.Length == 1) fmt = "%" + fmt;
    Console.WriteLine("{0,10}: {1:" + fmt + "}", fmt, ts);
}
Console.WriteLine();

for (int ctr = 1; ctr <= 7; ctr++) {
    fmt = new String('f', ctr);
    Console.WriteLine("{0,10}: {1:s\\.{" + fmt + "}}", "s\\.{" + fmt, ts);
}
// The example displays the following output:
//          %f: 8
//          ff: 87
//          fff: 876
//          ffff: 8765
//          fffff: 87654
//          ffffff: 876543
//          ffffffff: 8765432
//
//          s\.f: 29.8
//          s\.ff: 29.87
//          s\.fff: 29.876
//          s\.ffff: 29.8765
//          s\.fffff: 29.87654
//          s\.fffffff: 29.876543
//          s\.fffffff: 29.8765432

```

[Back to table](#)

The "fff" custom format specifier

The "fff" custom format specifier (with three "f" characters) outputs the milliseconds in a time interval. In a formatting operation, any remaining fractional digits are truncated. In a parsing operation that calls the [TimeSpan.ParseExact](#) or [TimeSpan.TryParseExact](#) method, the input string must contain exactly three fractional digits.

The following example uses the "fff" custom format specifier to display the milliseconds in a [TimeSpan](#) value. "fff" is used first as the only format specifier, and then combined with the "s" specifier in a custom format string.

C#

```

TimeSpan ts = new TimeSpan(1003498765432);
string fmt;
Console.WriteLine(ts.ToString("c"));
Console.WriteLine();

for (int ctr = 1; ctr <= 7; ctr++) {
    fmt = new String('f', ctr);
    if (fmt.Length == 1) fmt = "%" + fmt;
    Console.WriteLine("{0,10}: {1:" + fmt + "}", fmt, ts);
}
Console.WriteLine();

for (int ctr = 1; ctr <= 7; ctr++) {
    fmt = new String('f', ctr);
    Console.WriteLine("{0,10}: {1:s\\.{" + fmt + "}}", "s\\.{" + fmt, ts);
}
// The example displays the following output:
//          %f: 8
//          ff: 87
//          fff: 876
//          ffff: 8765
//          fffff: 87654
//          ffffff: 876543
//          ffffffff: 8765432
//
//          s\.f: 29.8
//          s\.ff: 29.87
//          s\.fff: 29.876
//          s\.ffff: 29.8765
//          s\.fffff: 29.87654
//          s\.fffffff: 29.876543
//          s\.fffffff: 29.8765432

```

[Back to table](#)

The "ffff" custom format specifier

The "ffff" custom format specifier (with four "f" characters) outputs the ten-thousandths of a second in a time interval. In a formatting operation, any remaining fractional digits are truncated. In a parsing operation that calls the [TimeSpan.ParseExact](#) or [TimeSpan.TryParseExact](#) method, the input string must contain exactly four fractional digits.

The following example uses the "ffff" custom format specifier to display the ten-thousandths of a second in a [TimeSpan](#) value. "ffff" is used first as the only format specifier, and then combined with the "s" specifier in a custom format string.

C#

```

TimeSpan ts = new TimeSpan(1003498765432);
string fmt;
Console.WriteLine(ts.ToString("c"));
Console.WriteLine();

for (int ctr = 1; ctr <= 7; ctr++) {
    fmt = new String('f', ctr);
    if (fmt.Length == 1) fmt = "%" + fmt;
    Console.WriteLine("{0,10}: {1:" + fmt + "}", fmt, ts);
}
Console.WriteLine();

for (int ctr = 1; ctr <= 7; ctr++) {
    fmt = new String('f', ctr);
    Console.WriteLine("{0,10}: {1:s\\.{" + fmt + "}}", "s\\.{" + fmt, ts);
}
// The example displays the following output:
//          %f: 8
//          ff: 87
//          fff: 876
//          ffff: 8765
//          fffff: 87654
//          ffffff: 876543
//          ffffffff: 8765432
//
//          s\.f: 29.8
//          s\.ff: 29.87
//          s\.fff: 29.876
//          s\.ffff: 29.8765
//          s\.fffff: 29.87654
//          s\.fffffff: 29.876543
//          s\.fffffff: 29.8765432

```

[Back to table](#)

The "fffff" custom format specifier

The "fffff" custom format specifier (with five "f" characters) outputs the hundred-thousandths of a second in a time interval. In a formatting operation, any remaining fractional digits are truncated. In a parsing operation that calls the [TimeSpan.ParseExact](#) or [TimeSpan.TryParseExact](#) method, the input string must contain exactly five fractional digits.

The following example uses the "fffff" custom format specifier to display the hundred-thousandths of a second in a [TimeSpan](#) value. "fffff" is used first as the only format specifier, and then combined with the "s" specifier in a custom format string.

C#

```

TimeSpan ts = new TimeSpan(1003498765432);
string fmt;
Console.WriteLine(ts.ToString("c"));
Console.WriteLine();

for (int ctr = 1; ctr <= 7; ctr++) {
    fmt = new String('f', ctr);
    if (fmt.Length == 1) fmt = "%" + fmt;
    Console.WriteLine("{0,10}: {1:" + fmt + "}", fmt, ts);
}
Console.WriteLine();

for (int ctr = 1; ctr <= 7; ctr++) {
    fmt = new String('f', ctr);
    Console.WriteLine("{0,10}: {1:s\\.{" + fmt + "}}", "s\\.{" + fmt, ts);
}
// The example displays the following output:
//          %f: 8
//          ff: 87
//          fff: 876
//          ffff: 8765
//          fffff: 87654
//          ffffff: 876543
//          ffffffff: 8765432
//
//          s\.f: 29.8
//          s\.ff: 29.87
//          s\.fff: 29.876
//          s\.ffff: 29.8765
//          s\.fffff: 29.87654
//          s\.fffffff: 29.876543
//          s\.fffffff: 29.8765432

```

[Back to table](#)

The "fffffff" custom format specifier

The "fffffff" custom format specifier (with six "f" characters) outputs the millionths of a second in a time interval. In a formatting operation, any remaining fractional digits are truncated. In a parsing operation that calls the [TimeSpan.ParseExact](#) or [TimeSpan.TryParseExact](#) method, the input string must contain exactly six fractional digits.

The following example uses the "fffffff" custom format specifier to display the millionths of a second in a [TimeSpan](#) value. It is used first as the only format specifier, and then combined with the "s" specifier in a custom format string.

C#

```

TimeSpan ts = new TimeSpan(1003498765432);
string fmt;
Console.WriteLine(ts.ToString("c"));
Console.WriteLine();

for (int ctr = 1; ctr <= 7; ctr++) {
    fmt = new String('f', ctr);
    if (fmt.Length == 1) fmt = "%" + fmt;
    Console.WriteLine("{0,10}: {1:" + fmt + "}", fmt, ts);
}
Console.WriteLine();

for (int ctr = 1; ctr <= 7; ctr++) {
    fmt = new String('f', ctr);
    Console.WriteLine("{0,10}: {1:s\\.{" + fmt + "}}", "s\\.{" + fmt, ts);
}
// The example displays the following output:
//          %f: 8
//          ff: 87
//          fff: 876
//          ffff: 8765
//          fffff: 87654
//          ffffff: 876543
//          ffffffff: 8765432
//
//          s\.f: 29.8
//          s\.ff: 29.87
//          s\.fff: 29.876
//          s\.ffff: 29.8765
//          s\.fffff: 29.87654
//          s\.fffffff: 29.876543
//          s\.fffffff: 29.8765432

```

[Back to table](#)

The "fffffff" custom format specifier

The "fffffff" custom format specifier (with seven "f" characters) outputs the ten-millionths of a second (or the fractional number of ticks) in a time interval. In a parsing operation that calls the `TimeSpan.ParseExact` or `TimeSpan.TryParseExact` method, the input string must contain exactly seven fractional digits.

The following example uses the "fffffff" custom format specifier to display the fractional number of ticks in a `TimeSpan` value. It is used first as the only format specifier, and then combined with the "s" specifier in a custom format string.

C#

```

TimeSpan ts = new TimeSpan(1003498765432);
string fmt;
Console.WriteLine(ts.ToString("c"));
Console.WriteLine();

for (int ctr = 1; ctr <= 7; ctr++) {
    fmt = new String('f', ctr);
    if (fmt.Length == 1) fmt = "%" + fmt;
    Console.WriteLine("{0,10}: {1:" + fmt + "}", fmt, ts);
}
Console.WriteLine();

for (int ctr = 1; ctr <= 7; ctr++) {
    fmt = new String('f', ctr);
    Console.WriteLine("{0,10}: {1:s\\.{" + fmt + "}}", "s\\.{" + fmt, ts);
}
// The example displays the following output:
//          %f: 8
//          ff: 87
//          fff: 876
//          ffff: 8765
//          fffff: 87654
//          ffffff: 876543
//          ffffffff: 8765432
//
//          s\.f: 29.8
//          s\.ff: 29.87
//          s\.fff: 29.876
//          s\.ffff: 29.8765
//          s\.fffff: 29.87654
//          s\.fffffff: 29.876543
//          s\.fffffff: 29.8765432

```

[Back to table](#)

The "F" custom format specifier

The "F" custom format specifier outputs the tenths of a second in a time interval. In a formatting operation, any remaining fractional digits are truncated. If the value of the time interval's tenths of a second is zero, it isn't included in the result string. In a parsing operation that calls the [TimeSpan.ParseExact](#) or [TimeSpan.TryParseExact](#) method, the presence of the tenths of a second digit is optional.

If the "F" custom format specifier is used alone, specify "%F" so that it isn't misinterpreted as a standard format string.

The following example uses the "F" custom format specifier to display the tenths of a second in a [TimeSpan](#) value. It also uses this custom format specifier in a parsing

operation.

C#

```
Console.WriteLine("Formatting:");
TimeSpan ts1 = TimeSpan.Parse("0:0:3.669");
Console.WriteLine("{0} ('%F') --> {0:%F}", ts1);

TimeSpan ts2 = TimeSpan.Parse("0:0:3.091");
Console.WriteLine("{0} ('ss\\.F') --> {0:ss\\.F}", ts2);
Console.WriteLine();

Console.WriteLine("Parsing:");
string[] inputs = { "0:0:03.", "0:0:03.1", "0:0:03.12" };
string fmt = @"h\:m\:ss\.F";
TimeSpan ts3;

foreach (string input in inputs) {
    if (TimeSpan.TryParseExact(input, fmt, null, out ts3))
        Console.WriteLine("{0} ('{1}') --> {2}", input, fmt, ts3);
    else
        Console.WriteLine("Cannot parse {0} with '{1}'.",
                         input, fmt);
}
// The example displays the following output:
//      Formatting:
//      00:00:03.6690000 ('%F') --> 6
//      00:00:03.0910000 ('ss\.F') --> 03.

//
//      Parsing:
//      0:0:03. ('h\:m\:ss\.F') --> 00:00:03
//      0:0:03.1 ('h\:m\:ss\.F') --> 00:00:03.100000
//      Cannot parse 0:0:03.12 with 'h\:m\:ss\.F'.
```

[Back to table](#)

The "FF" custom format specifier

The "FF" custom format specifier outputs the hundredths of a second in a time interval. In a formatting operation, any remaining fractional digits are truncated. If there are any trailing fractional zeros, they aren't included in the result string. In a parsing operation that calls the [TimeSpan.ParseExact](#) or [TimeSpan.TryParseExact](#) method, the presence of the tenths and hundredths of a second digit is optional.

The following example uses the "FF" custom format specifier to display the hundredths of a second in a [TimeSpan](#) value. It also uses this custom format specifier in a parsing operation.

C#

```
Console.WriteLine("Formatting:");
TimeSpan ts1 = TimeSpan.Parse("0:0:3.697");
Console.WriteLine("{0} ('FF') --> {0:FF}", ts1);

TimeSpan ts2 = TimeSpan.Parse("0:0:3.809");
Console.WriteLine("{0} ('ss\\.FF') --> {0:ss\\.FF}", ts2);
Console.WriteLine();

Console.WriteLine("Parsing:");
string[] inputs = { "0:0:03.", "0:0:03.1", "0:0:03.127" };
string fmt = @"h\:m\:ss\.FF";
TimeSpan ts3;

foreach (string input in inputs) {
    if (TimeSpan.TryParseExact(input, fmt, null, out ts3))
        Console.WriteLine("{0} ('{1}') --> {2}", input, fmt, ts3);
    else
        Console.WriteLine("Cannot parse {0} with '{1}'.",
                         input, fmt);
}
// The example displays the following output:
//      Formatting:
//      00:00:03.6970000 ('FF') --> 69
//      00:00:03.8090000 ('ss\.FF') --> 03.8
//
//      Parsing:
//      0:0:03. ('h\:m\:ss\.FF') --> 00:00:03
//      0:0:03.1 ('h\:m\:ss\.FF') --> 00:00:03.1000000
//      Cannot parse 0:0:03.127 with 'h\:m\:ss\.FF'.
```

[Back to table](#)

The "FFF" custom format specifier

The "FFF" custom format specifier (with three "F" characters) outputs the milliseconds in a time interval. In a formatting operation, any remaining fractional digits are truncated. If there are any trailing fractional zeros, they aren't included in the result string. In a parsing operation that calls the [TimeSpan.ParseExact](#) or [TimeSpan.TryParseExact](#) method, the presence of the tenths, hundredths, and thousandths of a second digit is optional.

The following example uses the "FFF" custom format specifier to display the thousandths of a second in a [TimeSpan](#) value. It also uses this custom format specifier in a parsing operation.

C#

```

Console.WriteLine("Formatting:");
TimeSpan ts1 = TimeSpan.Parse("0:0:3.6974");
Console.WriteLine("{0} ('FFF') --> {0:FFF}", ts1);

TimeSpan ts2 = TimeSpan.Parse("0:0:3.8009");
Console.WriteLine("{0} ('ss\\.FFF') --> {0:ss\\.FFF}", ts2);
Console.WriteLine();

Console.WriteLine("Parsing:");
string[] inputs = { "0:0:03.", "0:0:03.12", "0:0:03.1279" };
string fmt = @"h\:m\:ss\.FFF";
TimeSpan ts3;

foreach (string input in inputs) {
    if (TimeSpan.TryParseExact(input, fmt, null, out ts3))
        Console.WriteLine("{0} ('{1}') --> {2}", input, fmt, ts3);
    else
        Console.WriteLine("Cannot parse {0} with '{1}'.",
                          input, fmt);
}
// The example displays the following output:
//      Formatting:
//      00:00:03.6974000 ('FFF') --> 697
//      00:00:03.8009000 ('ss\.FFF') --> 03.8
//
//      Parsing:
//      0:0:03. ('h\:m\:ss\.FFF') --> 00:00:03
//      0:0:03.12 ('h\:m\:ss\.FFF') --> 00:00:03.1200000
//      Cannot parse 0:0:03.1279 with 'h\:m\:ss\.FFF'.

```

[Back to table](#)

The "FFFF" custom format specifier

The "FFFF" custom format specifier (with four "F" characters) outputs the ten-thousandths of a second in a time interval. In a formatting operation, any remaining fractional digits are truncated. If there are any trailing fractional zeros, they aren't included in the result string. In a parsing operation that calls the [TimeSpan.ParseExact](#) or [TimeSpan.TryParseExact](#) method, the presence of the tenths, hundredths, thousandths, and ten-thousandths of a second digit is optional.

The following example uses the "FFFF" custom format specifier to display the ten-thousandths of a second in a [TimeSpan](#) value. It also uses the "FFFF" custom format specifier in a parsing operation.

C#

```

Console.WriteLine("Formatting:");
TimeSpan ts1 = TimeSpan.Parse("0:0:3.69749");
Console.WriteLine("{0} ('FFFF') --> {0:FFFF}", ts1);

TimeSpan ts2 = TimeSpan.Parse("0:0:3.80009");
Console.WriteLine("{0} ('ss\\.FFFF') --> {0:ss\\.FFFF}", ts2);
Console.WriteLine();

Console.WriteLine("Parsing:");
string[] inputs = { "0:0:03.", "0:0:03.12", "0:0:03.12795" };
string fmt = @"h\:m\:ss\.FFFF";
TimeSpan ts3;

foreach (string input in inputs) {
    if (TimeSpan.TryParseExact(input, fmt, null, out ts3))
        Console.WriteLine("{0} ('{1}') --> {2}", input, fmt, ts3);
    else
        Console.WriteLine("Cannot parse {0} with '{1}'.",
                          input, fmt);
}
// The example displays the following output:
//      Formatting:
//      00:00:03.6974900 ('FFFF') --> 6974
//      00:00:03.8000900 ('ss\.FFFF') --> 03.8
//
//      Parsing:
//      0:0:03. ('h\:m\:ss\.FFFF') --> 00:00:03
//      0:0:03.12 ('h\:m\:ss\.FFFF') --> 00:00:03.1200000
//      Cannot parse 0:0:03.12795 with 'h\:m\:ss\.FFFF'.

```

[Back to table](#)

The "FFFFF" custom format specifier

The "FFFFF" custom format specifier (with five "F" characters) outputs the hundred-thousandths of a second in a time interval. In a formatting operation, any remaining fractional digits are truncated. If there are any trailing fractional zeros, they aren't included in the result string. In a parsing operation that calls the [TimeSpan.ParseExact](#) or [TimeSpan.TryParseExact](#) method, the presence of the tenths, hundredths, thousandths, ten-thousandths, and hundred-thousandths of a second digit is optional.

The following example uses the "FFFFF" custom format specifier to display the hundred-thousandths of a second in a [TimeSpan](#) value. It also uses the "FFFFF" custom format specifier in a parsing operation.

C#

```

Console.WriteLine("Formatting:");
TimeSpan ts1 = TimeSpan.Parse("0:0:3.697497");
Console.WriteLine("{0} ('FFFFF') --> {0:FFFFF}", ts1);

TimeSpan ts2 = TimeSpan.Parse("0:0:3.800009");
Console.WriteLine("{0} ('ss\\.FFFFF') --> {0:ss\\.FFFFF}", ts2);
Console.WriteLine();

Console.WriteLine("Parsing:");
string[] inputs = { "0:0:03.", "0:0:03.12", "0:0:03.127956" };
string fmt = @"h\:m\:ss\.FFFFF";
TimeSpan ts3;

foreach (string input in inputs) {
    if (TimeSpan.TryParseExact(input, fmt, null, out ts3))
        Console.WriteLine("{0} ('{1}') --> {2}", input, fmt, ts3);
    else
        Console.WriteLine("Cannot parse {0} with '{1}'.",
                          input, fmt);
}
// The example displays the following output:
//      Formatting:
//      00:00:03.6974970 ('FFFFF') --> 69749
//      00:00:03.8000090 ('ss\\.FFFFF') --> 03.8
//
//      Parsing:
//      0:0:03. ('h\:m\:ss\.FFFF') --> 00:00:03
//      0:0:03.12 ('h\:m\:ss\.FFFF') --> 00:00:03.1200000
//      Cannot parse 0:0:03.127956 with 'h\:m\:ss\.FFFF'.

```

[Back to table](#)

The "FFFFFF" custom format specifier

The "FFFFFF" custom format specifier (with six "F" characters) outputs the millionths of a second in a time interval. In a formatting operation, any remaining fractional digits are truncated. If there are any trailing fractional zeros, they aren't included in the result string. In a parsing operation that calls the [TimeSpan.ParseExact](#) or [TimeSpan.TryParseExact](#) method, the presence of the tenths, hundredths, thousandths, ten-thousandths, hundred-thousandths, and millionths of a second digit is optional.

The following example uses the "FFFFFF" custom format specifier to display the millionths of a second in a [TimeSpan](#) value. It also uses this custom format specifier in a parsing operation.

C#

```

Console.WriteLine("Formatting:");
TimeSpan ts1 = TimeSpan.Parse("0:0:3.6974974");
Console.WriteLine("{0} ('FFFFFF') --> {0:FFFFFF}", ts1);

TimeSpan ts2 = TimeSpan.Parse("0:0:3.8000009");
Console.WriteLine("{0} ('ss\\.FFFFFF') --> {0:ss\\.FFFFFF}", ts2);
Console.WriteLine();

Console.WriteLine("Parsing:");
string[] inputs = { "0:0:03.", "0:0:03.12", "0:0:03.1279569" };
string fmt = @"h\:m\:ss\.FFFFFF";
TimeSpan ts3;

foreach (string input in inputs) {
    if (TimeSpan.TryParseExact(input, fmt, null, out ts3))
        Console.WriteLine("{0} ('{1}') --> {2}", input, fmt, ts3);
    else
        Console.WriteLine("Cannot parse {0} with '{1}'.",
                          input, fmt);
}
// The example displays the following output:
//      Formatting:
//      00:00:03.6974974 ('FFFFFF') --> 697497
//      00:00:03.8000009 ('ss\\.FFFFFF') --> 03.8
//
//      Parsing:
//      0:0:03. ('h\:m\:ss\.FFFFFF') --> 00:00:03
//      0:0:03.12 ('h\:m\:ss\.FFFFFF') --> 00:00:03.1200000
//      Cannot parse 0:0:03.1279569 with 'h\:m\:ss\.FFFFFF'.

```

[Back to table](#)

The "FFFFFF" custom format specifier

The "FFFFFF" custom format specifier (with seven "F" characters) outputs the ten-millionths of a second (or the fractional number of ticks) in a time interval. If there are any trailing fractional zeros, they aren't included in the result string. In a parsing operation that calls the [TimeSpan.ParseExact](#) or [TimeSpan.TryParseExact](#) method, the presence of the seven fractional digits in the input string is optional.

The following example uses the "FFFFFF" custom format specifier to display the fractional parts of a second in a [TimeSpan](#) value. It also uses this custom format specifier in a parsing operation.

C#

```

Console.WriteLine("Formatting:");
TimeSpan ts1 = TimeSpan.Parse("0:0:3.6974974");

```

```

Console.WriteLine("{0} ('FFFFFFF') --> {0:FFFFFFF}", ts1);

TimeSpan ts2 = TimeSpan.Parse("0:0:3.9500000");
Console.WriteLine("{0} ('ss\\.FFFFFFF') --> {0:ss\\.FFFFFFF}", ts2);
Console.WriteLine();

Console.WriteLine("Parsing:");
string[] inputs = { "0:0:03.", "0:0:03.12", "0:0:03.1279569" };
string fmt = @"h\:m\:ss\.FFFFFFF";
TimeSpan ts3;

foreach (string input in inputs) {
    if (TimeSpan.TryParseExact(input, fmt, null, out ts3))
        Console.WriteLine("{0} ('{1}') --> {2}", input, fmt, ts3);
    else
        Console.WriteLine("Cannot parse {0} with '{1}'.",
                          input, fmt);
}
// The example displays the following output:
//   Formatting:
//   00:00:03.6974974 ('FFFFFFF') --> 6974974
//   00:00:03.9500000 ('ss\\.FFFFFFF') --> 03.95
//
//   Parsing:
//   0:0:03. ('h\:m\:ss\\.FFFFFFF') --> 00:00:03
//   0:0:03.12 ('h\:m\:ss\\.FFFFFFF') --> 00:00:03.1200000
//   0:0:03.1279569 ('h\:m\:ss\\.FFFFFFF') --> 00:00:03.1279569

```

[Back to table](#)

Other characters

Any other unescaped character in a format string, including a white-space character, is interpreted as a custom format specifier. In most cases, the presence of any other unescaped character results in a [FormatException](#).

There are two ways to include a literal character in a format string:

- Enclose it in single quotation marks (the literal string delimiter).
- Precede it with a backslash ("\"), which is interpreted as an escape character. This means that, in C#, the format string must either be @-quoted, or the literal character must be preceded by an additional backslash.

In some cases, you may have to use conditional logic to include an escaped literal in a format string. The following example uses conditional logic to include a sign symbol for negative time intervals.

```

using System;

public class Example
{
    public static void Main()
    {
        TimeSpan result = new DateTime(2010, 01, 01) - DateTime.Now;
        String fmt = (result < TimeSpan.Zero ? "\\" : "") +
"dd\\\\.hh\\:\\mm";

        Console.WriteLine(result.ToString(fmt));
        Console.WriteLine("Interval: {0:" + fmt + "}", result);
    }
}

// The example displays output like the following:
//      -1291.10:54
//      Interval: -1291.10:54

```

.NET doesn't define a grammar for separators in time intervals. This means that the separators between days and hours, hours and minutes, minutes and seconds, and seconds and fractions of a second must all be treated as character literals in a format string.

The following example uses both the escape character and the single quote to define a custom format string that includes the word "minutes" in the output string.

C#

```

TimeSpan interval = new TimeSpan(0, 32, 45);
// Escape literal characters in a format string.
String fmt = @"mm\:ss\ \m\i\n\u\t\e\s";
Console.WriteLine(interval.ToString(fmt));
// Delimit literal characters in a format string with the ' symbol.
fmt = "mm':'ss' minutes'";
Console.WriteLine(interval.ToString(fmt));
// The example displays the following output:
//      32:45 minutes
//      32:45 minutes

```

Enumeration format strings

Article • 06/20/2023

You can use the [Enum.ToString](#) method to create a new string object that represents the numeric, hexadecimal, or string value of an enumeration member. This method takes one of the enumeration formatting strings to specify the value that you want returned.

The following sections list the enumeration formatting strings and the values they return. These format specifiers aren't case-sensitive.

G or g

Displays the enumeration entry as a string value, if possible, and otherwise displays the integer value of the current instance. If the enumeration is defined with the [FlagsAttribute](#) set, the string values of each valid entry are concatenated together, separated by commas. If the [Flags](#) attribute isn't set, an invalid value is displayed as a numeric entry. The following example illustrates the `G` format specifier.

C#

```
Console.WriteLine(((DayOfWeek)7).ToString("G"));      // 7
Console.WriteLine(ConsoleColor.Red.ToString("G"));    // Red

var attributes = FileAttributes.Hidden | FileAttributes.Archive;
Console.WriteLine(attributes.ToString("G"));          // Hidden, Archive
```

F or f

Displays the enumeration entry as a string value, if possible. If the value can be displayed as a summation of the entries in the enumeration (even if the [Flags](#) attribute isn't present), the string values of each valid entry are concatenated together, separated by commas. If the value can't be determined by the enumeration entries, then the value is formatted as the integer value. The following example illustrates the `F` format specifier.

C#

```
Console.WriteLine(((DayOfWeek)7).ToString("F"));      // Monday, Saturday
Console.WriteLine(ConsoleColor.Blue.ToString("F"));   // Blue
```

```
var attributes = FileAttributes.Hidden | FileAttributes.Archive;
Console.WriteLine(attributes.ToString("F")); // Hidden, Archive
```

D or d

Displays the enumeration entry as an integer value in the shortest representation possible. The following example illustrates the `D` format specifier.

C#

```
Console.WriteLine(((DayOfWeek)7).ToString("D")); // 7
Console.WriteLine(ConsoleColor.Cyan.ToString("D")); // 11

var attributes = FileAttributes.Hidden | FileAttributes.Archive;
Console.WriteLine(attributes.ToString("D")); // 34
```

X or x

Displays the enumeration entry as a hexadecimal value. The value is represented with leading zeros as necessary, to ensure that the result string has two characters for each byte in the enumeration type's [underlying numeric type](#). The following example illustrates the X format specifier. In the example, the underlying types of `DayOfWeek`, `ConsoleColor` and `FileAttributes` is `Int32`, or a 32-bit (or 4-byte) integer, which produces an 8-character result string.

C#

```
Console.WriteLine(((DayOfWeek)7).ToString("X")); // 00000007
Console.WriteLine(ConsoleColor.Cyan.ToString("X")); // 0000000B

var attributes = FileAttributes.Hidden | FileAttributes.Archive;
Console.WriteLine(attributes.ToString("X")); // 00000022
```

Example

The following example defines an enumeration called `Colors` that consists of three entries: `Red`, `Blue`, and `Green`.

C#

```
public enum Color { Red = 1, Blue = 2, Green = 3 };
```

After the enumeration is defined, an instance can be declared in the following manner.

C#

```
Color myColor = Color.Green;
```

The `Color.ToString(System.String)` method can then be used to display the enumeration value in different ways, depending on the format specifier passed to it.

C#

```
Console.WriteLine("The value of myColor is {0}.",
                  myColor.ToString("G"));
Console.WriteLine("The value of myColor is {0}.",
                  myColor.ToString("F"));
Console.WriteLine("The value of myColor is {0}.",
                  myColor.ToString("D"));
Console.WriteLine("The value of myColor is 0x{0}.",
                  myColor.ToString("X"));
// The example displays the following output to the console:
//      The value of myColor is Green.
//      The value of myColor is Green.
//      The value of myColor is 3.
//      The value of myColor is 0x00000003.
```

Composite formatting

Article • 08/14/2023

The .NET composite formatting feature takes a list of objects and a composite format string as input. A composite format string consists of fixed text intermixed with indexed placeholders, called format items. These format items correspond to the objects in the list. The formatting operation yields a result string that consists of the original fixed text intermixed with the string representation of the objects in the list.

ⓘ Important

Instead of using composite format strings, you can use *interpolated strings* if the language and its version that you're using support them. An interpolated string contains *interpolated expressions*. Each interpolated expression is resolved with the expression's value and included in the result string when the string is assigned. For more information, see [String interpolation \(C# Reference\)](#) and [Interpolated strings \(Visual Basic Reference\)](#).

The following methods support the composite formatting feature:

- [String.Format](#), which returns a formatted result string.
- [StringBuilder.AppendFormat](#), which appends a formatted result string to a [StringBuilder](#) object.
- Some overloads of the [Console.WriteLine](#) method, which display a formatted result string to the console.
- Some overloads of the [TextWriter.WriteLine](#) method, which write the formatted result string to a stream or file. The classes derived from [TextWriter](#), such as [StreamWriter](#) and [HtmlTextWriter](#), also share this functionality.
- [Debug.WriteLine\(String, Object\[\]\)](#), which outputs a formatted message to trace listeners.
- The [Trace.TraceError\(String, Object\[\]\)](#), [Trace.TraceInformation\(String, Object\[\]\)](#), and [Trace.TraceWarning\(String, Object\[\]\)](#) methods, which output formatted messages to trace listeners.
- The [TraceSource.TraceInformation\(String, Object\[\]\)](#) method, which writes an informational method to trace listeners.

Composite format string

A composite format string and object list are used as arguments of methods that support the composite formatting feature. A composite format string consists of zero or more runs of fixed text intermixed with one or more format items. The fixed text is any string that you choose, and each format item corresponds to an object or boxed structure in the list. The string representation of each object replaces the corresponding format item.

Consider the following [Format](#) code fragment:

C#

```
string.Format("Name = {0}, hours = {1:hh}", "Fred", DateTime.Now);
```

The fixed text is `Name =` and `, hours =`. The format items are `{0}`, whose index of 0 corresponds to the object `name`, and `{1:hh}`, whose index of 1 corresponds to the object `DateTime.Now`.

Format item syntax

Each format item takes the following form and consists of the following components:

```
{index[,alignment][:formatString]}
```

The matching braces (`{` and `}`) are required.

Index component

The mandatory *index* component, which is also called a parameter specifier, is a number starting from 0 that identifies a corresponding item in the list of objects. That is, the format item whose parameter specifier is `0` formats the first object in the list. The format item whose parameter specifier is `1` formats the second object in the list, and so on. The following example includes four parameter specifiers, numbered zero through three, to represent prime numbers less than 10:

C#

```
string.Format("Name = {0}, hours = {1:hh}", "Fred", DateTime.Now);
```

Multiple format items can refer to the same element in the list of objects by specifying the same parameter specifier. For example, you can format the same numeric value in

hexadecimal, scientific, and number format by specifying a composite format string such as `"0x{0:X} {0:E} {0:N}"`, as the following example shows:

```
C#
```

```
string multiple = string.Format("0x{0:X} {0:E} {0:N}",
                                 Int64.MaxValue);
Console.WriteLine(multiple);

// The example displays the following output:
//      0x7FFFFFFFFFFFFF 9.223372E+018 9,223,372,036,854,775,807.00
```

Each format item can refer to any object in the list. For example, if there are three objects, you can format the second, first, and third object by specifying a composite format string such as `{1} {0} {2}`. An object that isn't referenced by a format item is ignored. A [FormatException](#) is thrown at run time if a parameter specifier designates an item outside the bounds of the list of objects.

Alignment component

The optional *alignment* component is a signed integer indicating the preferred formatted field width. If the value of *alignment* is less than the length of the formatted string, *alignment* is ignored, and the length of the formatted string is used as the field width. The formatted data in the field is right-aligned if *alignment* is positive and left-aligned if *alignment* is negative. If padding is necessary, white space is used. The comma is required if *alignment* is specified.

The following example defines two arrays, one containing the names of employees and the other containing the hours they worked over two weeks. The composite format string left-aligns the names in a 20-character field and right-aligns their hours in a 5-character field. The "N1" standard format string formats the hours with one fractional digit.

```
C#
```

```
string[] names = { "Adam", "Bridgette", "Carla", "Daniel",
                   "Ebenezer", "Francine", "George" };
decimal[] hours = { 40, 6.667m, 40.39m, 82,
                     40.333m, 80, 16.75m };

Console.WriteLine("{0,-20} {1,5}\n", "Name", "Hours");

for (int counter = 0; counter < names.Length; counter++)
    Console.WriteLine("{0,-20} {1,5:N1}", names[counter], hours[counter]);

// The example displays the following output:
```

```
//      Name          Hours
//      Adam          40.0
//      Bridgette    6.7
//      Carla         40.4
//      Daniel        82.0
//      Ebenezer     40.3
//      Francine      80.0
//      George        16.8
```

Format string component

The optional *formatString* component is a format string that's appropriate for the type of object being formatted. You can specify:

- A standard or custom numeric format string if the corresponding object is a numeric value.
- A standard or custom date and time format string if the corresponding object is a [DateTime](#) object.
- An [enumeration format string](#) if the corresponding object is an enumeration value.

If *formatString* isn't specified, the general ("G") format specifier for a numeric, date and time, or enumeration type is used. The colon is required if *formatString* is specified.

The following table lists types or categories of types in the .NET class library that support a predefined set of format strings, and provides links to the articles that list the supported format strings. String formatting is an extensible mechanism that makes it possible to define new format strings for all existing types and to define a set of format strings supported by an application-defined type.

For more information, see the [IFormattable](#) and [ICustomFormatter](#) interface articles.

| Type or type category | See |
|--|---|
| Date and time types (DateTime , DateTimeOffset) | Standard Date and Time Format Strings |
| | Custom Date and Time Format Strings |

Escaping braces

Opening and closing braces are interpreted as starting and ending a format item. To display a literal opening brace or closing brace, you must use an escape sequence. Specify two opening braces ({{}) in the fixed text to display one opening brace ({}), or two closing braces (}}) to display one closing brace (}).

Escaped braces with a format item are parsed differently between .NET and .NET Framework.

.NET

Braces can be escaped around a format item. For example, consider the format item {{{0:D}}} , which is intended to display an opening brace, a numeric value formatted as a decimal number, and a closing brace. The format item is interpreted in the following manner:

1. The first two opening braces ({{}) are escaped and yield one opening brace.
2. The next three characters ({{0:}) are interpreted as the start of a format item.
3. The next character (D) is interpreted as the Decimal standard numeric format specifier.
4. The next brace (}) is interpreted as the end of the format item.
5. The final two closing braces are escaped and yield one closing brace.
6. The final result that's displayed is the literal string, {{6324}}.

C#

```
int value = 6324;
string output = string.Format("{{{{0:D}}}}", value);

Console.WriteLine(output);
```

```
// The example displays the following output:  
// {6324}
```

.NET Framework

Braces in a format item are interpreted sequentially in the order they're encountered. Interpreting nested braces isn't supported.

The way escaped braces are interpreted can lead to unexpected results. For example, consider the format item `{{{0:D}}}`, which is intended to display an opening brace, a numeric value formatted as a decimal number, and a closing brace. However, the format item is interpreted in the following manner:

1. The first two opening braces (`{{`) are escaped and yield one opening brace.
2. The next three characters (`{0: D}`) are interpreted as the start of a format item.
3. The next character (`D`) would be interpreted as the Decimal standard numeric format specifier, but the next two escaped braces (`}}`) yield a single brace. Because the resulting string (`D}`) isn't a standard numeric format specifier, the resulting string is interpreted as a custom format string that means display the literal string `D}` .
4. The last brace (`}`) is interpreted as the end of the format item.
5. The final result that's displayed is the literal string, `{D}`. The numeric value that was to be formatted isn't displayed.

C#

```
int value = 6324;  
string output = string.Format("{{{0:D}}}",  
                             value);  
Console.WriteLine(output);  
  
// The example displays the following output:  
// {D}
```

One way to write your code to avoid misinterpreting escaped braces and format items is to format the braces and format items separately. That is, in the first format operation, display a literal opening brace. In the next operation, display the result of the format item, and in the final operation, display a literal closing brace. The following example illustrates this approach:

C#

```
int value = 6324;
string output = string.Format("{0}{1:D}{2}",
                             "{", value, "}");
Console.WriteLine(output);

// The example displays the following output:
//      {6324}
```

Processing order

If the call to the composite formatting method includes an [IFormatProvider](#) argument whose value isn't `null`, the runtime calls its [IFormatProvider.GetFormat](#) method to request an [ICustomFormatter](#) implementation. If the method can return an [ICustomFormatter](#) implementation, it's cached during the call of the composite formatting method.

Each value in the parameter list that corresponds to a format item is converted to a string as follows:

1. If the value to be formatted is `null`, an empty string [String.Empty](#) is returned.
2. If an [ICustomFormatter](#) implementation is available, the runtime calls its [Format](#) method. The runtime passes the format item's `formatString` value (or `null` if it's not present) to the method. The runtime also passes the [IFormatProvider](#) implementation to the method. If the call to the [ICustomFormatter.Format](#) method returns `null`, execution proceeds to the next step. Otherwise, the result of the [ICustomFormatter.Format](#) call is returned.
3. If the value implements the [IFormattable](#) interface, the interface's [ToString\(String, IFormatProvider\)](#) method is called. If one is present in the format item, the `formatString` value is passed to the method. Otherwise, `null` is passed. The [IFormatProvider](#) argument is determined as follows:
 - For a numeric value, if a composite formatting method with a non-null [IFormatProvider](#) argument is called, the runtime requests a [NumberFormatInfo](#) object from its [IFormatProvider.GetFormat](#) method. If it's unable to supply one, if the value of the argument is `null`, or if the composite formatting method doesn't have an [IFormatProvider](#) parameter, the [NumberFormatInfo](#) object for the current culture is used.
 - For a date and time value, if a composite formatting method with a non-null [IFormatProvider](#) argument is called, the runtime requests a [DateTimeFormatInfo](#) object from its [IFormatProvider.GetFormat](#) method. In

the following situations, the [DateTimeFormatInfo](#) object for the current culture is used instead:

- The [IFormatProvider.GetFormat](#) method is unable to supply a [DateTimeFormatInfo](#) object.
 - The value of the argument is `null`.
 - The composite formatting method doesn't have an [IFormatProvider](#) parameter.
- For objects of other types, if a composite formatting method is called with an [IFormatProvider](#) argument, its value is passed directly to the [IFormattable.ToString](#) implementation. Otherwise, `null` is passed to the [IFormattable.ToString](#) implementation.

4. The type's parameterless `ToString` method, which either overrides [Object.ToString\(\)](#) or inherits the behavior of its base class, is called. In this case, the format string specified by the `formatString` component in the format item, if it's present, is ignored.

Alignment is applied after the preceding steps have been performed.

Code examples

The following example shows one string created using composite formatting and another created using an object's `ToString` method. Both types of formatting produce equivalent results.

C#

```
string formatString1 = string.Format("{0:ddd MMMM}", DateTime.Now);
string formatString2 = DateTime.Now.ToString("ddd MMMM");
```

Assuming that the current day is a Thursday in May, the value of both strings in the preceding example is `Thursday May` in the U.S. English culture.

[Console.WriteLine](#) exposes the same functionality as [String.Format](#). The only difference between the two methods is that [String.Format](#) returns its result as a string, while [Console.WriteLine](#) writes the result to the output stream associated with the [Console](#) object. The following example uses the [Console.WriteLine](#) method to format the value of `myNumber` to a currency value:

C#

```
int myNumber = 100;
Console.WriteLine("{0:C}", myNumber);

// The example displays the following output
// if en-US is the current culture:
//      $100.00
```

The following example demonstrates formatting multiple objects, including formatting one object in two different ways:

C#

```
string myName = "Fred";
Console.WriteLine(string.Format("Name = {0}, hours = {1:hh}, minutes =
{1:mm}",
                               myName, DateTime.Now));

// Depending on the current time, the example displays output like the
// following:
//      Name = Fred, hours = 11, minutes = 30
```

The following example demonstrates the use of alignment in formatting. The arguments that are formatted are placed between vertical bar characters (|) to highlight the resulting alignment.

C#

```
string firstName = "Fred";
string lastName = "Opals";
int myNumber = 100;

string formatFirstName = string.Format("First Name = |{0,10}|", firstName);
string formatLastName = string.Format("Last Name = |{0,10}|", lastName);
string formatPrice = string.Format("Price = |{0,10:C}|", myNumber);
Console.WriteLine(formatFirstName);
Console.WriteLine(formatLastName);
Console.WriteLine(formatPrice);
Console.WriteLine();

formatFirstName = string.Format("First Name = |{0,-10}|", firstName);
formatLastName = string.Format("Last Name = |{0,-10}|", lastName);
formatPrice = string.Format("Price = |{0,-10:C}|", myNumber);
Console.WriteLine(formatFirstName);
Console.WriteLine(formatLastName);
Console.WriteLine(formatPrice);

// The example displays the following output on a system whose current
// culture is en-US:
//      First Name = |      Fred|
//      Last Name = |      Opals|
```

```
//      Price =      | $100.00|
//  
//      First Name = |Fred      |
//      Last Name =  |Opals     |
//      Price =       |$100.00|
```

How to: Pad a Number with Leading Zeros

Article • 09/08/2022

You can add leading zeros to an integer by using the "D" [standard numeric format string](#) with a precision specifier. You can add leading zeros to both integer and floating-point numbers by using a [custom numeric format string](#). This article shows how to use both methods to pad a number with leading zeros.

To pad an integer with leading zeros to a specific length

1. Determine the minimum number of digits you want the integer value to display. Include any leading digits in this number.
2. Determine whether you want to display the integer as a decimal or hexadecimal value.
 - To display the integer as a decimal value, call its `ToString(String)` method, and pass the string "Dn" as the value of the `format` parameter, where *n* represents the minimum length of the string.
 - To display the integer as a hexadecimal value, call its `ToString(String)` method and pass the string "Xn" as the value of the `format` parameter, where *n* represents the minimum length of the string.

You can also use the format string in an interpolated string in both [C#](#) and [Visual Basic](#). Alternatively, you can call a method such as `String.Format` or `Console.WriteLine` that uses [composite formatting](#).

The following example formats several integer values with leading zeros so that the total length of the formatted number is at least eight characters.

C#

```
byte byteValue = 254;
short shortValue = 10342;
int intValue = 1023983;
long lngValue = 6985321;
ulong ulngValue = UInt64.MaxValue;

// Display integer values by calling the ToString method.
```

```

Console.WriteLine("{0,22} {1,22}", byteValue.ToString("D8"),
byteValue.ToString("X8"));
Console.WriteLine("{0,22} {1,22}", shortValue.ToString("D8"),
shortValue.ToString("X8"));
Console.WriteLine("{0,22} {1,22}", intValue.ToString("D8"),
intValue.ToString("X8"));
Console.WriteLine("{0,22} {1,22}", lngValue.ToString("D8"),
lngValue.ToString("X8"));
Console.WriteLine("{0,22} {1,22}", ulngValue.ToString("D8"),
ulngValue.ToString("X8"));
Console.WriteLine();

// Display the same integer values by using composite formatting.
Console.WriteLine("{0,22:D8} {0,22:X8}", byteValue);
Console.WriteLine("{0,22:D8} {0,22:X8}", shortValue);
Console.WriteLine("{0,22:D8} {0,22:X8}", intValue);
Console.WriteLine("{0,22:D8} {0,22:X8}", lngValue);
Console.WriteLine("{0,22:D8} {0,22:X8}", ulngValue);
// The example displays the following output:
//          00000254          000000FE
//          00010342          00002866
//          01023983          000F9FEF
//          06985321          006A9669
//      18446744073709551615      FFFFFFFFFFFFFF
//
//          00000254          000000FE
//          00010342          00002866
//          01023983          000F9FEF
//          06985321          006A9669
//      18446744073709551615      FFFFFFFFFFFFFF
//      18446744073709551615      FFFFFFFFFFFFFF

```

To pad an integer with a specific number of leading zeros

1. Determine how many leading zeros you want the integer value to display.
2. Determine whether you want to display the integer as a decimal or a hexadecimal value.
 - Formatting it as a decimal value requires the "D" standard format specifier.
 - Formatting it as a hexadecimal value requires the "X" standard format specifier.
3. Determine the length of the unpadded numeric string by calling the integer value's `ToString("D").Length` or `ToString("X").Length` method.

4. Add to the length of the unpadded numeric string the number of leading zeros that you want in the formatted string. The result is the total length of the padded string.
5. Call the integer value's `ToString(String)` method, and pass the string "Dn" for decimal strings and "Xn" for hexadecimal strings, where *n* represents the total length of the padded string. You can also use the "Dn" or "Xn" format string in a method that supports composite formatting.

The following example pads an integer value with five leading zeros:

C#

```
int value = 160934;
int decimalLength = value.ToString("D").Length + 5;
int hexLength = value.ToString("X").Length + 5;
Console.WriteLine(value.ToString("D" + decimalLength.ToString()));
Console.WriteLine(value.ToString("X" + hexLength.ToString()));
// The example displays the following output:
//      00000160934
//      00000274A6
```

To pad a numeric value with leading zeros to a specific length

1. Determine how many digits to the left of the decimal you want the string representation of the number to have. Include any leading zeros in this total number of digits.
2. Define a custom numeric format string that uses the zero placeholder ("0") to represent the minimum number of zeros.
3. Call the number's `ToString(String)` method and pass it the custom format string. You can also use the custom format string with string interpolation or a method that supports composite formatting.

The following example formats several numeric values with leading zeros. As a result, the total length of the formatted number is at least eight digits to the left of the decimal.

C#

```
string fmt = "00000000.##";
int intValue = 1053240;
```

```

decimal decValue = 103932.52m;
float sngValue = 1549230.10873992f;
double dblValue = 9034521202.93217412;

// Display the numbers using the ToString method.
Console.WriteLine(intValue.ToString(fmt));
Console.WriteLine(decValue.ToString(fmt));
Console.WriteLine(sngValue.ToString(fmt));
Console.WriteLine(dblValue.ToString(fmt));
Console.WriteLine();

// Display the numbers using composite formatting.
string formatString = " {0,15:" + fmt + "}";
Console.WriteLine(formatString, intValue);
Console.WriteLine(formatString, decValue);
Console.WriteLine(formatString, sngValue);
Console.WriteLine(formatString, dblValue);
// The example displays the following output:
//      01053240
//      00103932.52
//      01549230
//      9034521202.93
//
//          01053240
//          00103932.52
//          01549230
//          9034521202.93

```

To pad a numeric value with a specific number of leading zeros

1. Determine how many leading zeros you want the numeric value to have.
2. Determine the number of digits to the left of the decimal in the unpadded numeric string:
 - a. Determine whether the string representation of a number includes a decimal point symbol.
 - b. If it does include a decimal point symbol, determine the number of characters to the left of the decimal point. If it doesn't include a decimal point symbol, determine the string's length.
3. Create a custom format string that uses:
 - The zero placeholder ("0") for each of the leading zeros to appear in the string.

- Either the zero placeholder or the digit placeholder "#" to represent each digit in the default string.

4. Supply the custom format string as a parameter either to the number's `ToString(String)` method or to a method that supports composite formatting.

The following example pads two `Double` values with five leading zeros:

C#

```
double[] dblValues = { 9034521202.93217412, 9034521202 };
foreach (double dblValue in dblValues)
{
    string decSeparator =
System.Globalization.NumberFormatInfo.CurrentInfo.NumberDecimalSeparator;
    string fmt, formatString;

    if (dblValue.ToString().Contains(decSeparator))
    {
        int digits = dblValue.ToString().IndexOf(decSeparator);
        fmt = new String('0', 5) + new String('#', digits) + ".##";
    }
    else
    {
        fmt = new String('0', dblValue.ToString().Length);
    }
    formatString = "{0,20:" + fmt + "}";

    Console.WriteLine(dblValue.ToString(fmt));
    Console.WriteLine(formatString, dblValue);
}
// The example displays the following output:
//      000009034521202.93
//      000009034521202.93
//      9034521202
//                  9034521202
```

How to: Extract the Day of the Week from a Specific Date

Article • 10/04/2022

.NET makes it easy to determine the ordinal day of the week for a particular date, and to display the localized weekday name for a particular date. An enumerated value that indicates the day of the week corresponding to a particular date is available from the [DayOfWeek](#) or [DayOfWeek](#) property. In contrast, retrieving the weekday name is a formatting operation that can be performed by calling a formatting method, such as a date and time value's `ToString` method or the `String.Format` method. This article shows how to perform these formatting operations.

Extract a number indicating the day of the week

1. Use the static `DateTime.Parse` or `DateTimeOffset.Parse` method to convert the string representation of a date to a `DateTime` or a `DateTimeOffset` value.
2. Use the `DateTime.DayOfWeek` or `DateTimeOffset.DayOfWeek` property to retrieve a `DayOfWeek` value that indicates the day of the week.
3. If necessary, cast (in C#) or convert (in Visual Basic) the `DayOfWeek` value to an integer.

The following example displays an integer that represents the day of the week of a specific date:

C#

```
using System;

public class Example
{
    public static void Main()
    {
        DateTime dateValue = new DateTime(2008, 6, 11);
        Console.WriteLine((int) dateValue.DayOfWeek);
    }
} // The example displays the following output:
//      3
```

Extract the abbreviated weekday name

1. Use the static [DateTime.Parse](#) or [DateTimeOffset.Parse](#) method to convert the string representation of a date to a [DateTime](#) or a [DateTimeOffset](#) value.
2. You can extract the abbreviated weekday name of the current culture or of a specific culture:
 - a. To extract the abbreviated weekday name for the current culture, call the date and time value's [DateTime.ToString\(String\)](#) or [DateTimeOffset.ToString\(String\)](#) instance method, and pass the string `ddd` as the `format` parameter. The following example illustrates the call to the [ToString\(String\)](#) method:

C#

```
using System;

public class Example
{
    public static void Main()
    {
        DateTime dateValue = new DateTime(2008, 6, 11);
        Console.WriteLine(dateValue.ToString("ddd"));
    }
}
// The example displays the following output:
//      Wed
```

- a. To extract the abbreviated weekday name for a specific culture, call the date and time value's [DateTime.ToString\(String, IFormatProvider\)](#) or [DateTimeOffset.ToString\(String, IFormatProvider\)](#) instance method. Pass the string `ddd` as the `format` parameter. Pass either a [CultureInfo](#) or a [DateTimeFormatInfo](#) object that represents the culture whose weekday name you want to retrieve as the `provider` parameter. The following code illustrates a call to the [ToString\(String, IFormatProvider\)](#) method using a [CultureInfo](#) object that represents the fr-FR culture:

C#

```
using System;
using System.Globalization;

public class Example
{
    public static void Main()
    {
        DateTime dateValue = new DateTime(2008, 6, 11);
```

```

        Console.WriteLine(dateValue.ToString("ddd",
            new CultureInfo("fr-FR")));
    }
}
// The example displays the following output:
//      mer.

```

Extract the full weekday name

1. Use the static [DateTime.Parse](#) or [DateTimeOffset.Parse](#) method to convert the string representation of a date to a [DateTime](#) or a [DateTimeOffset](#) value.
2. You can extract the full weekday name of the current culture or of a specific culture:
 - a. To extract the weekday name for the current culture, call the date and time value's [DateTime.ToString\(String\)](#) or [DateTimeOffset.ToString\(String\)](#) instance method, and pass the string `dddd` as the `format` parameter. The following example illustrates the call to the [ToString\(String\)](#) method:

C#

```

using System;

public class Example
{
    public static void Main()
    {
        DateTime dateValue = new DateTime(2008, 6, 11);
        Console.WriteLine(dateValue.ToString("dddd"));
    }
}
// The example displays the following output:
//      Wednesday

```

- b. To extract the weekday name for a specific culture, call the date and time value's [DateTime.ToString\(String, IFormatProvider\)](#) or [DateTimeOffset.ToString\(String, IFormatProvider\)](#) instance method. Pass the string `dddd` as the `format` parameter. Pass either a [CultureInfo](#) or a [DateTimeFormatInfo](#) object that represents the culture whose weekday name you want to retrieve as the `provider` parameter. The following code illustrates a call to the [ToString\(String, IFormatProvider\)](#) method using a [CultureInfo](#) object that represents the es-ES culture:

C#

```

using System;
using System.Globalization;

public class Example
{
    public static void Main()
    {
        DateTime dateValue = new DateTime(2008, 6, 11);
        Console.WriteLine(dateValue.ToString("dddd",
                                             new CultureInfo("es-ES")));
    }
}
// The example displays the following output:
//       miércoles.

```

Example

The following example illustrates calls to the [DateTime.DayOfWeek](#) and [DateTimeOffset.DayOfWeek](#) properties to retrieve the number that represents the day of the week for a particular date. It also includes calls to the [DateTime.ToString](#) and [DateTimeOffset.ToString](#) methods to extract the abbreviated weekday name and the full weekday name.

C#

```

using System;
using System.Globalization;

public class Example
{
    public static void Main()
    {
        string dateString = "6/11/2007";
        DateTime dateValue;
        DateTimeOffset dateOffsetValue;

        try
        {
            DateTimeFormatInfo dateTimeFormats;
            // Convert date representation to a date value
            dateValue = DateTime.Parse(dateString,
                                       CultureInfo.InvariantCulture);
            dateOffsetValue = new DateTimeOffset(dateValue,
                                                 TimeZoneInfo.Local.GetUtcOffset(dateValue));

            // Convert date representation to a number indicating the day of
            // week
            Console.WriteLine((int) dateValue.DayOfWeek);
        }
    }
}

```

```

        Console.WriteLine((int) dateOffsetValue.DayOfWeek);

        // Display abbreviated weekday name using current culture
        Console.WriteLine(dateValue.ToString("ddd"));
        Console.WriteLine(dateOffsetValue.ToString("ddd"));

        // Display full weekday name using current culture
        Console.WriteLine(dateValue.ToString("ddd"));
        Console.WriteLine(dateOffsetValue.ToString("ddd"));

        // Display abbreviated weekday name for de-DE culture
        Console.WriteLine(dateValue.ToString("ddd", new CultureInfo("de-
DE")));
        Console.WriteLine(dateOffsetValue.ToString("ddd",
                                         new CultureInfo("de-
DE")));

        // Display abbreviated weekday name with de-DE DateTimeFormatInfo
object
        dateTimeFormats = new CultureInfo("de-DE").DateTimeFormat;
        Console.WriteLine(dateValue.ToString("ddd", dateTimeFormats));
        Console.WriteLine(dateOffsetValue.ToString("ddd",
                                         dateTimeFormats));

        // Display full weekday name for fr-FR culture
        Console.WriteLine(dateValue.ToString("ddd", new CultureInfo("fr-
FR")));
        Console.WriteLine(dateOffsetValue.ToString("ddd",
                                         new CultureInfo("fr-
FR")));

        // Display abbreviated weekday name with fr-FR DateTimeFormatInfo
object
        dateTimeFormats = new CultureInfo("fr-FR").DateTimeFormat;
        Console.WriteLine(dateValue.ToString("ddd", dateTimeFormats));
        Console.WriteLine(dateOffsetValue.ToString("ddd",
                                         dateTimeFormats));
    }
    catch (FormatException)
    {
        Console.WriteLine("Unable to convert {0} to a date.", dateString);
    }
}
// The example displays the following output:
//      1
//      1
//      Mon
//      Mon
//      Monday
//      Monday
//      Mo
//      Mo
//      Mo
//      Mo

```

```
//      lun.  
//      lun.  
//      lundi  
//      lundi
```

Individual languages might provide functionality that duplicates or supplements the functionality provided by .NET. For example, Visual Basic includes two such functions:

- `Weekday`, which returns a number that indicates the day of the week of a particular date. It considers the ordinal value of the first day of the week to be one, whereas the `DateTime.DayOfWeek` property considers it to be zero.
- `WeekdayName`, which returns the name of the week in the current culture that corresponds to a particular weekday number.

The following example illustrates the use of the Visual Basic `Weekday` and `WeekdayName` functions:

VB

```
Imports System.Globalization  
Imports System.Threading  
  
Module Example  
    Public Sub Main()  
        Dim dateValue As Date = #6/11/2008#  
  
        ' Get weekday number using Visual Basic Weekday function  
        Console.WriteLine(Weekday(dateValue))                      ' Displays 4  
        ' Compare with .NET DateTime.DayOfWeek property  
        Console.WriteLine(dateValue.DayOfWeek)                     ' Displays 3  
  
        ' Get weekday name using Weekday and WeekdayName functions  
        Console.WriteLine(WeekdayName(Weekday(dateValue)))       ' Displays  
Wednesday  
  
        ' Change culture to de-DE  
        Dim originalCulture As CultureInfo =  
Thread.CurrentCulture  
        Thread.CurrentCulture = New CultureInfo("de-DE")  
        ' Get weekday name using Weekday and WeekdayName functions  
        Console.WriteLine(WeekdayName(Weekday(dateValue)))       ' Displays  
Donnerstag  
  
        ' Restore original culture  
        Thread.CurrentCulture = originalCulture  
    End Sub  
End Module
```

You can also use the value returned by the `DateTime.DayOfWeek` property to retrieve the weekday name of a particular date. This process requires only a call to the `ToString` method on the `DayOfWeek` value returned by the property. However, this technique doesn't produce a localized weekday name for the current culture, as the following example illustrates:

C#

```
using System;
using System.Globalization;
using System.Threading;

public class Example
{
    public static void Main()
    {
        // Change current culture to fr-FR
        CultureInfo originalCulture = Thread.CurrentThread.CurrentCulture;
        Thread.CurrentThread.CurrentCulture = new CultureInfo("fr-FR");

        DateTime dateValue = new DateTime(2008, 6, 11);
        // Display the DayOfWeek string representation
        Console.WriteLine(dateValue.DayOfWeek.ToString());
        // Restore original current culture
        Thread.CurrentThread.CurrentCulture = originalCulture;
    }
}
// The example displays the following output:
//       Wednesday
```

How to: Define and Use Custom Numeric Format Providers

Article • 09/15/2021

.NET gives you extensive control over the string representation of numeric values. It supports the following features for customizing the format of numeric values:

- Standard numeric format strings, which provide a predefined set of formats for converting numbers to their string representation. You can use them with any numeric formatting method, such as `Decimal.ToString(String)`, that has a `format` parameter. For details, see [Standard Numeric Format Strings](#).
- Custom numeric format strings, which provide a set of symbols that can be combined to define custom numeric format specifiers. They can also be used with any numeric formatting method, such as `Decimal.ToString(String)`, that has a `format` parameter. For details, see [Custom Numeric Format Strings](#).
- Custom `CultureInfo` or `NumberFormatInfo` objects, which define the symbols and format patterns used in displaying the string representations of numeric values. You can use them with any numeric formatting method, such as `ToString`, that has a `provider` parameter. Typically, the `provider` parameter is used to specify culture-specific formatting.

In some cases (such as when an application must display a formatted account number, an identification number, or a postal code) these three techniques are inappropriate. .NET also enables you to define a formatting object that is neither a `CultureInfo` nor a `NumberFormatInfo` object to determine how a numeric value is formatted. This topic provides the step-by-step instructions for implementing such an object, and provides an example that formats telephone numbers.

Define a custom format provider

1. Define a class that implements the `IFormatProvider` and `ICustomFormatter` interfaces.
2. Implement the `IFormatProvider.GetFormat` method. `GetFormat` is a callback method that the formatting method (such as the `String.Format(IFormatProvider, String, Object[])` method) invokes to retrieve the object that is actually responsible for performing custom formatting. A typical implementation of `GetFormat` does the following:

- a. Determines whether the `Type` object passed as a method parameter represents an `ICustomFormatter` interface.
 - b. If the parameter does represent the `ICustomFormatter` interface, `GetFormat` returns an object that implements the `ICustomFormatter` interface that is responsible for providing custom formatting. Typically, the custom formatting object returns itself.
 - c. If the parameter does not represent the `ICustomFormatter` interface, `GetFormat` returns `null`.
3. Implement the `Format` method. This method is called by the `String.Format(IFormatProvider, String, Object[])` method and is responsible for returning the string representation of a number. Implementing the method typically involves the following:
- a. Optionally, make sure that the method is legitimately intended to provide formatting services by examining the `provider` parameter. For formatting objects that implement both `IFormatProvider` and `ICustomFormatter`, this involves testing the `provider` parameter for equality with the current formatting object.
 - b. Determine whether the formatting object should support custom format specifiers. (For example, an "N" format specifier might indicate that a U.S. telephone number should be output in NANP format, and an "I" might indicate output in ITU-T Recommendation E.123 format.) If format specifiers are used, the method should handle the specific format specifier. It is passed to the method in the `format` parameter. If no specifier is present, the value of the `format` parameter is `String.Empty`.
 - c. Retrieve the numeric value passed to the method as the `arg` parameter. Perform whatever manipulations are required to convert it to its string representation.
 - d. Return the string representation of the `arg` parameter.

Use a custom numeric formatting object

1. Create a new instance of the custom formatting class.
2. Call the `String.Format(IFormatProvider, String, Object[])` formatting method, passing it the custom formatting object, the formatting specifier (or `String.Empty`, if one is not used), and the numeric value to be formatted.

Example

The following example defines a custom numeric format provider named `TelephoneFormatter` that converts a number that represents a U.S. telephone number to its NANP or E.123 format. The method handles two format specifiers, "N" (which outputs the NANP format) and "I" (which outputs the international E.123 format).

C#

```
using System;
using System.Globalization;

public class TelephoneFormatter : IFormatProvider, ICustomFormatter
{
    public object GetFormat(Type formatType)
    {
        if (formatType == typeof(ICustomFormatter))
            return this;
        else
            return null;
    }

    public string Format(string format, object arg, IFormatProvider
formatProvider)
    {
        // Check whether this is an appropriate callback
        if (! this.Equals(formatProvider))
            return null;

        // Set default format specifier
        if (string.IsNullOrEmpty(format))
            format = "N";

        string numericString = arg.ToString();

        if (format == "N")
        {
            if (numericString.Length <= 4)
                return numericString;
            else if (numericString.Length == 7)
                return numericString.Substring(0, 3) + "-" +
numericString.Substring(3, 4);
            else if (numericString.Length == 10)
                return "(" + numericString.Substring(0, 3) + ")" +
numericString.Substring(3, 3) + "-" +
numericString.Substring(6);
            else
                throw new FormatException(
                    string.Format("{0}' cannot be used to format {1}.",
format, arg.ToString()));
        }
        else if (format == "I")
    }
```

```

    {
        if (numericString.Length < 10)
            throw new FormatException(string.Format("{0} does not have 10
digits.", arg.ToString()));
        else
            numericString = "+1 " + numericString.Substring(0, 3) + " " +
numericString.Substring(3, 3) + " " + numericString.Substring(6);
    }
    else
    {
        throw new FormatException(string.Format("The {0} format specifier
is invalid.", format));
    }
    return numericString;
}
}

public class TestTelephoneFormatter
{
    public static void Main()
    {
        Console.WriteLine(String.Format(new TelephoneFormatter(), "{0}", 0));
        Console.WriteLine(String.Format(new TelephoneFormatter(), "{0}",
911));
        Console.WriteLine(String.Format(new TelephoneFormatter(), "{0}",
8490216));
        Console.WriteLine(String.Format(new TelephoneFormatter(), "{0}",
4257884748));

        Console.WriteLine(String.Format(new TelephoneFormatter(), "{0:N}",
0));
        Console.WriteLine(String.Format(new TelephoneFormatter(), "{0:N}",
911));
        Console.WriteLine(String.Format(new TelephoneFormatter(), "{0:N}",
8490216));
        Console.WriteLine(String.Format(new TelephoneFormatter(), "{0:N}",
4257884748));

        Console.WriteLine(String.Format(new TelephoneFormatter(), "{0:I}",
4257884748));
    }
}

```

The custom numeric format provider can be used only with the [String.Format\(IFormatProvider, String, Object\[\]\)](#) method. The other overloads of numeric formatting methods (such as [ToString](#)) that have a parameter of type [IFormatProvider](#) all pass the [IFormatProvider.GetFormat](#) implementation a [Type](#) object that represents the [NumberFormatInfo](#) type. In return, they expect the method to return a [NumberFormatInfo](#) object. If it does not, the custom numeric format provider is ignored, and the [NumberFormatInfo](#) object for the current culture is used in its place. In the example, the [TelephoneFormatter.GetFormat](#) method handles the possibility that it may

be inappropriately passed to a numeric formatting method by examining the method parameter and returning `null` if it represents a type other than [ICustomFormatter](#).

If a custom numeric format provider supports a set of format specifiers, make sure you provide a default behavior if no format specifier is supplied in the format item used in the [String.Format\(IFormatProvider, String, Object\[\]\)](#) method call. In the example, "N" is the default format specifier. This allows for a number to be converted to a formatted telephone number by providing an explicit format specifier. The following example illustrates such a method call.

C#

```
Console.WriteLine(String.Format(new TelephoneFormatter(), "{0:N}",  
4257884748));
```

But it also allows the conversion to occur if no format specifier is present. The following example illustrates such a method call.

C#

```
Console.WriteLine(String.Format(new TelephoneFormatter(), "{0}",  
4257884748));
```

If no default format specifier is defined, your implementation of the [ICustomFormatter.Format](#) method should include code such as the following so that .NET can provide formatting that your code does not support.

C#

```
if (arg is IFormattable)  
    s = ((IFormattable)arg).ToString(format, formatProvider);  
else if (arg != null)  
    s = arg.ToString();
```

In the case of this example, the method that implements [ICustomFormatter.Format](#) is intended to serve as a callback method for the [String.Format\(IFormatProvider, String, Object\[\]\)](#) method. Therefore, it examines the `formatProvider` parameter to determine whether it contains a reference to the current `TelephoneFormatter` object. However, the method can also be called directly from code. In that case, you can use the `formatProvider` parameter to provide a [CultureInfo](#) or [NumberFormatInfo](#) object that supplies culture-specific formatting information.

How to: Round-trip Date and time values

Article • 12/21/2022

In many applications, a date and time value is intended to unambiguously identify a single point in time. This article shows how to save and restore a [DateTime](#) value, a [DateTimeOffset](#) value, and a date and time value with time zone information so that the restored value identifies the same time as the saved value.

Round-trip a DateTime value

1. Convert the [DateTime](#) value to its string representation by calling the [DateTime.ToString\(String\)](#) method with the "o" format specifier.
2. Save the string representation of the [DateTime](#) value to a file, or pass it across a process, application domain, or machine boundary.
3. Retrieve the string that represents the [DateTime](#) value.
4. Call the [DateTime.Parse\(String, IFormatProvider, DateTimeStyles\)](#) method, and pass [DateTimeStyles.RoundtripKind](#) as the value of the `styles` parameter.

The following example illustrates how to round-trip a [DateTime](#) value.

C#

```
const string fileName = @"\DateFile.txt";

StreamWriter outFile = new StreamWriter(fileName);

// Save DateTime value.
DateTime dateToSave = DateTime.SpecifyKind(new DateTime(2008, 6, 12, 18, 45,
15),
                                            DateTimeKind.Local);
string? dateString = dateToSave.ToString("o");
Console.WriteLine("Converted {0} ({1}) to {2}.",
                  dateToSave.ToString(),
                  dateToSave.Kind.ToString(),
                  dateString);
outFile.WriteLine(dateString);
Console.WriteLine("Wrote {0} to {1}.", dateString, fileName);
outFile.Close();

// Restore DateTime value.
DateTime restoredDate;
```

```

using StreamReader inFile = new StreamReader(fileName);
dateString = inFile.ReadLine();

if (dateString is not null)
{
    restoredDate = DateTime.Parse(dateString, null,
    DateTimeStyles.RoundtripKind);
    Console.WriteLine("Read {0} ({2}) from {1}.", restoredDate.ToString(),
                      fileName,
    restoredDate.Kind.ToString());
}

// The example displays the following output:
//     Converted 6/12/2008 6:45:15 PM (Local) to 2008-06-12T18:45:15.0000000-
// 05:00.
//     Wrote 2008-06-12T18:45:15.0000000-05:00 to .\DateFile.txt.
//     Read 6/12/2008 6:45:15 PM (Local) from .\DateFile.txt.

```

When round-tripping a `DateTime` value, this technique successfully preserves the time for all local and universal times. For example, if a local `DateTime` value is saved on a system in the U.S. Pacific Standard Time zone and is restored on a system in the U.S. Central Standard Time zone, the restored date and time will be two hours later than the original time, which reflects the time difference between the two time zones. However, this technique is not necessarily accurate for unspecified times. All `DateTime` values whose `Kind` property is `Unspecified` are treated as if they are local times. If it's not a local time, the `DateTime` doesn't successfully identify the correct point in time. The workaround for this limitation is to tightly couple a date and time value with its time zone for the save and restore operation.

Round-trip a `DateTimeOffset` value

1. Convert the `DateTimeOffset` value to its string representation by calling the `DateTimeOffset.ToString(String)` method with the "o" format specifier.
2. Save the string representation of the `DateTimeOffset` value to a file, or pass it across a process, application domain, or machine boundary.
3. Retrieve the string that represents the `DateTimeOffset` value.
4. Call the `DateTimeOffset.Parse(String, IFormatProvider, DateTimeStyles)` method, and pass `DateTimeStyles.RoundtripKind` as the value of the `styles` parameter.

The following example illustrates how to round-trip a `DateTimeOffset` value.

C#

```
const string fileName = @".\DateOff.txt";

StreamWriter outFile = new StreamWriter(fileName);

// Save DateTime value.
DateTimeOffset dateToSave = new DateTimeOffset(2008, 6, 12, 18, 45, 15,
                                                new TimeSpan(7, 0, 0));
string? dateString = dateToSave.ToString("o");
Console.WriteLine("Converted {0} to {1}.", dateToSave.ToString(),
                  dateString);
outFile.WriteLine(dateString);
Console.WriteLine("Wrote {0} to {1}.", dateString, fileName);
outFile.Close();

// Restore DateTime value.
DateTimeOffset restoredDateOff;

using StreamReader inFile = new StreamReader(fileName);
dateString = inFile.ReadLine();

if (dateString is not null)
{
    restoredDateOff = DateTimeOffset.Parse(dateString, null,
                                            DateTimeStyles.RoundtripKind);
    Console.WriteLine("Read {0} from {1}.", restoredDateOff.ToString(),
                      fileName);
}

// The example displays the following output:
//     Converted 6/12/2008 6:45:15 PM +07:00 to 2008-06-
12T18:45:15.0000000+07:00.
//     Wrote 2008-06-12T18:45:15.0000000+07:00 to .\DateOff.txt.
//     Read 6/12/2008 6:45:15 PM +07:00 from .\DateOff.txt.
```

This technique always unambiguously identifies a [DateTimeOffset](#) value as a single point in time. The value can then be converted to Coordinated Universal Time (UTC) by calling the [DateTimeOffset.ToUniversalTime](#) method, or it can be converted to the time in a particular time zone by calling the [DateTimeOffset.ToOffset](#) or [TimeZoneInfo.ConvertTime\(DateTimeOffset, TimeZoneInfo\)](#) method. The major limitation of this technique is that date and time arithmetic, when performed on a [DateTimeOffset](#) value that represents the time in a particular time zone, may not produce accurate results for that time zone. This is because when a [DateTimeOffset](#) value is instantiated, it is disassociated from its time zone. Therefore, that time zone's adjustment rules can no longer be applied when you perform date and time calculations. You can work around this problem by defining a custom type that includes both a date and time value and its accompanying time zone.

Compile the code

These examples require that the following namespaces be imported with C# `using` directives or Visual Basic `Imports` statements:

- [System](#) (C# only)
- [System.Globalization](#)
- [System.IO](#)

How to: Display milliseconds in date and time values

Article • 10/04/2022

The default date and time formatting methods, such as [DateTime.ToString\(\)](#), include the hours, minutes, and seconds of a time value but exclude its milliseconds component. This article shows how to include a date and time's millisecond component in formatted date and time strings.

To display the millisecond component of a DateTime value

1. If you're working with the string representation of a date, convert it to a [DateTime](#) or a [DateTimeOffset](#) value by using the static [DateTime.Parse\(String\)](#) or [DateTimeOffset.Parse\(String\)](#) method.
2. To extract the string representation of a time's millisecond component, call the date and time value's [DateTime.ToString\(String\)](#) or [ToString](#) method, and pass the `fff` or `FFF` custom format pattern alone or with other custom format specifiers as the `format` parameter.

Tip

The [System.Globalization.NumberFormatInfo.NumberDecimalSeparator](#) property specifies the millisecond separator.

Example

The example displays the millisecond component of a [DateTime](#) and a [DateTimeOffset](#) value to the console, alone and included in a longer date and time string.

C#

```
using System.Globalization;
using System.Text.RegularExpressions;

string dateString = "7/16/2008 8:32:45.126 AM";

try
{
```

```

DateTime dateValue = DateTime.Parse(dateString);
DateTimeOffset dateOffsetValue = DateTimeOffset.Parse(dateString);

// Display Millisecond component alone.
Console.WriteLine("Millisecond component only: {0}",
    dateValue.ToString("fff"));
Console.WriteLine("Millisecond component only: {0}",
    dateOffsetValue.ToString("fff"));

// Display Millisecond component with full date and time.
Console.WriteLine("Date and Time with Milliseconds: {0}",
    dateValue.ToString("MM/dd/yyyy hh:mm:ss.fff tt"));
Console.WriteLine("Date and Time with Milliseconds: {0}",
    dateOffsetValue.ToString("MM/dd/yyyy hh:mm:ss.fff tt"));

string fullPattern = DateTimeFormatInfo.CurrentInfo.FullDateTimePattern;

// Create a format similar to .fff but based on the current culture.
string millisecondFormat = $""
{NumberFormatInfo.CurrentInfo.NumberDecimalSeparator}fff";

// Append millisecond pattern to current culture's full date time
pattern.
fullPattern = Regex.Replace(fullPattern, "(:ss|:s)",
"${$1${millisecondFormat}}");

// Display Millisecond component with modified full date and time
pattern.
Console.WriteLine("Modified full date time pattern: {0}",
    dateValue.ToString(fullPattern));
Console.WriteLine("Modified full date time pattern: {0}",
    dateOffsetValue.ToString(fullPattern));
}

catch (FormatException)
{
    Console.WriteLine("Unable to convert {0} to a date.", dateString);
}

// The example displays the following output if the current culture is en-
US:
//    Millisecond component only: 126
//    Millisecond component only: 126
//    Date and Time with Milliseconds: 07/16/2008 08:32:45.126 AM
//    Date and Time with Milliseconds: 07/16/2008 08:32:45.126 AM
//    Modified full date time pattern: Wednesday, July 16, 2008 8:32:45.126
AM
//    Modified full date time pattern: Wednesday, July 16, 2008 8:32:45.126
AM

```

The `fff` format pattern includes any trailing zeros in the millisecond value. The `FFF` format pattern suppresses them. The following example illustrates the difference:

C#

```
DateTime dateValue = new DateTime(2008, 7, 16, 8, 32, 45, 180);
Console.WriteLine(dateValue.ToString("fff"));
Console.WriteLine(dateValue.ToString("FFF"));
// The example displays the following output to the console:
//    180
//    18
```

A problem with defining a complete custom format specifier that includes the millisecond component of a date and time is that it defines a hard-coded format that might not correspond to the arrangement of time elements in the application's current culture. A better alternative is to retrieve one of the date and time display patterns defined by the current culture's [DateTimeFormatInfo](#) object and modify it to include milliseconds. The example also illustrates this approach. It retrieves the current culture's full date and time pattern from the [DateTimeFormatInfo.FullDateTimePattern](#) property and then inserts the custom pattern `fff` along with the current culture's millisecond separator. The example uses a regular expression to do this operation in a single method call.

You can also use a custom format specifier to display a fractional part of seconds other than milliseconds. For example, the `f` or `F` custom format specifier displays tenths of a second, the `ff` or `FF` custom format specifier displays hundredths of a second, and the `ffff` or `FFFF` custom format specifier displays ten-thousandths of a second. Fractional parts of a millisecond are truncated instead of rounded in the returned string. These format specifiers are used in the following example:

C#

```
DateTime dateValue = new DateTime(2008, 7, 16, 8, 32, 45, 180);
Console.WriteLine("{0} seconds", dateValue.ToString("s.f"));
Console.WriteLine("{0} seconds", dateValue.ToString("s.ff"));
Console.WriteLine("{0} seconds", dateValue.ToString("s.ffff"));
// The example displays the following output to the console:
//    45.1 seconds
//    45.18 seconds
//    45.1800 seconds
```

ⓘ Note

It's possible to display very small fractional units of a second, such as ten-thousandths of a second or hundred-thousandths of a second. However, these values might not be meaningful. The precision of a date and time value depends on the resolution of the operating system clock. For more information, see the API your operating system uses:

- Windows 7: `GetSystemTimeAsFileTime`
- Windows 8 and above: `GetSystemTimePreciseAsFileTime`
- Linux and macOS: `clock_gettime` ↗

How to: Display Dates in Non-Gregorian Calendars

Article • 10/06/2022

The [DateTime](#) and [DateTimeOffset](#) types use the Gregorian calendar as their default calendar. This means that calling a date and time value's `ToString` method displays the string representation of that date and time in the Gregorian calendar, even if that date and time was created using another calendar. This is illustrated in the following example, which uses two different ways to create a date and time value with the Persian calendar, but still displays those date and time values in the Gregorian calendar when it calls the `ToString` method. This example reflects two commonly used but incorrect techniques for displaying the date in a particular calendar.

C#

```
PersianCalendar persianCal = new PersianCalendar();

DateTime persianDate = persianCal.ToDateTime(1387, 3, 18, 12, 0, 0, 0);
Console.WriteLine(persianDate.ToString());

persianDate = new DateTime(1387, 3, 18, persianCal);
Console.WriteLine(persianDate.ToString());
// The example displays the following output to the console:
//      6/7/2008 12:00:00 PM
//      6/7/2008 12:00:00 AM
```

Two different techniques can be used to display the date in a particular calendar. The first requires that the calendar be the default calendar for a particular culture. The second can be used with any calendar.

To display the date for a culture's default calendar

1. Instantiate a calendar object derived from the [Calendar](#) class that represents the calendar to be used.
2. Instantiate a [CultureInfo](#) object representing the culture whose formatting will be used to display the date.
3. Call the [Array.Exists](#) method to determine whether the calendar object is a member of the array returned by the [CultureInfo.OptionalCalendars](#) property. This indicates that the calendar can serve as the default calendar for the [CultureInfo](#) object. If it is

not a member of the array, follow the instructions in the "To Display the Date in Any Calendar" section.

4. Assign the calendar object to the [Calendar](#) property of the [DateTimeFormatInfo](#) object returned by the [CultureInfo.DateTimeFormat](#) property.

 **Note**

The [CultureInfo](#) class also has a [Calendar](#) property. However, it is read-only and constant; it does not change to reflect the new default calendar assigned to the [DateTimeFormatInfo.Calendar](#) property.

5. Call either the [ToString](#) or the [ToString](#) method, and pass it the [CultureInfo](#) object whose default calendar was modified in the previous step.

To display the date in any calendar

1. Instantiate a calendar object derived from the [Calendar](#) class that represents the calendar to be used.
2. Determine which date and time elements should appear in the string representation of the date and time value.
3. For each date and time element that you want to display, call the calendar object's [Get ...](#) method. The following methods are available:
 - [GetYear](#), to display the year in the appropriate calendar.
 - [GetMonth](#), to display the month in the appropriate calendar.
 - [GetDayOfMonth](#), to display the number of the day of the month in the appropriate calendar.
 - [GetHour](#), to display the hour of the day in the appropriate calendar.
 - [GetMinute](#), to display the minutes in the hour in the appropriate calendar.
 - [GetSecond](#), to display the seconds in the minute in the appropriate calendar.
 - [GetMilliseconds](#), to display the milliseconds in the second in the appropriate calendar.

Example

The example displays a date using two different calendars. It displays the date after defining the Hijri calendar as the default calendar for the ar-JO culture, and displays the date using the Persian calendar, which is not supported as an optional calendar by the fa-IR culture.

C#

```
using System;
using System.Globalization;

public class CalendarDates
{
    public static void Main()
    {
        HijriCalendar hijriCal = new HijriCalendar();
        CalendarUtility hijriUtil = new CalendarUtility(hijriCal);
        DateTime dateValue1 = new DateTime(1429, 6, 29, hijriCal);
        DateTimeOffset dateValue2 = new DateTimeOffset(dateValue1,
            TimeZoneInfo.Local.GetUtcOffset(dateValue1));
        CultureInfo jc = CultureInfo.CreateSpecificCulture("ar-JO");

        // Display the date using the Gregorian calendar.
        Console.WriteLine("Using the system default culture: {0}",
            dateValue1.ToString("d"));
        // Display the date using the ar-JO culture's original default
        // calendar.
        Console.WriteLine("Using the ar-JO culture's original default
calendar: {0}",
            dateValue1.ToString("d", jc));
        // Display the date using the Hijri calendar.
        Console.WriteLine("Using the ar-JO culture with Hijri as the default
calendar:");
        // Display a Date value.
        Console.WriteLine(hijriUtil.DisplayDate(dateValue1, jc));
        // Display a DateTimeOffset value.
        Console.WriteLine(hijriUtil.DisplayDate(dateValue2, jc));

        Console.WriteLine();

        PersianCalendar persianCal = new PersianCalendar();
        CalendarUtility persianUtil = new CalendarUtility(persianCal);
        CultureInfo ic = CultureInfo.CreateSpecificCulture("fa-IR");

        // Display the date using the ir-FA culture's default calendar.
        Console.WriteLine("Using the ir-FA culture's default calendar: {0}",
            dateValue1.ToString("d", ic));
        // Display a Date value.
        Console.WriteLine(persianUtil.DisplayDate(dateValue1, ic));
        // Display a DateTimeOffset value.
        Console.WriteLine(persianUtil.DisplayDate(dateValue2, ic));
    }
}
```

```
public class CalendarUtility
{
    private Calendar thisCalendar;
    private CultureInfo targetCulture;

    public CalendarUtility(Calendar cal)
    {
        this.thisCalendar = cal;
    }

    private bool CalendarExists(CultureInfo culture)
    {
        this.targetCulture = culture;
        return Array.Exists(this.targetCulture.OptionalCalendars,
                            this.HasSameName);
    }

    private bool HasSameName(Calendar cal)
    {
        if (cal.ToString() == thisCalendar.ToString())
            return true;
        else
            return false;
    }

    public string DisplayDate(DateTime dateToDisplay, CultureInfo culture)
    {
        DateTimeOffset displayOffsetDate = dateToDisplay;
        return DisplayDate(displayOffsetDate, culture);
    }

    public string DisplayDate(DateTimeOffset dateToDisplay,
                             CultureInfo culture)
    {
        string specifier = "yyyy/MM/dd";

        if (this.CalendarExists(culture))
        {
            Console.WriteLine("Displaying date in supported {0} calendar...",
                              this.thisCalendar.GetType().Name);
            culture.DateTimeFormat.Calendar = this.thisCalendar;
            return dateToDisplay.ToString(specifier, culture);
        }
        else
        {
            Console.WriteLine("Displaying date in unsupported {0} calendar...",
                              thisCalendar.GetType().Name);

            string separator = targetCulture.DateTimeFormat.DateSeparator;

            return
thisCalendar.GetYear(dateToDisplay.DateTime).ToString("0000") +
                    separator +
                    thisCalendar.GetMonth(dateToDisplay.DateTime).ToString("00")
        }
    }
}
```

```

+
separator +

thisCalendar.GetDayOfMonth(dateToDisplay.DateTime).ToString("00");
    }
}
// The example displays the following output to the console:
//      Using the system default culture: 7/3/2008
//      Using the ar-JO culture's original default calendar: 03/07/2008
//      Using the ar-JO culture with Hijri as the default calendar:
//          Displaying date in supported HijriCalendar calendar...
//          1429/06/29
//          Displaying date in supported HijriCalendar calendar...
//          1429/06/29
//
//      Using the ir-FA culture's default calendar: 7/3/2008
//      Displaying date in unsupported PersianCalendar calendar...
//      1387/04/13
//      Displaying date in unsupported PersianCalendar calendar...
//      1387/04/13

```

Each [CultureInfo](#) object can support one or more calendars, which are indicated by the [OptionalCalendars](#) property. One of these is designated as the culture's default calendar and is returned by the read-only [CultureInfo.Calendar](#) property. Another of the optional calendars can be designated as the default by assigning a [Calendar](#) object that represents that calendar to the [DateTimeFormatInfo.Calendar](#) property returned by the [CultureInfo.DateFormat](#) property. However, some calendars, such as the Persian calendar represented by the [PersianCalendar](#) class, do not serve as optional calendars for any culture.

The example defines a reusable calendar utility class, [CalendarUtility](#), to handle many of the details of generating the string representation of a date using a particular calendar. The [CalendarUtility](#) class has the following members:

- A parameterized constructor whose single parameter is a [Calendar](#) object in which a date is to be represented. This is assigned to a private field of the class.
- [CalendarExists](#), a private method that returns a Boolean value indicating whether the calendar represented by the [CalendarUtility](#) object is supported by the [CultureInfo](#) object that is passed to the method as a parameter. The method wraps a call to the [Array.Exists](#) method, to which it passes the [CultureInfo.OptionalCalendars](#) array.
- [HasSameName](#), a private method assigned to the [Predicate<T>](#) delegate that is passed as a parameter to the [Array.Exists](#) method. Each member of the array is passed to the method until the method returns [true](#). The method determines

whether the name of an optional calendar is the same as the calendar represented by the `CalendarUtility` object.

- `DisplayDate`, an overloaded public method that is passed two parameters: either a `DateTime` or `DateTimeOffset` value to express in the calendar represented by the `CalendarUtility` object; and the culture whose formatting rules are to be used. Its behavior in returning the string representation of a date depends on whether the target calendar is supported by the culture whose formatting rules are to be used.

Regardless of the calendar used to create a `DateTime` or `DateTimeOffset` value in this example, that value is typically expressed as a Gregorian date. This is because the `DateTime` and `DateTimeOffset` types do not preserve any calendar information.

Internally, they are represented as the number of ticks that have elapsed since midnight of January 1, 0001. The interpretation of that number depends on the calendar. For most cultures, the default calendar is the Gregorian calendar.

Character encoding in .NET

Article • 02/14/2023

This article provides an introduction to character encoding systems that are used by .NET. The article explains how the [String](#), [Char](#), [Rune](#), and [StringInfo](#) types work with Unicode, UTF-16, and UTF-8.

The term *character* is used here in the general sense of *what a reader perceives as a single display element*. Common examples are the letter "a", the symbol "@", and the emoji "🐂". Sometimes what looks like one character is actually composed of multiple independent display elements, as the section on [grapheme clusters](#) explains.

The string and char types

An instance of the [string](#) class represents some text. A `string` is logically a sequence of 16-bit values, each of which is an instance of the [char](#) struct. The `string.Length` property returns the number of `char` instances in the `string` instance.

The following sample function prints out the values in hexadecimal notation of all the `char` instances in a `string`:

```
C#  
  
void PrintChars(string s)  
{  
    Console.WriteLine($"\"{s}\".Length = {s.Length}");  
    for (int i = 0; i < s.Length; i++)  
    {  
        Console.WriteLine($"s[{i}] = '{s[i]}' ('\\u{(int)s[i]:x4}')");  
    }  
    Console.WriteLine();  
}
```

Pass the string "Hello" to this function, and you get the following output:

```
C#  
  
PrintChars("Hello");
```

Output

```
"Hello".Length = 5  
s[0] = 'H' ('\u0048')
```

```
s[1] = 'e' ('\u0065')
s[2] = 'l' ('\u006c')
s[3] = 'l' ('\u006c')
s[4] = 'o' ('\u006f')
```

Each character is represented by a single `char` value. That pattern holds true for most of the world's languages. For example, here's the output for two Chinese characters that sound like *nǐ hǎo* and mean *Hello*:

C#

```
PrintChars("你好");
```

Output

```
"你好".Length = 2
s[0] = '你' ('\u4f60')
s[1] = '好' ('\u597d')
```

However, for some languages and for some symbols and emoji, it takes two `char` instances to represent a single character. For example, compare the characters and `char` instances in the word that means *Osage* in the Osage language:

C#

```
PrintChars("ଓସାଜେ ଓସାଜେ");
```

Output

```
"ଓସାଜେ ଓସାଜେ".Length = 17
s[0] = 'ଡ' ('\ud801')
s[1] = 'ଡ' ('\udccf')
s[2] = 'ଡ' ('\ud801')
s[3] = 'ଡ' ('\udcd8')
s[4] = 'ଡ' ('\ud801')
s[5] = 'ଡ' ('\udcfb')
s[6] = 'ଡ' ('\ud801')
s[7] = 'ଡ' ('\udcd8')
s[8] = 'ଡ' ('\ud801')
s[9] = 'ଡ' ('\udcfb')
s[10] = 'ଡ' ('\ud801')
s[11] = 'ଡ' ('\udcdf')
s[12] = ' ' ('\u0020')
s[13] = 'ଡ' ('\ud801')
s[14] = 'ଡ' ('\udcbb')
```

```
s[15] = '߻' ('\\ud801')
s[16] = '߻' ('\\udcdf')
```

In the preceding example, each character except the space is represented by two `char` instances.

A single Unicode emoji is also represented by two `char`s, as seen in the following example showing an ox emoji:

Output

```
"🐂".Length = 2
s[0] = '߻' ('\\ud83d')
s[1] = '߻' ('\\udc02')
```

These examples show that the value of `string.Length`, which indicates the number of `char` instances, doesn't necessarily indicate the number of displayed characters. A single `char` instance by itself doesn't necessarily represent a character.

The `char` pairs that map to a single character are called *surrogate pairs*. To understand how they work, you need to understand Unicode and UTF-16 encoding.

Unicode code points

Unicode is an international encoding standard for use on various platforms and with various languages and scripts.

The Unicode Standard defines over 1.1 million [code points](#). A code point is an integer value that can range from 0 to `U+10FFFF` (decimal 1,114,111). Some code points are assigned to letters, symbols, or emoji. Others are assigned to actions that control how text or characters are displayed, such as advance to a new line. Many code points are not yet assigned.

Here are some examples of code point assignments, with links to Unicode charts in which they appear:

| Decimal | Hex | Example | Description |
|---------|---------------------|---------|--|
| 10 | <code>U+000A</code> | N/A | LINE FEED |
| 97 | <code>U+0061</code> | a | LATIN SMALL LETTER A |
| 562 | <code>U+0232</code> | Ŷ | LATIN CAPITAL LETTER Y WITH MACRON |

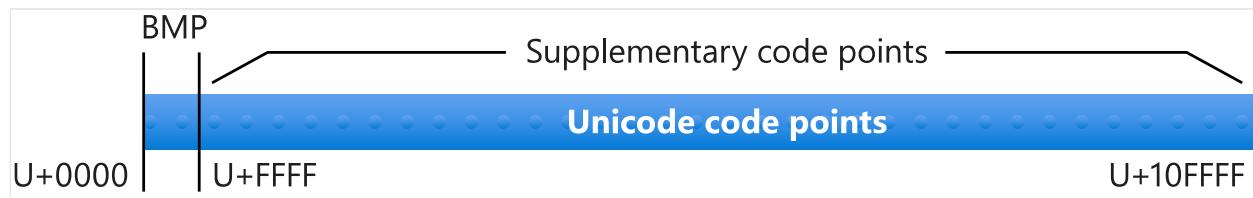

| Decimal | Hex | Example | Description |
|---------|---------|---------|-------------------------------|
| 68,675 | U+10C43 | ꝧ | OLD TURKIC LETTER ORKHON AT ↗ |
| 127,801 | U+1F339 | 🌹 | ROSE emoji ↗ |

Code points are customarily referred to by using the syntax `U+xxxx`, where `xxxx` is the hex-encoded integer value.

Within the full range of code points there are two subranges:

- The **Basic Multilingual Plane (BMP)** in the range `U+0000..U+FFFF`. This 16-bit range provides 65,536 code points, enough to cover the majority of the world's writing systems.
- **Supplementary code points** in the range `U+10000..U+10FFFF`. This 21-bit range provides more than a million additional code points that can be used for less well-known languages and other purposes such as emojis.

The following diagram illustrates the relationship between the BMP and the supplementary code points.

UTF-16 code units

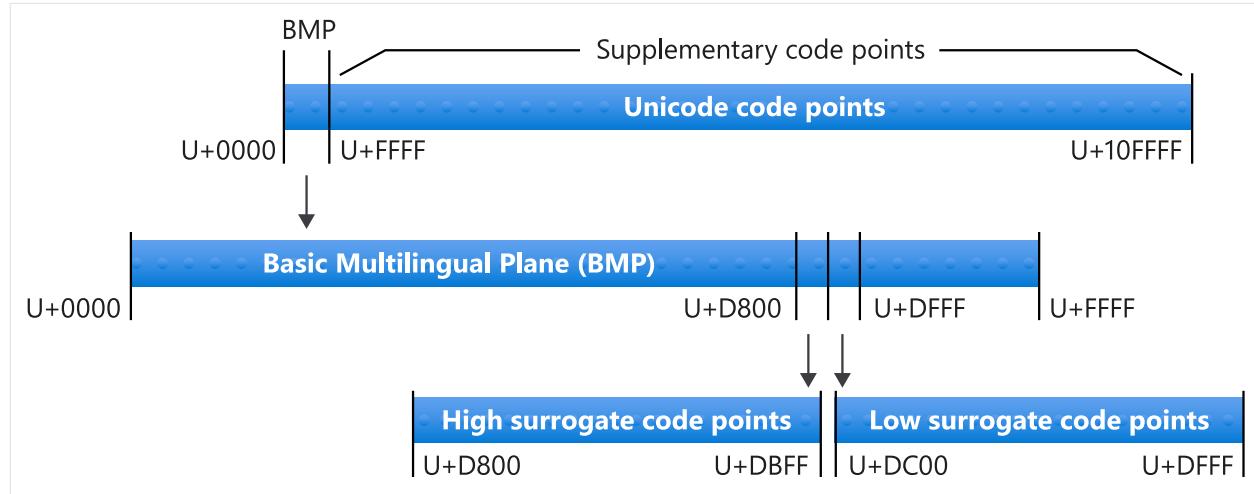

16-bit Unicode Transformation Format ([UTF-16](#)) is a character encoding system that uses 16-bit *code units* to represent Unicode code points. .NET uses UTF-16 to encode the text in a `string`. A `char` instance represents a 16-bit code unit.

A single 16-bit code unit can represent any code point in the 16-bit range of the Basic Multilingual Plane. But for a code point in the supplementary range, two `char` instances are needed.

Surrogate pairs

The translation of two 16-bit values to a single 21-bit value is facilitated by a special range called the *surrogate code points*, from `U+D800` to `U+DFFF` (decimal 55,296 to 57,343), inclusive.

The following diagram illustrates the relationship between the BMP and the surrogate code points.

When a *high surrogate* code point (U+D800..U+DBFF) is immediately followed by a *low surrogate* code point (U+DC00..U+DFFF), the pair is interpreted as a supplementary code point by using the following formula:

```
code point = 0x10000 +
    ((high surrogate code point - 0xD800) * 0x0400) +
    (low surrogate code point - 0xDC00)
```

Here's the same formula using decimal notation:

```
code point = 65,536 +
    ((high surrogate code point - 55,296) * 1,024) +
    (low surrogate code point - 56,320)
```

A *high surrogate* code point doesn't have a higher number value than a *low surrogate* code point. The high surrogate code point is called "high" because it's used to calculate the higher-order 10 bits of a 20-bit code point range. The low surrogate code point is used to calculate the lower-order 10 bits.

For example, the actual code point that corresponds to the surrogate pair `0xD83C` and `0xDF39` is computed as follows:

```
actual = 0x10000 + ((0xD83C - 0xD800) * 0x0400) + (0xDF39 - 0xDC00)
        = 0x10000 + (0x003C * 0x0400) + 0x0339
```

```
= 0x10000 + 0xF000 + 0x0339  
= 0x1F339
```

Here's the same calculation using decimal notation:

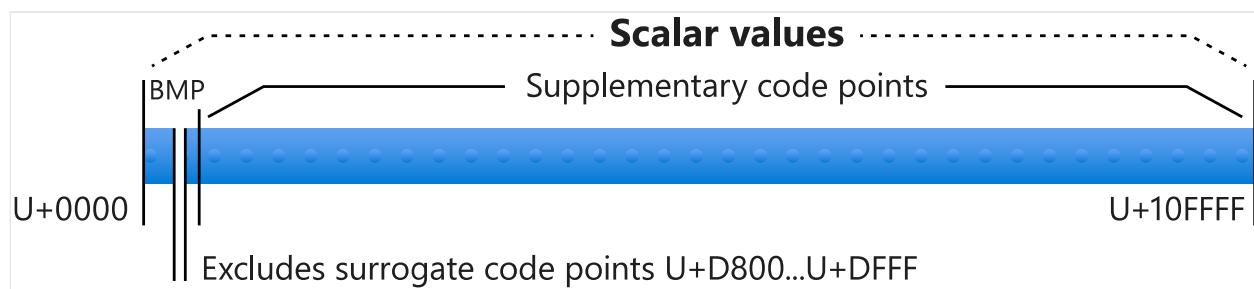

```
actual = 65,536 + ((55,356 - 55,296) * 1,024) + (57,145 - 56320)  
= 65,536 + (60 * 1,024) + 825  
= 65,536 + 61,440 + 825  
= 127,801
```

The preceding example demonstrates that `"\ud83c\udf39"` is the UTF-16 encoding of the `U+1F339 ROSE ('🌹')` code point mentioned earlier.

Unicode scalar values

The term [Unicode scalar value](#) refers to all code points other than the surrogate code points. In other words, a scalar value is any code point that is assigned a character or can be assigned a character in the future. "Character" here refers to anything that can be assigned to a code point, which includes such things as actions that control how text or characters are displayed.

The following diagram illustrates the scalar value code points.

The Rune type as a scalar value

Beginning with .NET Core 3.0, the `System.Text.Rune` type represents a Unicode scalar value. `Rune` is not available in .NET Core 2.x or .NET Framework 4.x.

The `Rune` constructors validate that the resulting instance is a valid Unicode scalar value, otherwise they throw an exception. The following example shows code that successfully instantiates `Rune` instances because the input represents valid scalar values:

```
C#
```

```
Rune a = new Rune('a');
Rune b = new Rune(0x0061);
Rune c = new Rune('\u0061');
Rune d = new Rune(0x10421);
Rune e = new Rune('\ud801', '\udc21');
```

The following example throws an exception because the code point is in the surrogate range and isn't part of a surrogate pair:

C#

```
Rune f = new Rune('\ud801');
```

The following example throws an exception because the code point is beyond the supplementary range:

C#

```
Rune g = new Rune(0x12345678);
```

Rune usage example: changing letter case

An API that takes a `char` and assumes it is working with a code point that is a scalar value doesn't work correctly if the `char` is from a surrogate pair. For example, consider the following method that calls `Char.ToUpperInvariant` on each char in a string:

C#

```
// THE FOLLOWING METHOD SHOWS INCORRECT CODE.
// DO NOT DO THIS IN A PRODUCTION APPLICATION.
static string ConvertToUpperBadExample(string input)
{
    StringBuilder builder = new StringBuilder(input.Length);
    for (int i = 0; i < input.Length; i++) /* or 'foreach' */
    {
        builder.Append(char.ToUpperInvariant(input[i]));
    }
    return builder.ToString();
}
```

If the `input` string contains the lowercase Deseret letter `er` (⊛), this code won't convert it to uppercase (⊛). The code calls `char.ToUpperInvariant` separately on each surrogate code point, `U+D801` and `U+DC49`. But `U+D801` doesn't have enough information by itself to identify it as a lowercase letter, so `char.ToUpperInvariant` leaves it alone. And it

handles `U+DC49` the same way. The result is that lowercase 'ɸ' in the `input` string doesn't get converted to uppercase 'Φ'.

Here are two options for correctly converting a string to uppercase:

- Call [String.ToUpperInvariant](#) on the input string rather than iterating `char`-by-`char`. The `string.ToUpperInvariant` method has access to both parts of each surrogate pair, so it can handle all Unicode code points correctly.
- Iterate through the Unicode scalar values as `Rune` instances instead of `char` instances, as shown in the following example. Since a `Rune` instance is a valid Unicode scalar value, it can be passed to APIs that expect to operate on a scalar value. For example, calling [Rune.ToUpperInvariant](#) as shown in the following example gives correct results:

C#

```
static string ConvertToUpper(string input)
{
    StringBuilder builder = new StringBuilder(input.Length);
    foreach (Rune rune in input.EnumerateRunes())
    {
        builder.Append(Rune.ToUpperInvariant(rune));
    }
    return builder.ToString();
}
```

Other Rune APIs

The `Rune` type exposes analogs of many of the `char` APIs. For example, the following methods mirror static APIs on the `char` type:

- [Rune.IsLetter](#)
- [Rune.IsWhiteSpace](#)
- [Rune.IsLetterOrDigit](#)
- [Rune.GetUnicodeCategory](#)

To get the raw scalar value from a `Rune` instance, use the [Rune.Value](#) property.

To convert a `Rune` instance back to a sequence of `char`s, use [Rune.ToString](#) or the [Rune.EncodeToUtf16](#) method.

Since any Unicode scalar value is representable by a single `char` or by a surrogate pair, any `Rune` instance can be represented by at most 2 `char` instances. Use

`Rune.Utf16SequenceLength` to see how many `char` instances are required to represent a `Rune` instance.

For more information about the .NET `Rune` type, see the [Rune API reference](#).

Grapheme clusters

What looks like one character might result from a combination of multiple code points, so a more descriptive term that is often used in place of "character" is [grapheme cluster](#). The equivalent term in .NET is [text element](#).

Consider the `string` instances "a", "á", "á", and "". If your operating system handles them as specified by the Unicode standard, each of these `string` instances appears as a single text element or grapheme cluster. But the last two are represented by more than one scalar value code point.

- The string "a" is represented by one scalar value and contains one `char` instance.
 - `U+0061 LATIN SMALL LETTER A`
- The string "á" is represented by one scalar value and contains one `char` instance.
 - `U+00E1 LATIN SMALL LETTER A WITH ACUTE`
- The string "á" looks the same as "á" but is represented by two scalar values and contains two `char` instances.
 - `U+0061 LATIN SMALL LETTER A`
 - `U+0301 COMBINING ACUTE ACCENT`
- Finally, the string "" is represented by four scalar values and contains seven `char` instances.
 - `U+1F469 WOMAN` (supplementary range, requires a surrogate pair)
 - `U+1F3FD EMOJI MODIFIER FITZPATRICK TYPE-4` (supplementary range, requires a surrogate pair)
 - `U+200D ZERO WIDTH JOINER`
 - `U+1F692 FIRE ENGINE` (supplementary range, requires a surrogate pair)

In some of the preceding examples - such as the combining accent modifier or the skin tone modifier - the code point does not display as a standalone element on the screen. Rather, it serves to modify the appearance of a text element that came before it. These examples show that it might take multiple scalar values to make up what we think of as a single "character," or "grapheme cluster."

To enumerate the grapheme clusters of a `string`, use the `StringInfo` class as shown in the following example. If you're familiar with Swift, the .NET `StringInfo` type is conceptually similar to Swift's `character type` ↗.

Example: count char, Rune, and text element instances

In .NET APIs, a grapheme cluster is called a *text element*. The following method demonstrates the differences between `char`, `Rune`, and text element instances in a `string`:

C#

```
static void PrintTextElementCount(string s)
{
    Console.WriteLine(s);
    Console.WriteLine($"Number of chars: {s.Length}");
    Console.WriteLine($"Number of runes: {s.EnumerateRunes().Count()}");

    TextElementEnumerator enumerator =
StringInfo.GetTextElementEnumerator(s);

    int textElementCount = 0;
    while (enumerator.MoveNext())
    {
        textElementCount++;
    }

    Console.WriteLine($"Number of text elements: {textElementCount}");
}
```

C#

```
PrintTextElementCount("a");
// Number of chars: 1
// Number of runes: 1
// Number of text elements: 1

PrintTextElementCount("á");
// Number of chars: 2
// Number of runes: 2
// Number of text elements: 1

PrintTextElementCount("𠮷𠮶𠮶");
// Number of chars: 7
// Number of runes: 4
// Number of text elements: 1
```

If you run this code in .NET Framework or .NET Core 3.1 or earlier, the text element count for the emoji shows 4. That is due to a bug in the `StringInfo` class that is fixed in .NET 5.

Example: splitting string instances

When splitting `string` instances, avoid splitting surrogate pairs and grapheme clusters. Consider the following example of incorrect code, which intends to insert line breaks every 10 characters in a string:

C#

```
// THE FOLLOWING METHOD SHOWS INCORRECT CODE.  
// DO NOT DO THIS IN A PRODUCTION APPLICATION.  
static string InsertNewlinesEveryTencharsBadExample(string input)  
{  
    StringBuilder builder = new StringBuilder();  
  
    // First, append chunks in multiples of 10 chars  
    // followed by a newline.  
    int i = 0;  
    for (; i < input.Length - 10; i += 10)  
    {  
        builder.Append(input, i, 10);  
        builder.AppendLine(); // newline  
    }  
  
    // Then append any leftover data followed by  
    // a final newline.  
    builder.Append(input, i, input.Length - i);  
    builder.AppendLine(); // newline  
  
    return builder.ToString();  
}
```

Because this code enumerates `char` instances, a surrogate pair that happens to straddle a 10-`char` boundary will be split and a newline injected between them. This insertion introduces data corruption, because surrogate code points are meaningful only as pairs.

The potential for data corruption isn't eliminated if you enumerate `Rune` instances (scalar values) instead of `char` instances. A set of `Rune` instances might make up a grapheme cluster that straddles a 10-`char` boundary. If the grapheme cluster set is split up, it can't be interpreted correctly.

A better approach is to break the string by counting grapheme clusters, or text elements, as in the following example:

C#

```
static string InsertNewlinesEveryTenTextElements(string input)
{
    StringBuilder builder = new StringBuilder();

    // Append chunks in multiples of 10 chars

    TextElementEnumerator enumerator =
    StringInfo.GetTextElementEnumerator(input);

    int textElementCount = 1;
    while (enumerator.MoveNext())
    {
        builder.Append(enumerator.Current);
        if (textElementCount % 10 == 0 && textElementCount > 0)
        {
            builder.AppendLine(); // newline
        }
        textElementCount++;
    }

    // Add a final newline.
    builder.AppendLine(); // newline
    return builder.ToString();
}
```

As noted earlier, prior to .NET 5, the `StringInfo` class had a bug causing some grapheme clusters to be handled incorrectly.

UTF-8 and UTF-32

The preceding sections focused on UTF-16 because that's what .NET uses to encode `string` instances. There are other encoding systems for Unicode - [UTF-8 ↗](#) and [UTF-32 ↗](#). These encodings use 8-bit code units and 32-bit code units, respectively.

Like UTF-16, UTF-8 requires multiple code units to represent some Unicode scalar values. UTF-32 can represent any scalar value in a single 32-bit code unit.

Here are some examples showing how the same Unicode code point is represented in each of these three Unicode encoding systems:

| | |
|---|---------------------------------------|
| Scalar: U+0061 LATIN SMALL LETTER A ('a') | |
| UTF-8 : [61] | (1x 8-bit code unit = 8 bits total) |
| UTF-16: [0061] | (1x 16-bit code unit = 16 bits total) |

```
UTF-32: [ 00000061 ]      (1x 32-bit code unit = 32 bits total)

Scalar: U+0429 CYRILLIC CAPITAL LETTER SHCHA ('Щ')
UTF-8 : [ D0 A9 ]          (2x 8-bit code units = 16 bits total)
UTF-16: [ 0429 ]           (1x 16-bit code unit = 16 bits total)
UTF-32: [ 00000429 ]       (1x 32-bit code unit = 32 bits total)

Scalar: U+A992 JAVANESE LETTER GA ('া')
UTF-8 : [ EA A6 92 ]       (3x 8-bit code units = 24 bits total)
UTF-16: [ A992 ]           (1x 16-bit code unit = 16 bits total)
UTF-32: [ 0000A992 ]       (1x 32-bit code unit = 32 bits total)

Scalar: U+104CC OSAGE CAPITAL LETTER TSHA ('ଡ')
UTF-8 : [ F0 90 93 8C ]    (4x 8-bit code units = 32 bits total)
UTF-16: [ D801 DCCC ]      (2x 16-bit code units = 32 bits total)
UTF-32: [ 000104CC ]       (1x 32-bit code unit = 32 bits total)
```

As noted earlier, a single UTF-16 code unit from a [surrogate pair](#) is meaningless by itself. In the same way, a single UTF-8 code unit is meaningless by itself if it's in a sequence of two, three, or four used to calculate a scalar value.

ⓘ Note

Beginning with C# 11, you can represent UTF-8 string literals using the "u8" suffix on a literal string. For more information on UTF-8 string literals, see the "string literals" section of the article on [built in reference types](#) in the C# Guide.

Endianness

In .NET, the UTF-16 code units of a string are stored in contiguous memory as a sequence of 16-bit integers (`char` instances). The bits of individual code units are laid out according to the [endianness](#) of the current architecture.

On a little-endian architecture, the string consisting of the UTF-16 code points `[D801 DCCC]` would be laid out in memory as the bytes `[0x01, 0xD8, 0xCC, 0xDC]`. On a big-endian architecture that same string would be laid out in memory as the bytes `[0x01, 0xDC, 0xCC]`.

Computer systems that communicate with each other must agree on the representation of data crossing the wire. Most network protocols use UTF-8 as a standard when transmitting text, partly to avoid issues that might result from a big-endian machine communicating with a little-endian machine. The string consisting of the UTF-8 code points `[F0 90 93 8C]` will always be represented as the bytes `[0xF0, 0x90, 0x93, 0x8C]` regardless of endianness.

To use UTF-8 for transmitting text, .NET applications often use code like the following example:

```
C#
```

```
string stringToWrite = GetString();
byte[] stringAsUtf8Bytes = Encoding.UTF8.GetBytes(stringToWrite);
await outputStream.WriteAsync(stringAsUtf8Bytes, 0,
stringAsUtf8Bytes.Length);
```

In the preceding example, the method `Encoding.UTF8.GetBytes` decodes the UTF-16 `string` back into a series of Unicode scalar values, then it re-encodes those scalar values into UTF-8 and places the resulting sequence into a `byte` array. The method `Encoding.UTF8.GetString` performs the opposite transformation, converting a UTF-8 `byte` array to a UTF-16 `string`.

⚠ Warning

Since UTF-8 is commonplace on the internet, it may be tempting to read raw bytes from the wire and to treat the data as if it were UTF-8. However, you should validate that it is indeed well-formed. A malicious client might submit ill-formed UTF-8 to your service. If you operate on that data as if it were well-formed, it could cause errors or security holes in your application. To validate UTF-8 data, you can use a method like `Encoding.UTF8.GetString`, which will perform validation while converting the incoming data to a `string`.

Well-formed encoding

A well-formed Unicode encoding is a string of code units that can be decoded unambiguously and without error into a sequence of Unicode scalar values. Well-formed data can be transcoded freely back and forth between UTF-8, UTF-16, and UTF-32.

The question of whether an encoding sequence is well-formed or not is unrelated to the endianness of a machine's architecture. An ill-formed UTF-8 sequence is ill-formed in the same way on both big-endian and little-endian machines.

Here are some examples of ill-formed encodings:

- In UTF-8, the sequence `[6C C2 61]` is ill-formed because `C2` cannot be followed by `61`.

- In UTF-16, the sequence [DC00 DD00] (or, in C#, the string "\udc00\udd00") is ill-formed because the low surrogate DC00 cannot be followed by another low surrogate DD00.
- In UTF-32, the sequence [0011ABCD] is ill-formed because 0011ABCD is outside the range of Unicode scalar values.

In .NET, `string` instances almost always contain well-formed UTF-16 data, but that isn't guaranteed. The following examples show valid C# code that creates ill-formed UTF-16 data in `string` instances.

- An ill-formed literal:

```
C#
```

```
const string s = "\ud800";
```

- A substring that splits up a surrogate pair:

```
C#
```

```
string x = "\ud83e\udd70"; // "𩿱"
string y = x.Substring(1, 1); // "\udd70" standalone low surrogate
```

APIs like `Encoding.UTF8.GetString` never return ill-formed `string` instances.

`Encoding.GetString` and `Encoding.GetBytes` methods detect ill-formed sequences in the input and perform character substitution when generating the output. For example, if `Encoding.ASCII.GetString(byte[])` sees a non-ASCII byte in the input (outside the range U+0000..U+007F), it inserts a '?' into the returned `string` instance.

`Encoding.UTF8.GetString(byte[])` replaces ill-formed UTF-8 sequences with `U+FFFD` REPLACEMENT CHARACTER ('ߏ') in the returned `string` instance. For more information, see the [Unicode Standard](#), Sections 5.22 and 3.9.

The built-in `Encoding` classes can also be configured to throw an exception rather than perform character substitution when ill-formed sequences are seen. This approach is often used in security-sensitive applications where character substitution might not be acceptable.

```
C#
```

```
byte[] utf8Bytes = ReadFromNetwork();
UTF8Encoding encoding = new UTF8Encoding(encoderShouldEmitUTF8Identifier:
    false, throwOnInvalidBytes: true);
```

```
string asString = encoding.GetString(utf8Bytes); // will throw if  
'utf8Bytes' is ill-formed
```

For information about how to use the built-in `Encoding` classes, see [How to use character encoding classes in .NET](#).

How to use character encoding classes in .NET

Article • 09/15/2021

This article explains how to use the classes that .NET provides for encoding and decoding text by using various encoding schemes. The instructions assume you have read [Introduction to character encoding in .NET](#).

Encoders and decoders

.NET provides encoding classes that encode and decode text by using various encoding systems. For example, the [UTF8Encoding](#) class describes the rules for encoding to, and decoding from, UTF-8. .NET uses UTF-16 encoding (represented by the [UnicodeEncoding](#) class) for `string` instances. Encoders and decoders are available for other encoding schemes.

Encoding and decoding can also include validation. For example, the [UnicodeEncoding](#) class checks all `char` instances in the surrogate range to make sure they're in valid surrogate pairs. A fallback strategy determines how an encoder handles invalid characters or how a decoder handles invalid bytes.

Warning

.NET encoding classes provide a way to store and convert character data. They should not be used to store binary data in string form. Depending on the encoding used, converting binary data to string format with the encoding classes can introduce unexpected behavior and produce inaccurate or corrupted data. To convert binary data to a string form, use the [Convert.ToString](#) method.

All character encoding classes in .NET inherit from the [System.Text.Encoding](#) class, which is an abstract class that defines the functionality common to all character encodings. To access the individual encoding objects implemented in .NET, do the following:

- Use the static properties of the [Encoding](#) class, which return objects that represent the standard character encodings available in .NET (ASCII, UTF-7, UTF-8, UTF-16, and UTF-32). For example, the [Encoding.Unicode](#) property returns a [UnicodeEncoding](#) object. Each object uses replacement fallback to handle strings that it cannot encode and bytes that it cannot decode. For more information, see [Replacement fallback](#).

- Call the encoding's class constructor. Objects for the ASCII, UTF-7, UTF-8, UTF-16, and UTF-32 encodings can be instantiated in this way. By default, each object uses replacement fallback to handle strings that it cannot encode and bytes that it cannot decode, but you can specify that an exception should be thrown instead. For more information, see [Replacement fallback](#) and [Exception fallback](#).
- Call the [Encoding\(Int32\)](#) constructor and pass it an integer that represents the encoding. Standard encoding objects use replacement fallback, and code page and double-byte character set (DBCS) encoding objects use best-fit fallback to handle strings that they cannot encode and bytes that they cannot decode. For more information, see [Best-fit fallback](#).
- Call the [Encoding.GetEncoding](#) method, which returns any standard, code page, or DBCS encoding available in .NET. Overloads let you specify a fallback object for both the encoder and the decoder.

You can retrieve information about all the encodings available in .NET by calling the [Encoding.GetEncodings](#) method. .NET supports the character encoding schemes listed in the following table.

| Encoding class | Description |
|------------------------|---|
| ASCII | Encodes a limited range of characters by using the lower seven bits of a byte. Because this encoding only supports character values from <code>U+0000</code> through <code>U+007F</code> , in most cases it is inadequate for internationalized applications. |
| UTF-7 | Represents characters as sequences of 7-bit ASCII characters. Non-ASCII Unicode characters are represented by an escape sequence of ASCII characters. UTF-7 supports protocols such as email and newsgroup. However, UTF-7 is not particularly secure or robust. In some cases, changing one bit can radically alter the interpretation of an entire UTF-7 string. In other cases, different UTF-7 strings can encode the same text. For sequences that include non-ASCII characters, UTF-7 requires more space than UTF-8, and encoding/decoding is slower. Consequently, you should use UTF-8 instead of UTF-7 if possible. |
| UTF-8 | Represents each Unicode code point as a sequence of one to four bytes. UTF-8 supports 8-bit data sizes and works well with many existing operating systems. For the ASCII range of characters, UTF-8 is identical to ASCII encoding and allows a broader set of characters. However, for Chinese-Japanese-Korean (CJK) scripts, UTF-8 can require three bytes for each character, and can cause larger data sizes than UTF-16. Sometimes the amount of ASCII data, such as HTML tags, justifies the increased size for the CJK range. |
| UTF-16 | Represents each Unicode code point as a sequence of one or two 16-bit integers. Most common Unicode characters require only one UTF-16 code point, although Unicode supplementary characters (<code>U+10000</code> and greater) require two UTF-16 |

| Encoding class | Description |
|--|---|
| | surrogate code points. Both little-endian and big-endian byte orders are supported. UTF-16 encoding is used by the common language runtime to represent Char and String values, and it is used by the Windows operating system to represent WCHAR values. |
| UTF-32 | Represents each Unicode code point as a 32-bit integer. Both little-endian and big-endian byte orders are supported. UTF-32 encoding is used when applications want to avoid the surrogate code point behavior of UTF-16 encoding on operating systems for which encoded space is too important. Single glyphs rendered on a display can still be encoded with more than one UTF-32 character. |
| ANSI/ISO encoding | Provides support for a variety of code pages. On Windows operating systems, code pages are used to support a specific language or group of languages. For a table that lists the code pages supported by .NET, see the Encoding class. You can retrieve an encoding object for a particular code page by calling the Encoding.GetEncoding(Int32) method. A code page contains 256 code points and is zero-based. In most code pages, code points 0 through 127 represent the ASCII character set, and code points 128 through 255 differ significantly between code pages. For example, code page 1252 provides the characters for Latin writing systems, including English, German, and French. The last 128 code points in code page 1252 contain the accent characters. Code page 1253 provides character codes that are required in the Greek writing system. The last 128 code points in code page 1253 contain the Greek characters. As a result, an application that relies on ANSI code pages cannot store Greek and German in the same text stream unless it includes an identifier that indicates the referenced code page. |
| Double-byte character set (DBCS) encodings | Supports languages, such as Chinese, Japanese, and Korean, that contain more than 256 characters. In a DBCS, a pair of code points (a double byte) represents each character. The Encoding.IsSingleByte property returns <code>false</code> for DBCS encodings. You can retrieve an encoding object for a particular DBCS by calling the Encoding.GetEncoding(Int32) method. When an application handles DBCS data, the first byte of a DBCS character (the lead byte) is processed in combination with the trail byte that immediately follows it. Because a single pair of double-byte code points can represent different characters depending on the code page, this scheme still does not allow for the combination of two languages, such as Japanese and Chinese, in the same data stream. |

These encodings enable you to work with Unicode characters as well as with encodings that are most commonly used in legacy applications. In addition, you can create a custom encoding by defining a class that derives from [Encoding](#) and overriding its members.

.NET Core encoding support

By default, .NET Core does not make available any code page encodings other than code page 28591 and the Unicode encodings, such as UTF-8 and UTF-16. However, you can add the code page encodings found in standard Windows apps that target .NET to your app. For more information, see the [CodePagesEncodingProvider](#) topic.

Selecting an Encoding Class

If you have the opportunity to choose the encoding to be used by your application, you should use a Unicode encoding, preferably either [UTF8Encoding](#) or [UnicodeEncoding](#). (.NET also supports a third Unicode encoding, [UTF32Encoding](#).)

If you are planning to use an ASCII encoding ([ASCIIEncoding](#)), choose [UTF8Encoding](#) instead. The two encodings are identical for the ASCII character set, but [UTF8Encoding](#) has the following advantages:

- It can represent every Unicode character, whereas [ASCIIEncoding](#) supports only the Unicode character values between U+0000 and U+007F.
- It provides error detection and better security.
- It has been tuned to be as fast as possible and should be faster than any other encoding. Even for content that is entirely ASCII, operations performed with [UTF8Encoding](#) are faster than operations performed with [ASCIIEncoding](#).

You should consider using [ASCIIEncoding](#) only for legacy applications. However, even for legacy applications, [UTF8Encoding](#) might be a better choice for the following reasons (assuming default settings):

- If your application has content that is not strictly ASCII and encodes it with [ASCIIEncoding](#), each non-ASCII character encodes as a question mark (?). If the application then decodes this data, the information is lost.
- If your application has content that is not strictly ASCII and encodes it with [UTF8Encoding](#), the result seems unintelligible if interpreted as ASCII. However, if the application then uses a UTF-8 decoder to decode this data, the data performs a round trip successfully.

In a web application, characters sent to the client in response to a web request should reflect the encoding used on the client. In most cases, you should set the [HttpResponse.ContentEncoding](#) property to the value returned by the [HttpRequest.ContentEncoding](#) property to display text in the encoding that the user expects.

Using an Encoding Object

An encoder converts a string of characters (most commonly, Unicode characters) to its numeric (byte) equivalent. For example, you might use an ASCII encoder to convert Unicode characters to ASCII so that they can be displayed at the console. To perform the conversion, you call the [Encoding.GetBytes](#) method. If you want to determine how many bytes are needed to store the encoded characters before performing the encoding, you can call the [GetByteCount](#) method.

The following example uses a single byte array to encode strings in two separate operations. It maintains an index that indicates the starting position in the byte array for the next set of ASCII-encoded bytes. It calls the [ASCIIEncoding.GetByteCount\(String\)](#) method to ensure that the byte array is large enough to accommodate the encoded string. It then calls the [ASCIIEncoding.GetBytes\(String, Int32, Int32, Byte\[\], Int32\)](#) method to encode the characters in the string.

C#

```
using System;
using System.Text;

public class Example
{
    public static void Main()
    {
        string[] strings= { "This is the first sentence. ",
                           "This is the second sentence. " };
        Encoding asciiEncoding = Encoding.ASCII;

        // Create array of adequate size.
        byte[] bytes = new byte[49];
        // Create index for current position of array.
        int index = 0;

        Console.WriteLine("Strings to encode:");
        foreach (var stringValue in strings) {
            Console.WriteLine("  {0}", stringValue);

            int count = asciiEncoding.GetByteCount(stringValue);
            if (count + index >= bytes.Length)
                Array.Resize(ref bytes, bytes.Length + 50);

            int written = asciiEncoding.GetBytes(stringValue, 0,
                                                 stringValue.Length,
                                                 bytes, index);

            index = index + written;
        }
        Console.WriteLine("\nEncoded bytes:");
    }
}
```

```

        Console.WriteLine("{0}", ShowByteValues(bytes, index));
        Console.WriteLine();

        // Decode Unicode byte array to a string.
        string newString = asciiEncoding.GetString(bytes, 0, index);
        Console.WriteLine("Decoded: {0}", newString);
    }

    private static string ShowByteValues(byte[] bytes, int last )
    {
        string returnString = "    ";
        for (int ctr = 0; ctr <= last - 1; ctr++) {
            if (ctr % 20 == 0)
                returnString += "\n    ";
            returnString += String.Format("{0:X2} ", bytes[ctr]);
        }
        return returnString;
    }
}

// The example displays the following output:
//      Strings to encode:
//          This is the first sentence.
//          This is the second sentence.
//
//      Encoded bytes:
//
//          54 68 69 73 20 69 73 20 74 68 65 20 66 69 72 73 74 20 73 65
//          6E 74 65 6E 63 65 2E 20 54 68 69 73 20 69 73 20 74 68 65 20
//          73 65 63 6F 6E 64 20 73 65 6E 74 65 6E 63 65 2E 20
//
//      Decoded: This is the first sentence. This is the second sentence.

```

A decoder converts a byte array that reflects a particular character encoding into a set of characters, either in a character array or in a string. To decode a byte array into a character array, you call the [Encoding.GetChars](#) method. To decode a byte array into a string, you call the [GetString](#) method. If you want to determine how many characters are needed to store the decoded bytes before performing the decoding, you can call the [GetCharCount](#) method.

The following example encodes three strings and then decodes them into a single array of characters. It maintains an index that indicates the starting position in the character array for the next set of decoded characters. It calls the [GetCharCount](#) method to ensure that the character array is large enough to accommodate all the decoded characters. It then calls the [ASCIIEncoding.GetChars\(Byte\[\], Int32, Int32, Char\[\], Int32\)](#) method to decode the byte array.

C#

```

using System;
using System.Text;

```

```
public class Example
{
    public static void Main()
    {
        string[] strings = { "This is the first sentence. ",
                            "This is the second sentence. ",
                            "This is the third sentence. " };
        Encoding asciiEncoding = Encoding.ASCII;
        // Array to hold encoded bytes.
        byte[] bytes;
        // Array to hold decoded characters.
        char[] chars = new char[50];
        // Create index for current position of character array.
        int index = 0;

        foreach (var stringValue in strings) {
            Console.WriteLine("String to Encode: {0}", stringValue);
            // Encode the string to a byte array.
            bytes = asciiEncoding.GetBytes(stringValue);
            // Display the encoded bytes.
            Console.Write("Encoded bytes: ");
            for (int ctr = 0; ctr < bytes.Length; ctr++)
                Console.Write(" {0}{1:X2}",
                             ctr % 20 == 0 ? Environment.NewLine : "",
                             bytes[ctr]);
            Console.WriteLine();

            // Decode the bytes to a single character array.
            int count = asciiEncoding.GetCharCount(bytes);
            if (count + index >= chars.Length)
                Array.Resize(ref chars, chars.Length + 50);

            int written = asciiEncoding.GetChars(bytes, 0,
                                                 bytes.Length,
                                                 chars, index);
            index = index + written;
            Console.WriteLine();
        }

        // Instantiate a single string containing the characters.
        string decodedString = new string(chars, 0, index - 1);
        Console.WriteLine("Decoded string: ");
        Console.WriteLine(decodedString);
    }
}

// The example displays the following output:
// String to Encode: This is the first sentence.
// Encoded bytes:
// 54 68 69 73 20 69 73 20 74 68 65 20 66 69 72 73 74 20 73 65
// 6E 74 65 6E 63 65 2E 20
//
// String to Encode: This is the second sentence.
// Encoded bytes:
// 54 68 69 73 20 69 73 20 74 68 65 20 73 65 63 6F 6E 64 20 73
```

```
// 65 6E 74 65 6E 63 65 2E 20
//
// String to Encode: This is the third sentence.
// Encoded bytes:
// 54 68 69 73 20 69 73 20 74 68 65 20 74 68 69 72 64 20 73 65
// 6E 74 65 6E 63 65 2E 20
//
// Decoded string:
// This is the first sentence. This is the second sentence. This is the
third sentence.
```

The encoding and decoding methods of a class derived from [Encoding](#) are designed to work on a complete set of data; that is, all the data to be encoded or decoded is supplied in a single method call. However, in some cases, data is available in a stream, and the data to be encoded or decoded may be available only from separate read operations. This requires the encoding or decoding operation to remember any saved state from its previous invocation. Methods of classes derived from [Encoder](#) and [Decoder](#) are able to handle encoding and decoding operations that span multiple method calls.

An [Encoder](#) object for a particular encoding is available from that encoding's [Encoding.GetEncoder](#) property. A [Decoder](#) object for a particular encoding is available from that encoding's [Encoding.GetDecoder](#) property. For decoding operations, note that classes derived from [Decoder](#) include a [Decoder.GetChars](#) method, but they do not have a method that corresponds to [Encoding.GetString](#).

The following example illustrates the difference between using the [Encoding.GetString](#) and [Decoder.GetChars](#) methods for decoding a Unicode byte array. The example encodes a string that contains some Unicode characters to a file, and then uses the two decoding methods to decode them ten bytes at a time. Because a surrogate pair occurs in the tenth and eleventh bytes, it is decoded in separate method calls. As the output shows, the [Encoding.GetString](#) method is not able to correctly decode the bytes and instead replaces them with U+FFF (REPLACEMENT CHARACTER). On the other hand, the [Decoder.GetChars](#) method is able to successfully decode the byte array to get the original string.

C#

```
using System;
using System.IO;
using System.Text;

public class Example
{
    public static void Main()
    {
```

```

// Use default replacement fallback for invalid encoding.
UnicodeEncoding enc = new UnicodeEncoding(true, false, false);

// Define a string with various Unicode characters.
string str1 = "AB YZ 19 \uD800\udc05 \u00e4";
str1 += "Unicode characters. \u00a9 \u010C s \u0062\u0308";
Console.WriteLine("Created original string...\n");

// Convert string to byte array.
byte[] bytes = enc.GetBytes(str1);

FileStream fs = File.Create(@".\characters.bin");
BinaryWriter bw = new BinaryWriter(fs);
bw.Write(bytes);
bw.Close();

// Read bytes from file.
FileStream fsIn = File.OpenRead(@".\characters.bin");
BinaryReader br = new BinaryReader(fsIn);

const int count = 10;           // Number of bytes to read at a time.
byte[] bytesRead = new byte[10]; // Buffer (byte array).
int read;                     // Number of bytes actually read.
string str2 = String.Empty;    // Decoded string.

// Try using Encoding object for all operations.
do {
    read = br.Read(bytesRead, 0, count);
    str2 += enc.GetString(bytesRead, 0, read);
} while (read == count);
br.Close();
Console.WriteLine("Decoded string using
UnicodeEncoding.GetString()...\"");
CompareForEquality(str1, str2);
Console.WriteLine();

// Use Decoder for all operations.
fsIn = File.OpenRead(@".\characters.bin");
br = new BinaryReader(fsIn);
Decoder decoder = enc.GetDecoder();
char[] chars = new char[50];
int index = 0;                 // Next character to write in array.
int written = 0;               // Number of chars written to array.
do {
    read = br.Read(bytesRead, 0, count);
    if (index + decoder.GetCharCount(bytesRead, 0, read) - 1 >=
chars.Length)
        Array.Resize(ref chars, chars.Length + 50);

    written = decoder.GetChars(bytesRead, 0, read, chars, index);
    index += written;
} while (read == count);
br.Close();
// Instantiate a string with the decoded characters.
string str3 = new String(chars, 0, index);

```

```

        Console.WriteLine("Decoded string using
UnicodeEncoding.Decoder.GetString()...");
        CompareForEquality(str1, str3);
    }

private static void CompareForEquality(string original, string decoded)
{
    bool result = original.Equals(decoded);
    Console.WriteLine("original = decoded: {0}",
                      original.Equals(decoded, StringComparison.OrdinalIgnoreCase));
    if (!result) {
        Console.WriteLine("Code points in original string:");
        foreach (var ch in original)
            Console.Write("{0} ", Convert.ToInt16(ch).ToString("X4"));
        Console.WriteLine();

        Console.WriteLine("Code points in decoded string:");
        foreach (var ch in decoded)
            Console.Write("{0} ", Convert.ToInt16(ch).ToString("X4"));
        Console.WriteLine();
    }
}

// The example displays the following output:
//   Created original string...
//
//   Decoded string using UnicodeEncoding.GetString()...
//   original = decoded: False
//   Code points in original string:
//   0041 0042 0020 0059 005A 0020 0031 0039 0020 D800 DC05 0020 00E4 0055
006E 0069 0063 006F
//   0064 0065 0020 0063 0068 0061 0072 0061 0063 0074 0065 0072 0073 002E
0020 00A9 0020 010C
//   0020 0073 0020 0062 0308
//   Code points in decoded string:
//   0041 0042 0020 0059 005A 0020 0031 0039 0020 FFFD FFFD 0020 00E4 0055
006E 0069 0063 006F
//   0064 0065 0020 0063 0068 0061 0072 0061 0063 0074 0065 0072 0073 002E
0020 00A9 0020 010C
//   0020 0073 0020 0062 0308
//
//   Decoded string using UnicodeEncoding.Decoder.GetString()...
//   original = decoded: True

```

Choosing a Fallback Strategy

When a method tries to encode or decode a character but no mapping exists, it must implement a fallback strategy that determines how the failed mapping should be handled. There are three types of fallback strategies:

- Best-fit fallback

- Replacement fallback
- Exception fallback

ⓘ Important

The most common problems in encoding operations occur when a Unicode character cannot be mapped to a particular code page encoding. The most common problems in decoding operations occur when invalid byte sequences cannot be translated into valid Unicode characters. For these reasons, you should know which fallback strategy a particular encoding object uses. Whenever possible, you should specify the fallback strategy used by an encoding object when you instantiate the object.

Best-Fit Fallback

When a character does not have an exact match in the target encoding, the encoder can try to map it to a similar character. (Best-fit fallback is mostly an encoding rather than a decoding issue. There are very few code pages that contain characters that cannot be successfully mapped to Unicode.) Best-fit fallback is the default for code page and double-byte character set encodings that are retrieved by the [Encoding.GetEncoding\(Int32\)](#) and [Encoding.GetEncoding\(String\)](#) overloads.

ⓘ Note

In theory, the Unicode encoding classes provided in .NET ([UTF8Encoding](#), [UnicodeEncoding](#), and [UTF32Encoding](#)) support every character in every character set, so they can be used to eliminate best-fit fallback issues.

Best-fit strategies vary for different code pages. For example, for some code pages, full-width Latin characters map to the more common half-width Latin characters. For other code pages, this mapping is not made. Even under an aggressive best-fit strategy, there is no imaginable fit for some characters in some encodings. For example, a Chinese ideograph has no reasonable mapping to code page 1252. In this case, a replacement string is used. By default, this string is just a single QUESTION MARK (U+003F).

ⓘ Note

Best-fit strategies are not documented in detail. However, several code pages are documented at the [Unicode Consortium's](#) website. Please review the [readme.txt](#)

file in that folder for a description of how to interpret the mapping files.

The following example uses code page 1252 (the Windows code page for Western European languages) to illustrate best-fit mapping and its drawbacks. The [Encoding.GetEncoding\(Int32\)](#) method is used to retrieve an encoding object for code page 1252. By default, it uses a best-fit mapping for Unicode characters that it does not support. The example instantiates a string that contains three non-ASCII characters - CIRCLED LATIN CAPITAL LETTER S (U+24C8), SUPERSCRIPT FIVE (U+2075), and INFINITY (U+221E) - separated by spaces. As the output from the example shows, when the string is encoded, the three original non-space characters are replaced by QUESTION MARK (U+003F), DIGIT FIVE (U+0035), and DIGIT EIGHT (U+0038). DIGIT EIGHT is a particularly poor replacement for the unsupported INFINITY character, and QUESTION MARK indicates that no mapping was available for the original character.

C#

```
using System;
using System.Text;

public class Example
{
    public static void Main()
    {
        // Get an encoding for code page 1252 (Western Europe character set).
        Encoding cp1252 = Encoding.GetEncoding(1252);

        // Define and display a string.
        string str = "\u24c8 \u2075 \u221e";
        Console.WriteLine("Original string: " + str);
        Console.Write("Code points in string: ");
        foreach (var ch in str)
            Console.Write("{0} ", Convert.ToInt16(ch).ToString("X4"));

        Console.WriteLine("\n");

        // Encode a Unicode string.
        Byte[] bytes = cp1252.GetBytes(str);
        Console.Write("Encoded bytes: ");
        foreach (byte byt in bytes)
            Console.Write("{0:X2} ", byt);
        Console.WriteLine("\n");

        // Decode the string.
        string str2 = cp1252.GetString(bytes);
        Console.WriteLine("String round-tripped: {0}", str.Equals(str2));
        if (! str.Equals(str2)) {
            Console.WriteLine(str2);
            foreach (var ch in str2)
                Console.Write("{0} ", Convert.ToInt16(ch).ToString("X4"));
        }
    }
}
```

```
        }
    }

// The example displays the following output:
//     Original string: ® ² °
//     Code points in string: 24C8 0020 2075 0020 221E
//
//     Encoded bytes: 3F 20 35 20 38
//
//     String round-tripped: False
//     ? 5 8
//     003F 0020 0035 0020 0038
```

Best-fit mapping is the default behavior for an [Encoding](#) object that encodes Unicode data into code page data, and there are legacy applications that rely on this behavior. However, most new applications should avoid best-fit behavior for security reasons. For example, applications should not put a domain name through a best-fit encoding.

Note

You can also implement a custom best-fit fallback mapping for an encoding. For more information, see the [Implementing a Custom Fallback Strategy](#) section.

If best-fit fallback is the default for an encoding object, you can choose another fallback strategy when you retrieve an [Encoding](#) object by calling the [Encoding.GetEncoding\(Int32, EncoderFallback, DecoderFallback\)](#) or [Encoding.GetEncoding\(String, EncoderFallback, DecoderFallback\)](#) overload. The following section includes an example that replaces each character that cannot be mapped to code page 1252 with an asterisk (*).

C#

```
using System;
using System.Text;

public class Example
{
    public static void Main()
    {
        Encoding cp1252r = Encoding.GetEncoding(1252,
            new EncoderReplacementFallback("*"),
            new DecoderReplacementFallback("*"));

        string str1 = "\u24C8 \u2075 \u221E";
        Console.WriteLine(str1);
        foreach (var ch in str1)
            Console.Write("{0} ", Convert.ToInt16(ch).ToString("X4"));
```

```

        Console.WriteLine();

        byte[] bytes = cp1252r.GetBytes(str1);
        string str2 = cp1252r.GetString(bytes);
        Console.WriteLine("Round-trip: {0}", str1.Equals(str2));
        if (! str1.Equals(str2)) {
            Console.WriteLine(str2);
            foreach (var ch in str2)
                Console.Write("{0} ", Convert.ToInt16(ch).ToString("X4"));

            Console.WriteLine();
        }
    }
}

// The example displays the following output:
//      Ⓟ ॐ
//      24C8 0020 2075 0020 221E
//      Round-trip: False
//      * * *
//      002A 0020 002A 0020 002A

```

Replacement Fallback

When a character does not have an exact match in the target scheme, but there is no appropriate character that it can be mapped to, the application can specify a replacement character or string. This is the default behavior for the Unicode decoder, which replaces any two-byte sequence that it cannot decode with REPLACEMENT_CHARACTER (U+FFFD). It is also the default behavior of the [ASCIIEncoding](#) class, which replaces each character that it cannot encode or decode with a question mark. The following example illustrates character replacement for the Unicode string from the previous example. As the output shows, each character that cannot be decoded into an ASCII byte value is replaced by 0x3F, which is the ASCII code for a question mark.

C#

```

using System;
using System.Text;

public class Example
{
    public static void Main()
    {
        Encoding enc = Encoding.ASCII;

        string str1 = "\u24C8 \u2075 \u221E";
        Console.WriteLine(str1);
        foreach (var ch in str1)
            Console.Write("{0} ", Convert.ToInt16(ch).ToString("X4"));
    }
}

```

```
Console.WriteLine("\n");

// Encode the original string using the ASCII encoder.
byte[] bytes = enc.GetBytes(str1);
Console.Write("Encoded bytes: ");
foreach (var byt in bytes)
    Console.Write("{0:X2} ", byt);
Console.WriteLine("\n");

// Decode the ASCII bytes.
string str2 = enc.GetString(bytes);
Console.WriteLine("Round-trip: {0}", str1.Equals(str2));
if (! str1.Equals(str2)) {
    Console.WriteLine(str2);
    foreach (var ch in str2)
        Console.Write("{0} ", Convert.ToInt16(ch).ToString("X4"));

    Console.WriteLine();
}
}

}

// The example displays the following output:
//      ® ¤
//      24C8 0020 2075 0020 221E
//
//      Encoded bytes: 3F 20 3F 20 3F
//
//      Round-trip: False
//      ? ? ?
//
//      003F 0020 003F 0020 003F
```

.NET includes the [EncoderReplacementFallback](#) and [DecoderReplacementFallback](#) classes, which substitute a replacement string if a character does not map exactly in an encoding or decoding operation. By default, this replacement string is a question mark, but you can call a class constructor overload to choose a different string. Typically, the replacement string is a single character, although this is not a requirement. The following example changes the behavior of the code page 1252 encoder by instantiating an [EncoderReplacementFallback](#) object that uses an asterisk (*) as a replacement string.

C#

```
using System;
using System.Text;

public class Example
{
    public static void Main()
    {
        Encoding cp1252r = Encoding.GetEncoding(1252,
                                                new EncoderReplacementFallback("*"));
    }
}
```

```

        new DecoderReplacementFallback("*"));

    string str1 = "\u24C8 \u2075 \u221E";
    Console.WriteLine(str1);
    foreach (var ch in str1)
        Console.Write("{0} ", Convert.ToInt16(ch).ToString("X4"));

    Console.WriteLine();

    byte[] bytes = cp1252r.GetBytes(str1);
    string str2 = cp1252r.GetString(bytes);
    Console.WriteLine("Round-trip: {0}", str1.Equals(str2));
    if (!str1.Equals(str2)) {
        Console.WriteLine(str2);
        foreach (var ch in str2)
            Console.Write("{0} ", Convert.ToInt16(ch).ToString("X4"));

        Console.WriteLine();
    }
}
}

// The example displays the following output:
//      Ⓜ ጀ
//      24C8 0020 2075 0020 221E
//      Round-trip: False
//      * * *
//      002A 0020 002A 0020 002A

```

Note

You can also implement a replacement class for an encoding. For more information, see the [Implementing a Custom Fallback Strategy](#) section.

In addition to QUESTION MARK (U+003F), the Unicode REPLACEMENT CHARACTER (U+FFFD) is commonly used as a replacement string, particularly when decoding byte sequences that cannot be successfully translated into Unicode characters. However, you are free to choose any replacement string, and it can contain multiple characters.

Exception Fallback

Instead of providing a best-fit fallback or a replacement string, an encoder can throw an [EncoderFallbackException](#) if it is unable to encode a set of characters, and a decoder can throw a [DecoderFallbackException](#) if it is unable to decode a byte array. To throw an exception in encoding and decoding operations, you supply an [EncoderExceptionFallback](#) object and a [DecoderExceptionFallback](#) object, respectively, to

the `Encoding.GetEncoding(String, EncoderFallback, DecoderFallback)` method. The following example illustrates exception fallback with the `ASCIIEncoding` class.

C#

```
using System;
using System.Text;

public class Example
{
    public static void Main()
    {
        Encoding enc = Encoding.GetEncoding("us-ascii",
                                            new EncoderExceptionFallback(),
                                            new DecoderExceptionFallback());

        string str1 = "\u24C8 \u2075 \u221E";
        Console.WriteLine(str1);
        foreach (var ch in str1)
            Console.Write("{0} ", Convert.ToInt16(ch).ToString("X4"));

        Console.WriteLine("\n");

        // Encode the original string using the ASCII encoder.
        byte[] bytes = {};
        try {
            bytes = enc.GetBytes(str1);
            Console.Write("Encoded bytes: ");
            foreach (var byt in bytes)
                Console.Write("{0:X2} ", byt);

            Console.WriteLine();
        }
        catch (EncoderFallbackException e) {
            Console.Write("Exception: ");
            if (e.IsUnknownSurrogate())
                Console.WriteLine("Unable to encode surrogate pair 0x{0:X4} "
                    + "0x{1:X3} at index {2}.",
                    Convert.ToInt16(e.CharUnknownHigh),
                    Convert.ToInt16(e.CharUnknownLow),
                    e.Index);
            else
                Console.WriteLine("Unable to encode 0x{0:X4} at index {1}.",
                    Convert.ToInt16(e.CharUnknown),
                    e.Index);
            return;
        }
        Console.WriteLine();

        // Decode the ASCII bytes.
        try {
            string str2 = enc.GetString(bytes);
            Console.WriteLine("Round-trip: {0}", str1.Equals(str2));
            if (!str1.Equals(str2)) {
```

```

        Console.WriteLine(str2);
        foreach (var ch in str2)
            Console.Write("{0} ", Convert.ToInt16(ch).ToString("X4"));

        Console.WriteLine();
    }
}

catch (DecoderFallbackException e) {
    Console.Write("Unable to decode byte(s) ");
    foreach (byte unknown in e.BytesUnknown)
        Console.Write("0x{0:X2} ");

    Console.WriteLine("at index {0}", e.Index);
}
}

// The example displays the following output:
//      Ⓜ ̄
//      24C8 0020 2075 0020 221E
//
//      Exception: Unable to encode 0x24C8 at index 0.

```

ⓘ Note

You can also implement a custom exception handler for an encoding operation. For more information, see the [Implementing a Custom Fallback Strategy](#) section.

The [EncoderFallbackException](#) and [DecoderFallbackException](#) objects provide the following information about the condition that caused the exception:

- The [EncoderFallbackException](#) object includes an [IsUnknownSurrogate](#) method, which indicates whether the character or characters that cannot be encoded represent an unknown surrogate pair (in which case, the method returns `true`) or an unknown single character (in which case, the method returns `false`). The characters in the surrogate pair are available from the [EncoderFallbackException.CharUnknownHigh](#) and [EncoderFallbackException.CharUnknownLow](#) properties. The unknown single character is available from the [EncoderFallbackException.CharUnknown](#) property. The [EncoderFallbackException.Index](#) property indicates the position in the string at which the first character that could not be encoded was found.
- The [DecoderFallbackException](#) object includes a [BytesUnknown](#) property that returns an array of bytes that cannot be decoded. The [DecoderFallbackException.Index](#) property indicates the starting position of the unknown bytes.

Although the [EncoderFallbackException](#) and [DecoderFallbackException](#) objects provide adequate diagnostic information about the exception, they do not provide access to the encoding or decoding buffer. Therefore, they do not allow invalid data to be replaced or corrected within the encoding or decoding method.

Implementing a Custom Fallback Strategy

In addition to the best-fit mapping that is implemented internally by code pages, .NET includes the following classes for implementing a fallback strategy:

- Use [EncoderReplacementFallback](#) and [EncoderReplacementFallbackBuffer](#) to replace characters in encoding operations.
- Use [DecoderReplacementFallback](#) and [DecoderReplacementFallbackBuffer](#) to replace characters in decoding operations.
- Use [EncoderExceptionFallback](#) and [EncoderExceptionFallbackBuffer](#) to throw an [EncoderFallbackException](#) when a character cannot be encoded.
- Use [DecoderExceptionFallback](#) and [DecoderExceptionFallbackBuffer](#) to throw a [DecoderFallbackException](#) when a character cannot be decoded.

In addition, you can implement a custom solution that uses best-fit fallback, replacement fallback, or exception fallback, by following these steps:

1. Derive a class from [EncoderFallback](#) for encoding operations, and from [DecoderFallback](#) for decoding operations.
2. Derive a class from [EncoderFallbackBuffer](#) for encoding operations, and from [DecoderFallbackBuffer](#) for decoding operations.
3. For exception fallback, if the predefined [EncoderFallbackException](#) and [DecoderFallbackException](#) classes do not meet your needs, derive a class from an exception object such as [Exception](#) or [ArgumentException](#).

Deriving from EncoderFallback or DecoderFallback

To implement a custom fallback solution, you must create a class that inherits from [EncoderFallback](#) for encoding operations, and from [DecoderFallback](#) for decoding operations. Instances of these classes are passed to the [Encoding.GetEncoding\(String, EncoderFallback, DecoderFallback\)](#) method and serve as the intermediary between the encoding class and the fallback implementation.

When you create a custom fallback solution for an encoder or decoder, you must implement the following members:

- The [EncoderFallback.MaxCharCount](#) or [DecoderFallback.MaxCharCount](#) property, which returns the maximum possible number of characters that the best-fit, replacement, or exception fallback can return to replace a single character. For a custom exception fallback, its value is zero.
- The [EncoderFallback.CreateFallbackBuffer](#) or [DecoderFallback.CreateFallbackBuffer](#) method, which returns your custom [EncoderFallbackBuffer](#) or [DecoderFallbackBuffer](#) implementation. The method is called by the encoder when it encounters the first character that it is unable to successfully encode, or by the decoder when it encounters the first byte that it is unable to successfully decode.

Deriving from EncoderFallbackBuffer or DecoderFallbackBuffer

To implement a custom fallback solution, you must also create a class that inherits from [EncoderFallbackBuffer](#) for encoding operations, and from [DecoderFallbackBuffer](#) for decoding operations. Instances of these classes are returned by the [CreateFallbackBuffer](#) method of the [EncoderFallback](#) and [DecoderFallback](#) classes. The [EncoderFallback.CreateFallbackBuffer](#) method is called by the encoder when it encounters the first character that it is not able to encode, and the [DecoderFallback.CreateFallbackBuffer](#) method is called by the decoder when it encounters one or more bytes that it is not able to decode. The [EncoderFallbackBuffer](#) and [DecoderFallbackBuffer](#) classes provide the fallback implementation. Each instance represents a buffer that contains the fallback characters that will replace the character that cannot be encoded or the byte sequence that cannot be decoded.

When you create a custom fallback solution for an encoder or decoder, you must implement the following members:

- The [EncoderFallbackBuffer.Fallback](#) or [DecoderFallbackBuffer.Fallback](#) method. [EncoderFallbackBuffer.Fallback](#) is called by the encoder to provide the fallback buffer with information about the character that it cannot encode. Because the character to be encoded may be a surrogate pair, this method is overloaded. One overload is passed the character to be encoded and its index in the string. The second overload is passed the high and low surrogate along with its index in the string. The [DecoderFallbackBuffer.Fallback](#) method is called by the decoder to provide the fallback buffer with information about the bytes that it cannot decode. This method is passed an array of bytes that it cannot decode, along with the index of the first byte. The fallback method should return `true` if the fallback buffer can

supply a best-fit or replacement character or characters; otherwise, it should return `false`. For an exception fallback, the fallback method should throw an exception.

- The [EncoderFallbackBuffer.GetNextChar](#) or [DecoderFallbackBuffer.GetNextChar](#) method, which is called repeatedly by the encoder or decoder to get the next character from the fallback buffer. When all fallback characters have been returned, the method should return U+0000.
- The [EncoderFallbackBuffer.Remaining](#) or [DecoderFallbackBuffer.Remaining](#) property, which returns the number of characters remaining in the fallback buffer.
- The [EncoderFallbackBuffer.MovePrevious](#) or [DecoderFallbackBuffer.MovePrevious](#) method, which moves the current position in the fallback buffer to the previous character.
- The [EncoderFallbackBuffer.Reset](#) or [DecoderFallbackBuffer.Reset](#) method, which reinitializes the fallback buffer.

If the fallback implementation is a best-fit fallback or a replacement fallback, the classes derived from [EncoderFallbackBuffer](#) and [DecoderFallbackBuffer](#) also maintain two private instance fields: the exact number of characters in the buffer; and the index of the next character in the buffer to return.

An EncoderFallback Example

An earlier example used replacement fallback to replace Unicode characters that did not correspond to ASCII characters with an asterisk (*). The following example uses a custom best-fit fallback implementation instead to provide a better mapping of non-ASCII characters.

The following code defines a class named `CustomMapper` that is derived from [EncoderFallback](#) to handle the best-fit mapping of non-ASCII characters. Its `CreateFallbackBuffer` method returns a `CustomMapperFallbackBuffer` object, which provides the [EncoderFallbackBuffer](#) implementation. The `CustomMapper` class uses a `Dictionary< TKey, TValue >` object to store the mappings of unsupported Unicode characters (the key value) and their corresponding 8-bit characters (which are stored in two consecutive bytes in a 64-bit integer). To make this mapping available to the fallback buffer, the `CustomMapper` instance is passed as a parameter to the `CustomMapperFallbackBuffer` class constructor. Because the longest mapping is the string "INF" for the Unicode character U+221E, the `MaxCharCount` property returns 3.

C#

```

public class CustomMapper : EncoderFallback
{
    public string DefaultString;
    internal Dictionary<ushort, ulong> mapping;

    public CustomMapper() : this("*")
    {
    }

    public CustomMapper(string defaultString)
    {
        this.DefaultString = defaultString;

        // Create table of mappings
        mapping = new Dictionary<ushort, ulong>();
        mapping.Add(0x24C8, 0x53);
        mapping.Add(0x2075, 0x35);
        mapping.Add(0x221E, 0x49004E0046);
    }

    public override EncoderFallbackBuffer CreateFallbackBuffer()
    {
        return new CustomMapperFallbackBuffer(this);
    }

    public override int MaxCharCount
    {
        get { return 3; }
    }
}

```

The following code defines the `CustomMapperFallbackBuffer` class, which is derived from `EncoderFallbackBuffer`. The dictionary that contains best-fit mappings and that is defined in the `CustomMapper` instance is available from its class constructor. Its `Fallback` method returns `true` if any of the Unicode characters that the ASCII encoder cannot encode are defined in the mapping dictionary; otherwise, it returns `false`. For each fallback, the private `count` variable indicates the number of characters that remain to be returned, and the private `index` variable indicates the position in the string buffer, `charsToReturn`, of the next character to return.

C#

```

public class CustomMapperFallbackBuffer : EncoderFallbackBuffer
{
    int count = -1;                                // Number of characters to return
    int index = -1;                                 // Index of character to return
    CustomMapper fb;
    string charsToReturn;

```

```
public CustomMapperFallbackBuffer(CustomMapper fallback)
{
    this.fb = fallback;
}

public override bool Fallback(char charUnknownHigh, char charUnknownLow,
int index)
{
    // Do not try to map surrogates to ASCII.
    return false;
}

public override bool Fallback(char charUnknown, int index)
{
    // Return false if there are already characters to map.
    if (count >= 1) return false;

    // Determine number of characters to return.
    charsToReturn = String.Empty;

    ushort key = Convert.ToInt16(charUnknown);
    if (fb.mapping.ContainsKey(key)) {
        byte[] bytes = BitConverter.GetBytes(fb.mapping[key]);
        int ctr = 0;
        foreach (var byt in bytes) {
            if (byt > 0) {
                ctr++;
                charsToReturn += (char) byt;
            }
        }
        count = ctr;
    }
    else {
        // Return default.
        charsToReturn = fb.DefaultString;
        count = 1;
    }
    this.index = charsToReturn.Length - 1;

    return true;
}

public override char GetNextChar()
{
    // We'll return a character if possible, so subtract from the count of
    // chars to return.
    count--;
    // If count is less than zero, we've returned all characters.
    if (count < 0)
        return '\u0000';

    this.index--;
    return charsToReturn[this.index + 1];
}
```

```

public override bool MovePrevious()
{
    // Original: if count >= -1 and pos >= 0
    if (count >= -1) {
        count++;
        return true;
    }
    else {
        return false;
    }
}

public override int Remaining
{
    get { return count < 0 ? 0 : count; }
}

public override void Reset()
{
    count = -1;
    index = -1;
}
}

```

The following code then instantiates the `CustomMapper` object and passes an instance of it to the `Encoding.GetEncoding(String, EncoderFallback, DecoderFallback)` method. The output indicates that the best-fit fallback implementation successfully handles the three non-ASCII characters in the original string.

C#

```

using System;
using System.Collections.Generic;
using System.Text;

class Program
{
    static void Main()
    {
        Encoding enc = Encoding.GetEncoding("us-ascii", new CustomMapper(),
new DecoderExceptionFallback());

        string str1 = "\u24C8 \u2075 \u221E";
        Console.WriteLine(str1);
        for (int ctr = 0; ctr <= str1.Length - 1; ctr++) {
            Console.Write("{0} ", Convert.ToInt16(str1[ctr]).ToString("X4"));
            if (ctr == str1.Length - 1)
                Console.WriteLine();
        }
        Console.WriteLine();

        // Encode the original string using the ASCII encoder.
    }
}

```

```
byte[] bytes = enc.GetBytes(str1);
Console.WriteLine("Encoded bytes: ");
foreach (var byt in bytes)
    Console.WriteLine("{0:X2} ", byt);

Console.WriteLine("\n");

// Decode the ASCII bytes.
string str2 = enc.GetString(bytes);
Console.WriteLine("Round-trip: {0}", str1.Equals(str2));
if (!str1.Equals(str2)) {
    Console.WriteLine(str2);
    foreach (var ch in str2)
        Console.Write("{0} ", Convert.ToInt16(ch).ToString("X4"));

    Console.WriteLine();
}
}
```

Best practices for comparing strings in .NET

Article • 02/01/2023

.NET provides extensive support for developing localized and globalized applications, and makes it easy to apply the conventions of either the current culture or a specific culture when performing common operations such as sorting and displaying strings. But sorting or comparing strings isn't always a culture-sensitive operation. For example, strings that are used internally by an application typically should be handled identically across all cultures. When culturally independent string data, such as XML tags, HTML tags, user names, file paths, and the names of system objects, are interpreted as if they were culture-sensitive, application code can be subject to subtle bugs, poor performance, and, in some cases, security issues.

This article examines the string sorting, comparison, and casing methods in .NET, presents recommendations for selecting an appropriate string-handling method, and provides additional information about string-handling methods.

Recommendations for string usage

When you develop with .NET, follow these recommendations when you compare strings.

Tip

Various string-related methods perform comparison. Examples include [String.Equals](#), [String.Compare](#), [String.IndexOf](#), and [String.StartsWith](#).

- Use overloads that explicitly specify the string comparison rules for string operations. Typically, this involves calling a method overload that has a parameter of type [StringComparison](#).
- Use [StringComparison.Ordinal](#) or [StringComparison.OrdinalIgnoreCase](#) for comparisons as your safe default for culture-agnostic string matching.
- Use comparisons with [StringComparison.Ordinal](#) or [StringComparison.OrdinalIgnoreCase](#) for better performance.
- Use string operations that are based on [StringComparison.CurrentCulture](#) when you display output to the user.
- Use the non-linguistic [StringComparison.Ordinal](#) or [StringComparison.OrdinalIgnoreCase](#) values instead of string operations based on

`CultureInfo.InvariantCulture` when the comparison is linguistically irrelevant (symbolic, for example).

- Use the `String.ToUpperInvariant` method instead of the `String.ToLowerInvariant` method when you normalize strings for comparison.
- Use an overload of the `String.Equals` method to test whether two strings are equal.
- Use the `String.Compare` and `String.CompareTo` methods to sort strings, not to check for equality.
- Use culture-sensitive formatting to display non-string data, such as numbers and dates, in a user interface. Use formatting with the `invariant culture` to persist non-string data in string form.

Avoid the following practices when you compare strings:

- Don't use overloads that don't explicitly or implicitly specify the string comparison rules for string operations.
- Don't use string operations based on `StringComparison.InvariantCulture` in most cases. One of the few exceptions is when you're persisting linguistically meaningful but culturally agnostic data.
- Don't use an overload of the `String.Compare` or `CompareTo` method and test for a return value of zero to determine whether two strings are equal.

Specifying string comparisons explicitly

Most of the string manipulation methods in .NET are overloaded. Typically, one or more overloads accept default settings, whereas others accept no defaults and instead define the precise way in which strings are to be compared or manipulated. Most of the methods that don't rely on defaults include a parameter of type `StringComparison`, which is an enumeration that explicitly specifies rules for string comparison by culture and case. The following table describes the `StringComparison` enumeration members.

| StringComparison member | Description |
|---|---|
| <code>.CurrentCulture</code> | Performs a case-sensitive comparison using the current culture. |
| <code>.CurrentCultureIgnoreCase</code> | Performs a case-insensitive comparison using the current culture. |
| <code>InvariantCulture</code> | Performs a case-sensitive comparison using the invariant culture. |
| <code>InvariantCultureIgnoreCase</code> | Performs a case-insensitive comparison using the invariant culture. |
| <code>Ordinal</code> | Performs an ordinal comparison. |
| <code>OrdinalIgnoreCase</code> | Performs a case-insensitive ordinal comparison. |

For example, the [IndexOf](#) method, which returns the index of a substring in a [String](#) object that matches either a character or a string, has nine overloads:

- [IndexOf\(Char\)](#), [IndexOf\(Char, Int32\)](#), and [IndexOf\(Char, Int32, Int32\)](#), which by default performs an ordinal (case-sensitive and culture-insensitive) search for a character in the string.
- [IndexOf\(String\)](#), [IndexOf\(String, Int32\)](#), and [IndexOf\(String, Int32, Int32\)](#), which by default performs a case-sensitive and culture-sensitive search for a substring in the string.
- [IndexOf\(String, StringComparison\)](#), [IndexOf\(String, Int32, StringComparison\)](#), and [IndexOf\(String, Int32, Int32, StringComparison\)](#), which include a parameter of type [StringComparison](#) that allows the form of the comparison to be specified.

We recommend that you select an overload that doesn't use default values, for the following reasons:

- Some overloads with default parameters (those that search for a [Char](#) in the string instance) perform an ordinal comparison, whereas others (those that search for a string in the string instance) are culture-sensitive. It's difficult to remember which method uses which default value, and easy to confuse the overloads.
- The intent of the code that relies on default values for method calls isn't clear. In the following example, which relies on defaults, it's difficult to know whether the developer actually intended an ordinal or a linguistic comparison of two strings, or whether a case difference between `url.Scheme` and "https" might cause the test for equality to return `false`.

C#

```
Uri url = new("https://learn.microsoft.com/");

// Incorrect
if (string.Equals(url.Scheme, "https"))
{
    // ...Code to handle HTTPS protocol.
}
```

In general, we recommend that you call a method that doesn't rely on defaults, because it makes the intent of the code unambiguous. This, in turn, makes the code more readable and easier to debug and maintain. The following example addresses the questions raised about the previous example. It makes it clear that ordinal comparison is used and that differences in case are ignored.

C#

```
Uri url = new("https://learn.microsoft.com/");

// Correct
if (string.Equals(url.Scheme, "https", StringComparison.OrdinalIgnoreCase))
{
    // ...Code to handle HTTPS protocol.
}
```

The details of string comparison

String comparison is the heart of many string-related operations, particularly sorting and testing for equality. Strings sort in a determined order: If "my" appears before "string" in a sorted list of strings, "my" must compare less than or equal to "string". Additionally, comparison implicitly defines equality. The comparison operation returns zero for strings it deems equal. A good interpretation is that neither string is less than the other. Most meaningful operations involving strings include one or both of these procedures: comparing with another string, and executing a well-defined sort operation.

Note

You can download the [Sorting Weight Tables](#), a set of text files that contain information on the character weights used in sorting and comparison operations for Windows operating systems, and the [Default Unicode Collation Element Table](#), the latest version of the sort weight table for Linux and macOS. The specific version of the sort weight table on Linux and macOS depends on the version of the [International Components for Unicode](#) libraries installed on the system. For information on ICU versions and the Unicode versions that they implement, see [Downloading ICU](#).

However, evaluating two strings for equality or sort order doesn't yield a single, correct result; the outcome depends on the criteria used to compare the strings. In particular, string comparisons that are ordinal or that are based on the casing and sorting conventions of the current culture or the [invariant culture](#) (a locale-agnostic culture based on the English language) may produce different results.

In addition, string comparisons using different versions of .NET or using .NET on different operating systems or operating system versions may return different results. For more information, see [Strings and the Unicode Standard](#).

String comparisons that use the current culture

One criterion involves using the conventions of the current culture when comparing strings. Comparisons that are based on the current culture use the thread's current culture or locale. If the culture isn't set by the user, it defaults to the operating system's setting. You should always use comparisons that are based on the current culture when data is linguistically relevant, and when it reflects culture-sensitive user interaction.

However, comparison and casing behavior in .NET changes when the culture changes. This happens when an application executes on a computer that has a different culture than the computer on which the application was developed, or when the executing thread changes its culture. This behavior is intentional, but it remains non-obvious to many developers. The following example illustrates differences in sort order between the U.S. English ("en-US") and Swedish ("sv-SE") cultures. Note that the words "ångström", "Windows", and "Visual Studio" appear in different positions in the sorted string arrays.

C#

```
using System.Globalization;

// Words to sort
string[] values= { "able", "ångström", "apple", "Æble",
                   "Windows", "Visual Studio" };

// Current culture
Array.Sort(values);
DisplayArray(values);

// Change culture to Swedish (Sweden)
string originalCulture = CultureInfo.CurrentCulture.Name;
Thread.CurrentThread.CurrentCulture = new CultureInfo("sv-SE");
Array.Sort(values);
DisplayArray(values);

// Restore the original culture
Thread.CurrentThread.CurrentCulture = new CultureInfo(originalCulture);

static void DisplayArray(string[] values)
{
    Console.WriteLine($"Sorting using the {CultureInfo.CurrentCulture.Name}
culture:");

    foreach (string value in values)
        Console.WriteLine($"{value}");

    Console.WriteLine();
}

// The example displays the following output:
//      Sorting using the en-US culture:
//          able
```

```
//      Äble
//      ångström
//      apple
//      Visual Studio
//      Windows
//
//      Sorting using the sv-SE culture:
//      able
//      apple
//      Visual Studio
//      Windows
//      ångström
//      Äble
```

Case-insensitive comparisons that use the current culture are the same as culture-sensitive comparisons, except that they ignore case as dictated by the thread's current culture. This behavior may manifest itself in sort orders as well.

Comparisons that use current culture semantics are the default for the following methods:

- [String.Compare](#) overloads that don't include a [StringComparison](#) parameter.
- [String.CompareTo](#) overloads.
- The default [String.StartsWith\(String\)](#) method, and the [String.StartsWith\(String, Boolean, CultureInfo\)](#) method with a `null` [CultureInfo](#) parameter.
- The default [String.EndsWith\(String\)](#) method, and the [String.EndsWith\(String, Boolean, CultureInfo\)](#) method with a `null` [CultureInfo](#) parameter.
- [String.IndexOf](#) overloads that accept a [String](#) as a search parameter and that don't have a [StringComparison](#) parameter.
- [String.LastIndexOf](#) overloads that accept a [String](#) as a search parameter and that don't have a [StringComparison](#) parameter.

In any case, we recommend that you call an overload that has a [StringComparison](#) parameter to make the intent of the method call clear.

Subtle and not so subtle bugs can emerge when non-linguistic string data is interpreted linguistically, or when string data from a particular culture is interpreted using the conventions of another culture. The canonical example is the Turkish-I problem.

For nearly all Latin alphabets, including U.S. English, the character "i" (\u0069) is the lowercase version of the character "I" (\u0049). This casing rule quickly becomes the default for someone programming in such a culture. However, the Turkish ("tr-TR") alphabet includes an "I with a dot" character "İ" (\u0130), which is the capital version of "i". Turkish also includes a lowercase "i without a dot" character, "ı" (\u0131), which capitalizes to "I". This behavior occurs in the Azerbaijani ("az") culture as well.

Therefore, assumptions made about capitalizing "i" or lowercasing "I" aren't valid among all cultures. If you use the default overloads for string comparison routines, they will be subject to variance between cultures. If the data to be compared is non-linguistic, using the default overloads can produce undesirable results, as the following attempt to perform a case-insensitive comparison of the strings "bill" and "BILL" illustrates.

C#

```
using System.Globalization;

string name = "Bill";

Thread.CurrentThread.CurrentCulture = new CultureInfo("en-US");
Console.WriteLine($"Culture =
{Thread.CurrentThread.CurrentCulture.DisplayName}");
Console.WriteLine($"    Is 'Bill' the same as 'BILL'? {name.Equals("BILL",
 StringComparison.OrdinalIgnoreCase)}");
Console.WriteLine($"    Does 'Bill' start with 'BILL'?
{name.StartsWith("BILL", true, null)}");
Console.WriteLine();

Thread.CurrentThread.CurrentCulture = new CultureInfo("tr-TR");
Console.WriteLine($"Culture =
{Thread.CurrentThread.CurrentCulture.DisplayName}");
Console.WriteLine($"    Is 'Bill' the same as 'BILL'? {name.Equals("BILL",
 StringComparison.OrdinalIgnoreCase)}");
Console.WriteLine($"    Does 'Bill' start with 'BILL'?
{name.StartsWith("BILL", true, null)}");

// The example displays the following output:
//'
//'
//    Culture = English (United States)
//        Is 'Bill' the same as 'BILL'? True
//        Does 'Bill' start with 'BILL'? True
//'
//    Culture = Turkish (Türkçe)
//        Is 'Bill' the same as 'BILL'? True
//        Does 'Bill' start with 'BILL'? False
```

This comparison could cause significant problems if the culture is inadvertently used in security-sensitive settings, as in the following example. A method call such as `IsFileURI("file:")` returns `true` if the current culture is U.S. English, but `false` if the current culture is Turkish. Thus, on Turkish systems, someone could circumvent security measures that block access to case-insensitive URIs that begin with "FILE:".

C#

```
public static bool IsFileURI(string path) =>
    path.StartsWith("FILE:", true, null);
```

In this case, because "file:" is meant to be interpreted as a non-linguistic, culture-insensitive identifier, the code should instead be written as shown in the following example:

C#

```
public static bool IsFileURI(string path) =>
    path.StartsWith("FILE:", StringComparison.OrdinalIgnoreCase);
```

Ordinal string operations

Specifying the `StringComparison.Ordinal` or `StringComparison.OrdinalIgnoreCase` value in a method call signifies a non-linguistic comparison in which the features of natural languages are ignored. Methods that are invoked with these `StringComparison` values base string operation decisions on simple byte comparisons instead of casing or equivalence tables that are parameterized by culture. In most cases, this approach best fits the intended interpretation of strings while making code faster and more reliable.

Ordinal comparisons are string comparisons in which each byte of each string is compared without linguistic interpretation; for example, "windows" doesn't match "Windows". This is essentially a call to the C runtime `strcmp` function. Use this comparison when the context dictates that strings should be matched exactly or demands conservative matching policy. Additionally, ordinal comparison is the fastest comparison operation because it applies no linguistic rules when determining a result.

Strings in .NET can contain embedded null characters (and other non-printing characters). One of the clearest differences between ordinal and culture-sensitive comparison (including comparisons that use the invariant culture) concerns the handling of embedded null characters in a string. These characters are ignored when you use the `String.Compare` and `String.Equals` methods to perform culture-sensitive comparisons (including comparisons that use the invariant culture). As a result, strings that contain embedded null characters can be considered equal to strings that don't. Embedded non-printing characters might be skipped for the purpose of string comparison methods, such as `String.StartsWith`.

ⓘ Important

Although string comparison methods disregard embedded null characters, string search methods such as `String.Contains`, `String.EndsWith`, `String.IndexOf`, `String.LastIndexOf`, and `String.StartsWith` do not.

The following example performs a culture-sensitive comparison of the string "Aa" with a similar string that contains several embedded null characters between "A" and "a", and shows how the two strings are considered equal:

C#

```
string str1 = "Aa";
string str2 = "A" + new string('\u0000', 3) + "a";

Thread.CurrentThread.CurrentCulture =
System.Globalization.CultureInfo.GetCultureInfo("en-us");

Console.WriteLine($"Comparing '{str1}' ({ShowBytes(str1)}) and '{str2}'"
({ShowBytes(str2)}):");
Console.WriteLine("    With String.Compare:");
Console.WriteLine($"        Current Culture: {string.Compare(str1, str2,
 StringComparison.CurrentCulture)}");
Console.WriteLine($"        Invariant Culture: {string.Compare(str1, str2,
 StringComparison.InvariantCulture)}");
Console.WriteLine("    With String.Equals:");
Console.WriteLine($"        Current Culture: {string.Equals(str1, str2,
 StringComparison.CurrentCulture)}");
Console.WriteLine($"        Invariant Culture: {string.Equals(str1, str2,
 StringComparison.InvariantCulture)}");

string ShowBytes(string value)
{
    string hexString = string.Empty;
    for (int index = 0; index < value.Length; index++)
    {
        string result = Convert.ToInt32(value[index]).ToString("X4");
        result = string.Concat(" ", result.Substring(0,2), " ",
result.Substring(2, 2));
        hexString += result;
    }
    return hexString.Trim();
}

// The example displays the following output:
// Comparing 'Aa' (00 41 00 61) and 'Aa' (00 41 00 00 00 00 00 00 00
61):
//     With String.Compare:
//         Current Culture: 0
//         Invariant Culture: 0
//     With String.Equals:
//         Current Culture: True
//         Invariant Culture: True
```

However, the strings aren't considered equal when you use ordinal comparison, as the following example shows:

C#

```
string str1 = "Aa";
string str2 = "A" + new String('\u0000', 3) + "a";

Console.WriteLine($"Comparing '{str1}' ({ShowBytes(str1)}) and '{str2}'"
({ShowBytes(str2)}):");
Console.WriteLine("    With String.Compare:");
Console.WriteLine($"        Ordinal: {string.Compare(str1, str2,
 StringComparison.OrdinalIgnoreCase)}");
Console.WriteLine("    With String.Equals:");
Console.WriteLine($"        Ordinal: {string.Equals(str1, str2,
 StringComparison.OrdinalIgnoreCase)}");

string ShowBytes(string str)
{
    string hexString = string.Empty;
    for (int ctr = 0; ctr < str.Length; ctr++)
    {
        string result = Convert.ToInt32(str[ctr]).ToString("X4");
        result = " " + result.Substring(0, 2) + " " + result.Substring(2,
2);
        hexString += result;
    }
    return hexString.Trim();
}

// The example displays the following output:
// Comparing 'Aa' (00 41 00 61) and 'A a' (00 41 00 00 00 00 00 00
61):
//     With String.Compare:
//         Ordinal: 97
//     With String.Equals:
//         Ordinal: False
```

Case-insensitive ordinal comparisons are the next most conservative approach. These comparisons ignore most casing; for example, "windows" matches "Windows". When dealing with ASCII characters, this policy is equivalent to `StringComparison.OrdinalIgnoreCase`, except that it ignores the usual ASCII casing. Therefore, any character in [A, Z] (\u0041-\u005A) matches the corresponding character in [a,z] (\u0061-\u007A). Casing outside the ASCII range uses the invariant culture's tables. Therefore, the following comparison:

C#

```
string.Compare(strA, strB, StringComparison.OrdinalIgnoreCase);
```

is equivalent to (but faster than) this comparison:

C#

```
string.Compare(strA.ToUpperInvariant(), strB.ToUpperInvariant(),
StringComparison.OrdinalIgnoreCase);
```

These comparisons are still very fast.

Both [StringComparison.Ordinal](#) and [StringComparison.OrdinalIgnoreCase](#) use the binary values directly, and are best suited for matching. When you aren't sure about your comparison settings, use one of these two values. However, because they perform a byte-by-byte comparison, they don't sort by a linguistic sort order (like an English dictionary) but by a binary sort order. The results may look odd in most contexts if displayed to users.

Ordinal semantics are the default for [String.Equals](#) overloads that don't include a [StringComparison](#) argument (including the equality operator). In any case, we recommend that you call an overload that has a [StringComparison](#) parameter.

String operations that use the invariant culture

Comparisons with the invariant culture use the [CompareInfo](#) property returned by the static [CultureInfo.InvariantCulture](#) property. This behavior is the same on all systems; it translates any characters outside its range into what it believes are equivalent invariant characters. This policy can be useful for maintaining one set of string behavior across cultures, but it often provides unexpected results.

Case-insensitive comparisons with the invariant culture use the static [CompareInfo](#) property returned by the static [CultureInfo.InvariantCulture](#) property for comparison information as well. Any case differences among these translated characters are ignored.

Comparisons that use [StringComparison.InvariantCulture](#) and [StringComparison.OrdinalIgnoreCase](#) work identically on ASCII strings. However, [StringComparison.InvariantCulture](#) makes linguistic decisions that might not be appropriate for strings that have to be interpreted as a set of bytes. The [CultureInfo.InvariantCulture.CompareInfo](#) object makes the [Compare](#) method interpret certain sets of characters as equivalent. For example, the following equivalence is valid under the invariant culture:

InvariantCulture: a + ° = å

The LATIN SMALL LETTER A character "a" (\u0061), when it's next to the COMBINING RING ABOVE character "+" "\u030a", is interpreted as the LATIN SMALL LETTER A WITH RING ABOVE character "å" (\u00e5). As the following example shows, this behavior differs from ordinal comparison.

C#

```
string separated = "\u0061\u030a";
string combined = "\u00e5";

Console.WriteLine("Equal sort weight of {0} and {1} using InvariantCulture:
{2}",
separated, combined,
string.Compare(separated, combined,
StringComparison.InvariantCulture) == 0);

Console.WriteLine("Equal sort weight of {0} and {1} using Ordinal: {2}",
separated, combined,
string.Compare(separated, combined,
StringComparison.Ordinal) == 0);

// The example displays the following output:
//      Equal sort weight of aº and å using InvariantCulture: True
//      Equal sort weight of aº and å using Ordinal: False
```

When interpreting file names, cookies, or anything else where a combination such as "å" can appear, ordinal comparisons still offer the most transparent and fitting behavior.

On balance, the invariant culture has few properties that make it useful for comparison. It does comparison in a linguistically relevant manner, which prevents it from guaranteeing full symbolic equivalence, but it isn't the choice for display in any culture. One of the few reasons to use [StringComparison.InvariantCulture](#) for comparison is to persist ordered data for a cross-culturally identical display. For example, if a large data file that contains a list of sorted identifiers for display accompanies an application, adding to this list would require an insertion with invariant-style sorting.

Choosing a StringComparison member for your method call

The following table outlines the mapping from semantic string context to a [StringComparison](#) enumeration member:

| Data | Behavior | Corresponding System.StringComparison |
|--------------------------------------|---|--|
| | | value |
| Case-sensitive internal identifiers. | A non-linguistic identifier, where bytes match exactly. | Ordinal |
| | | |

| Data | Behavior | Corresponding System.StringComparison value |
|---|---|--|
| standards such as XML and HTTP. | Case-sensitive security-related settings. | |
| Case-insensitive internal identifiers. | A non-linguistic identifier, where case is irrelevant. | OrdinalIgnoreCase |
| Case-insensitive identifiers in standards such as XML and HTTP. | | |
| File paths. | | |
| Registry keys and values. | | |
| Environment variables. | | |
| Resource identifiers (for example, handle names). | | |
| Case-insensitive security-related settings. | | |
| Some persisted, linguistically relevant data. | Culturally agnostic data that still is linguistically relevant. | InvariantCulture -or- InvariantCultureIgnoreCase |
| Display of linguistic data that requires a fixed sort order. | | |
| Data displayed to the user. | Data that requires local linguistic customs. | CurrentCulture -or- CurrentCultureIgnoreCase |
| Most user input. | | |

Common string comparison methods in .NET

The following sections describe the methods that are most commonly used for string comparison.

String.Compare

Default interpretation: [StringComparison.CurrentCulture](#).

As the operation most central to string interpretation, all instances of these method calls should be examined to determine whether strings should be interpreted according to the current culture, or dissociated from the culture (symbolically). Typically, it's the latter, and a [StringComparison.Ordinal](#) comparison should be used instead.

The [System.Globalization.CompareInfo](#) class, which is returned by the [CultureInfo.CompareInfo](#) property, also includes a [Compare](#) method that provides a large number of matching options (ordinal, ignoring white space, ignoring kana type, and so on) by means of the [CompareOptions](#) flag enumeration.

String.CompareTo

Default interpretation: [StringComparison.CurrentCulture](#).

This method doesn't currently offer an overload that specifies a [StringComparison](#) type. It's usually possible to convert this method to the recommended [String.Compare\(String, String, StringComparison\)](#) form.

Types that implement the [IComparable](#) and [IComparable<T>](#) interfaces implement this method. Because it doesn't offer the option of a [StringComparison](#) parameter, implementing types often let the user specify a [StringComparer](#) in their constructor. The following example defines a [FileName](#) class whose class constructor includes a [StringComparer](#) parameter. This [StringComparer](#) object is then used in the [FileName.CompareTo](#) method.

C#

```
class FileName : IComparable
{
    private readonly StringComparer _comparer;

    public string Name { get; }

    public FileName(string name, StringComparer? comparer)
    {
        if (string.IsNullOrEmpty(name)) throw new
ArgumentNullException(nameof(name));

        Name = name;

        if (comparer != null)
            _comparer = comparer;
    }
}
```

```

        else
            _comparer = StringComparer.OrdinalIgnoreCase;
    }

    public int CompareTo(object? obj)
    {
        if (obj == null) return 1;

        if (obj is not FileName)
            return _comparer.Compare(Name, obj.ToString());
        else
            return _comparer.Compare(Name, ((FileName)obj).Name);
    }
}

```

String.Equals

Default interpretation: [StringComparison.Ordinal](#).

The [String](#) class lets you test for equality by calling either the static or instance [Equals](#) method overloads, or by using the static equality operator. The overloads and operator use ordinal comparison by default. However, we still recommend that you call an overload that explicitly specifies the [StringComparison](#) type even if you want to perform an ordinal comparison; this makes it easier to search code for a certain string interpretation.

String.ToUpper and String.ToLower

Default interpretation: [StringComparison.CurrentCulture](#).

Be careful when you use the [String.ToUpper\(\)](#) and [String.ToLower\(\)](#) methods, because forcing a string to uppercase or lowercase is often used as a small normalization for comparing strings regardless of case. If so, consider using a case-insensitive comparison.

The [String.ToUpperInvariant](#) and [String.ToLowerInvariant](#) methods are also available. [ToUpperInvariant](#) is the standard way to normalize case. Comparisons made using [StringComparison.OrdinalIgnoreCase](#) are behaviorally the composition of two calls: calling [ToUpperInvariant](#) on both string arguments, and doing a comparison using [StringComparison.Ordinal](#).

Overloads are also available for converting to uppercase and lowercase in a specific culture, by passing a [CultureInfo](#) object that represents that culture to the method.

Char.ToUpper and Char.ToLower

Default interpretation: [StringComparison.CurrentCulture](#).

The [Char.ToUpper\(Char\)](#) and [Char.ToLower\(Char\)](#) methods work similarly to the [String.ToUpper\(\)](#) and [String.ToLower\(\)](#) methods described in the previous section.

String.StartsWith and String.EndsWith

Default interpretation: [StringComparison.CurrentCulture](#).

By default, both of these methods perform a culture-sensitive comparison. In particular, they may ignore non-printing characters.

String.IndexOf and String.LastIndexOf

Default interpretation: [StringComparison.CurrentCulture](#).

There's a lack of consistency in how the default overloads of these methods perform comparisons. All [String.IndexOf](#) and [String.LastIndexOf](#) methods that include a [Char](#) parameter perform an ordinal comparison, but the default [String.IndexOf](#) and [String.LastIndexOf](#) methods that include a [String](#) parameter perform a culture-sensitive comparison.

If you call the [String.IndexOf\(String\)](#) or [String.LastIndexOf\(String\)](#) method and pass it a string to locate in the current instance, we recommend that you call an overload that explicitly specifies the [StringComparison](#) type. The overloads that include a [Char](#) argument don't allow you to specify a [StringComparison](#) type.

Methods that perform string comparison indirectly

Some non-string methods that have string comparison as a central operation use the [StringComparer](#) type. The [StringComparer](#) class includes six static properties that return [StringComparer](#) instances whose [StringComparer.Compare](#) methods perform the following types of string comparisons:

- Culture-sensitive string comparisons using the current culture. This [StringComparer](#) object is returned by the [StringComparer.CurrentCulture](#) property.
- Case-insensitive comparisons using the current culture. This [StringComparer](#) object is returned by the [StringComparer.CurrentCultureIgnoreCase](#) property.
- Culture-insensitive comparisons using the word comparison rules of the invariant culture. This [StringComparer](#) object is returned by the

`StringComparer.InvariantCulture` property.

- Case-insensitive and culture-insensitive comparisons using the word comparison rules of the invariant culture. This `StringComparer` object is returned by the `StringComparer.InvariantCultureIgnoreCase` property.
- Ordinal comparison. This `StringComparer` object is returned by the `StringComparer.Ordinal` property.
- Case-insensitive ordinal comparison. This `StringComparer` object is returned by the `StringComparer.OrdinalIgnoreCase` property.

Array.Sort and Array.BinarySearch

Default interpretation: `StringComparison.CurrentCulture`.

When you store any data in a collection, or read persisted data from a file or database into a collection, switching the current culture can invalidate the invariants in the collection. The `Array.BinarySearch` method assumes that the elements in the array to be searched are already sorted. To sort any string element in the array, the `Array.Sort` method calls the `String.Compare` method to order individual elements. Using a culture-sensitive comparer can be dangerous if the culture changes between the time that the array is sorted and its contents are searched. For example, in the following code, storage and retrieval operate on the comparer that is provided implicitly by the `Thread.CurrentCulture` property. If the culture can change between the calls to `StoreNames` and `DoesNameExist`, and especially if the array contents are persisted somewhere between the two method calls, the binary search may fail.

C#

```
// Incorrect
string[] _storedNames;

public void StoreNames(string[] names)
{
    _storedNames = new string[names.Length];

    // Copy the array contents into a new array
    Array.Copy(names, _storedNames, names.Length);

    Array.Sort(_storedNames); // Line A
}

public bool DoesNameExist(string name) =>
    Array.BinarySearch(_storedNames, name) >= 0; // Line B
```

A recommended variation appears in the following example, which uses the same ordinal (culture-insensitive) comparison method both to sort and to search the array.

The change code is reflected in the lines labeled **Line A** and **Line B** in the two examples.

```
C#  
  
// Correct  
string[] _storedNames;  
  
public void StoreNames(string[] names)  
{  
    _storedNames = new string[names.Length];  
  
    // Copy the array contents into a new array  
    Array.Copy(names, _storedNames, names.Length);  
  
    Array.Sort(_storedNames, StringComparer.Ordinal); // Line A  
}  
  
public bool DoesNameExist(string name) =>  
    Array.BinarySearch(_storedNames, name, StringComparer.Ordinal) >= 0; //  
Line B
```

If this data is persisted and moved across cultures, and sorting is used to present this data to the user, you might consider using [StringComparison.InvariantCulture](#), which operates linguistically for better user output but is unaffected by changes in culture. The following example modifies the two previous examples to use the invariant culture for sorting and searching the array.

```
C#  
  
// Correct  
string[] _storedNames;  
  
public void StoreNames(string[] names)  
{  
    _storedNames = new string[names.Length];  
  
    // Copy the array contents into a new array  
    Array.Copy(names, _storedNames, names.Length);  
  
    Array.Sort(_storedNames, StringComparer.InvariantCulture); // Line A  
}  
  
public bool DoesNameExist(string name) =>  
    Array.BinarySearch(_storedNames, name, StringComparer.InvariantCulture)  
    >= 0; // Line B
```

Collections example: Hashtable constructor

Hashing strings provides a second example of an operation that is affected by the way in which strings are compared.

The following example instantiates a [Hashtable](#) object by passing it the [StringComparer](#) object that is returned by the [StringComparer.OrdinalIgnoreCase](#) property. Because a class [StringComparer](#) that is derived from [StringComparer](#) implements the [IEqualityComparer](#) interface, its [GetHashCode](#) method is used to compute the hash code of strings in the hash table.

C#

```
using System.IO;
using System.Collections;

const int InitialCapacity = 100;

Hashtable creationTimeByFile = new(InitialCapacity,
StringComparer.OrdinalIgnoreCase);
string directoryToProcess = Directory.GetCurrentDirectory();

// Fill the hash table
PopulateFileTable(directoryToProcess);

// Get some of the files and try to find them with upper cased names
foreach (var file in Directory.GetFiles(directoryToProcess))
    PrintCreationTime(file.ToUpper());

void PopulateFileTable(string directory)
{
    foreach (string file in Directory.GetFiles(directory))
        creationTimeByFile.Add(file, File.GetCreationTime(file));
}

void PrintCreationTime(string targetFile)
{
    object? dt = creationTimeByFile[targetFile];

    if (dt is DateTime value)
        Console.WriteLine($"File {targetFile} was created at time
{value}.");
    else
        Console.WriteLine($"File {targetFile} does not exist.");
}
```

Best practices for displaying and persisting formatted data

Article • 01/27/2023

This article examines how formatted data, such as numeric data and date-and-time data, is handled for display and for storage.

When you develop with .NET, use culture-sensitive formatting to display non-string data, such as numbers and dates, in a user interface. Use formatting with the [invariant culture](#) to persist non-string data in string form. Do not use culture-sensitive formatting to persist numeric or date-and-time data in string form.

Display formatted data

When you display non-string data such as numbers and dates and times to users, format them by using the user's cultural settings. By default, the following all use the current culture in formatting operations:

- Interpolated strings supported by the [C#](#) and [Visual Basic](#) compilers.
- String concatenation operations that use the [C#](#) or [Visual Basic](#) concatenation operators or that call the [String.Concat](#) method directly.
- The [String.Format](#) method.
- The [ToString](#) methods of the numeric types and the date and time types.

To explicitly specify that a string should be formatted by using the conventions of a designated culture or the [invariant culture](#), you can do the following:

- When using the [String.Format](#) and [ToString](#) methods, call an overload that has a `provider` parameter, such as [String.Format\(IFormatProvider, String, Object\[\]\)](#) or [DateTime.ToString\(IFormatProvider\)](#), and pass it the [CultureInfo.CurrentCulture](#) property, a [CultureInfo](#) instance that represents the desired culture, or the [CultureInfo.InvariantCulture](#) property.
- For string concatenation, do not allow the compiler to perform any implicit conversions. Instead, perform an explicit conversion by calling a [ToString](#) overload that has a `provider` parameter. For example, the compiler implicitly uses the current culture when converting a [Double](#) value to a string in the following code:

C#

```
string concat1 = "The amount is " + 126.03 + ".";
Console.WriteLine(concat1);
```

Instead, you can explicitly specify the culture whose formatting conventions are used in the conversion by calling the [Double.ToString\(IFormatProvider\)](#) method, as the following code does:

C#

```
string concat2 = "The amount is " +
126.03.ToString(CultureInfo.InvariantCulture) + ".";
Console.WriteLine(concat2);
```

- For string interpolation, rather than assigning an interpolated string to a [String](#) instance, assign it to a [FormattableString](#). You can then call its [FormattableString.ToString\(\)](#) method to produce a result string that reflects the conventions of the current culture, or you can call the [FormattableString.ToString\(IFormatProvider\)](#) method to produce a result string that reflects the conventions of a specified culture.

You can also pass the formattable string to the static [FormattableString.Invariant](#) method to produce a result string that reflects the conventions of the invariant culture. The following example illustrates this approach. (The output from the example reflects a current culture of `en-US`.)

C#

```
using System;
using System.Globalization;

class Program
{
    static void Main()
    {
        Decimal value = 126.03m;
        FormattableString amount = $"The amount is {value:C}";
        Console.WriteLine(amount.ToString());
        Console.WriteLine(amount.ToString(new CultureInfo("fr-FR")));
        Console.WriteLine(FormattableString.Invariant(amount));
    }
}
// The example displays the following output:
//      The amount is $126.03
//      The amount is 126,03 €
//      The amount is #126.03
```

(!) Note

If you're using C# and formatting using the invariant culture, it's more performant to call `String.Create(IFormatProvider, DefaultInterpolatedStringHandler)` and pass `CultureInfo.InvariantCulture` for the first parameter. For more information, see [String interpolation in C# 10 and .NET 6](#).

Persist formatted data

You can persist non-string data either as binary data or as formatted data. If you choose to save it as formatted data, you should call a formatting method overload that includes a `provider` parameter and pass it the `CultureInfo.InvariantCulture` property. The invariant culture provides a consistent format for formatted data that is independent of culture and machine. In contrast, persisting data that is formatted by using cultures other than the invariant culture has a number of limitations:

- The data is likely to be unusable if it is retrieved on a system that has a different culture, or if the user of the current system changes the current culture and tries to retrieve the data.
- The properties of a culture on a specific computer can differ from standard values. At any time, a user can customize culture-sensitive display settings. Because of this, formatted data that is saved on a system may not be readable after the user customizes cultural settings. The portability of formatted data across computers is likely to be even more limited.
- International, regional, or national standards that govern the formatting of numbers or dates and times change over time, and these changes are incorporated into Windows operating system updates. When formatting conventions change, data that was formatted by using the previous conventions may become unreadable.

The following example illustrates the limited portability that results from using culture-sensitive formatting to persist data. The example saves an array of date and time values to a file. These are formatted by using the conventions of the English (United States) culture. After the application changes the current culture to French (Switzerland), it tries to read the saved values by using the formatting conventions of the current culture. The attempt to read two of the data items throws a `FormatException` exception, and the array of dates now contains two incorrect elements that are equal to `MinValue`.

```
using System;
using System.Globalization;
using System.IO;
using System.Text;
using System.Threading;

public class Example
{
    private static string filename = @".\dates.dat";

    public static void Main()
    {
        DateTime[] dates = { new DateTime(1758, 5, 6, 21, 26, 0),
                            new DateTime(1818, 5, 5, 7, 19, 0),
                            new DateTime(1870, 4, 22, 23, 54, 0),
                            new DateTime(1890, 9, 8, 6, 47, 0),
                            new DateTime(1905, 2, 18, 15, 12, 0) };
        // Write the data to a file using the current culture.
        WriteData(dates);
        // Change the current culture.
        Thread.CurrentThread.CurrentCulture =
CultureInfo.CreateSpecificCulture("fr-CH");
        // Read the data using the current culture.
        DateTime[] newDates = ReadData();
        foreach (var newDate in newDates)
            Console.WriteLine(newDate.ToString("g"));
    }

    private static void WriteData(DateTime[] dates)
    {
        StreamWriter sw = new StreamWriter(filename, false, Encoding.UTF8);
        for (int ctr = 0; ctr < dates.Length; ctr++) {
            sw.Write("{0}", dates[ctr].ToString("g",
CultureInfo.CurrentCulture));
            if (ctr < dates.Length - 1) sw.Write("|");
        }
        sw.Close();
    }

    private static DateTime[] ReadData()
    {
        bool exceptionOccurred = false;

        // Read file contents as a single string, then split it.
        StreamReader sr = new StreamReader(filename, Encoding.UTF8);
        string output = sr.ReadToEnd();
        sr.Close();

        string[] values = output.Split( new char[] { '|' } );
        DateTime[] newDates = new DateTime[values.Length];
        for (int ctr = 0; ctr < values.Length; ctr++) {
            try {
                newDates[ctr] = DateTime.Parse(values[ctr],
CultureInfo.CurrentCulture);
            }
        }
    }
}
```

```
        }
        catch (FormatException) {
            Console.WriteLine("Failed to parse {0}", values[ctr]);
            exceptionOccurred = true;
        }
    }
    if (exceptionOccurred) Console.WriteLine();
    return newDates;
}
}

// The example displays the following output:
//      Failed to parse 4/22/1870 11:54 PM
//      Failed to parse 2/18/1905 3:12 PM
//
//      05.06.1758 21:26
//      05.05.1818 07:19
//      01.01.0001 00:00
//      09.08.1890 06:47
//      01.01.0001 00:00
//      01.01.0001 00:00
```

However, if you replace the `CultureInfo.CurrentCulture` property with `CultureInfo.InvariantCulture` in the calls to `DateTime.ToString(String, IFormatProvider)` and `DateTime.Parse(String, IFormatProvider)`, the persisted date and time data is successfully restored, as the following output shows:

Console

```
06.05.1758 21:26
05.05.1818 07:19
22.04.1870 23:54
08.09.1890 06:47
18.02.1905 15:12
```

Behavior changes when comparing strings on .NET 5+

Article • 04/19/2023

.NET 5 introduces a runtime behavioral change where globalization APIs [use ICU by default](#) across all supported platforms. This is a departure from earlier versions of .NET Core and from .NET Framework, which utilize the operating system's national language support (NLS) functionality when running on Windows. For more information on these changes, including compatibility switches that can revert the behavior change, see [.NET globalization and ICU](#).

Reason for change

This change was introduced to unify .NET's globalization behavior across all supported operating systems. It also provides the ability for applications to bundle their own globalization libraries rather than depend on the OS's built-in libraries. For more information, see [the breaking change notification](#).

Behavioral differences

If you use functions like `string.IndexOf(string)` without calling the overload that takes a [StringComparison](#) argument, you might intend to perform an *ordinal* search, but instead you inadvertently take a dependency on culture-specific behavior. Since NLS and ICU implement different logic in their linguistic comparers, the results of methods like `string.IndexOf(string)` can return unexpected values.

This can manifest itself even in places where you aren't always expecting globalization facilities to be active. For example, the following code can produce a different answer depending on the current runtime.

C#

```
const string greeting = "He\0llo";
Console.WriteLine(${greeting.IndexOf("\0")});

// The snippet prints:
//
// '3' when running on .NET Core 2.x - 3.x (Windows)
// '0' when running on .NET 5 or later (Windows)
// '0' when running on .NET Core 2.x - 3.x or .NET 5 (non-Windows)
// '3' when running on .NET Core 2.x or .NET 5+ (in invariant mode)
```

```
string s = "Hello\r\nworld!";
int idx = s.IndexOf("\n");
Console.WriteLine(idx);

// The snippet prints:
//
// '6' when running on .NET Core 3.1
// '-1' when running on .NET 5 or .NET Core 3.1 (non-Windows OS)
// '-1' when running on .NET 5 (Windows 10 May 2019 Update or later)
// '6' when running on .NET 6+ (all Windows and non-Windows OS)
```

For more information, see [Globalization APIs use ICU libraries on Windows](#).

Guard against unexpected behavior

This section provides two options for dealing with unexpected behavior changes in .NET 5.

Enable code analyzers

[Code analyzers](#) can detect possibly buggy call sites. To help guard against any surprising behaviors, we recommend enabling .NET compiler platform (Roslyn) analyzers in your project. The analyzers help flag code that might inadvertently be using a linguistic comparer when an ordinal comparer was likely intended. The following rules should help flag these issues:

- [CA1307: Specify StringComparison for clarity](#)
- [CA1309: Use ordinal StringComparison](#)
- [CA1310: Specify StringComparison for correctness](#)

These specific rules aren't enabled by default. To enable them and show any violations as build errors, set the following properties in your project file:

XML

```
<PropertyGroup>
  <AnalysisMode>All</AnalysisMode>

  <WarningsAsErrors>$([WarningsAsErrors]);CA1307;CA1309;CA1310</WarningsAsErrors>
>
</PropertyGroup>
```

The following snippet shows examples of code that produces the relevant code analyzer warnings or errors.

C#

```
//  
// Potentially incorrect code - answer might vary based on locale.  
//  
string s = GetString();  
// Produces analyzer warning CA1310 for string; CA1307 matches on char ','  
int idx = s.IndexOf(",");  
Console.WriteLine(idx);  
  
//  
// Corrected code - matches the literal substring ",".  
//  
string s = GetString();  
int idx = s.IndexOf(",", StringComparison.Ordinal);  
Console.WriteLine(idx);  
  
//  
// Corrected code (alternative) - searches for the literal ',' character.  
//  
string s = GetString();  
int idx = s.IndexOf(',');  
Console.WriteLine(idx);
```

Similarly, when instantiating a sorted collection of strings or sorting an existing string-based collection, specify an explicit comparer.

C#

```
//  
// Potentially incorrect code - behavior might vary based on locale.  
//  
SortedSet<string> mySet = new SortedSet<string>();  
List<string> list = GetListOfStrings();  
list.Sort();  
  
//  
// Corrected code - uses ordinal sorting; doesn't vary by locale.  
//  
SortedSet<string> mySet = new SortedSet<string>(StringComparer.OrdinalIgnoreCase);  
List<string> list = GetListOfStrings();  
list.Sort(StringComparer.OrdinalIgnoreCase);
```

Revert back to NLS behaviors

To revert .NET 5+ applications back to older NLS behaviors when running on Windows, follow the steps in [.NET Globalization and ICU](#). This application-wide compatibility switch must be set at the application level. Individual libraries cannot opt-in or opt-out of this behavior.

💡 Tip

We strongly recommend you enable the [CA1307](#), [CA1309](#), and [CA1310](#) code analysis rules to help improve code hygiene and discover any existing latent bugs. For more information, see [Enable code analyzers](#).

Affected APIs

Most .NET applications won't encounter any unexpected behaviors due to the changes in .NET 5. However, due to the number of affected APIs and how foundational these APIs are to the wider .NET ecosystem, you should be aware of the potential for .NET 5 to introduce unwanted behaviors or to expose latent bugs that already exist in your application.

The affected APIs include:

- [System.String.Compare](#)
- [System.String.EndsWith](#)
- [System.String.IndexOf](#)
- [System.String.StartsWith](#)
- [System.String.ToLower](#)
- [System.String.ToLowerInvariant](#)
- [System.String.ToUpper](#)
- [System.String.ToUpperInvariant](#)
- [System.Globalization.TextInfo](#) (most members)
- [System.Globalization.CompareInfo](#) (most members)
- [System.Array.Sort](#) (when sorting arrays of strings)
- [System.Collections.Generic.List<T>.Sort\(\)](#) (when the list elements are strings)
- [System.Collections.Generic.SortedDictionary< TKey, TValue >](#) (when the keys are strings)
- [System.Collections.Generic.SortedList< TKey, TValue >](#) (when the keys are strings)
- [System.Collections.Generic.SortedSet< T >](#) (when the set contains strings)

⚠ Note

This is not an exhaustive list of affected APIs.

All of the above APIs use *linguistic* string searching and comparison using the thread's [current culture](#), by default. The differences between *linguistic* and *ordinal* search and comparison are called out in the [Ordinal vs. linguistic search and comparison](#).

Because ICU implements linguistic string comparisons differently from NLS, Windows-based applications that upgrade to .NET 5 from an earlier version of .NET Core or .NET Framework and that call one of the affected APIs may notice that the APIs begin exhibiting different behaviors.

Exceptions

- If an API accepts an explicit `StringComparison` or `CultureInfo` parameter, that parameter overrides the API's default behavior.
- `System.String` members where the first parameter is of type `char` (for example, `String.IndexOf(Char)`) use ordinal searching, unless the caller passes an explicit `StringComparison` argument that specifies `CurrentCulture[IgnoreCase]` or `InvariantCulture[IgnoreCase]`.

For a more detailed analysis of the default behavior of each `String` API, see the [Default search and comparison types](#) section.

Ordinal vs. linguistic search and comparison

Ordinal (also known as *non-linguistic*) search and comparison decomposes a string into its individual `char` elements and performs a char-by-char search or comparison. For example, the strings `"dog"` and `"dog"` compare as *equal* under an `Ordinal` comparer, since the two strings consist of the exact same sequence of chars. However, `"dog"` and `"Dog"` compare as *not equal* under an `Ordinal` comparer, because they don't consist of the exact same sequence of chars. That is, uppercase `'D'`'s code point `U+0044` occurs before lowercase `'d'`'s code point `U+0064`, resulting in `"Dog"` sorting before `"dog"`.

An `OrdinalIgnoreCase` comparer still operates on a char-by-char basis, but it eliminates case differences while performing the operation. Under an `OrdinalIgnoreCase` comparer, the char pairs `'d'` and `'D'` compare as *equal*, as do the char pairs `'á'` and `'Á'`. But the unaccented char `'a'` compares as *not equal* to the accented char `'á'`.

Some examples of this are provided in the following table:

| String 1 | String 2 | Ordinal comparison | OrdinalIgnoreCase comparison |
|-----------------------|-----------------------|--------------------|------------------------------|
| <code>"dog"</code> | <code>"dog"</code> | equal | equal |
| <code>"dog"</code> | <code>"Dog"</code> | not equal | equal |
| <code>"resume"</code> | <code>"résumé"</code> | not equal | not equal |

Unicode also allows strings to have several different in-memory representations. For example, an e-acute (é) can be represented in two possible ways:

- A single literal 'é' character (also written as '\u00E9').
- A literal unaccented 'e' character followed by a combining accent modifier character '\u0301'.

This means that the following *four* strings all display as "résumé", even though their constituent pieces are different. The strings use a combination of literal 'é' characters or literal unaccented 'e' characters plus the combining accent modifier '\u0301'.

- "r\u00E9sum\u00E9"
- "r\u00E9sume\u0301"
- "re\u0301sum\u00E9"
- "re\u0301sume\u0301"

Under an ordinal comparer, none of these strings compare as equal to each other. This is because they all contain different underlying char sequences, even though when they're rendered to the screen, they all look the same.

When performing a `string.IndexOf(..., StringComparison.OrdinalIgnoreCase)` operation, the runtime looks for an exact substring match. The results are as follows.

C#

```
Console.WriteLine("resume".IndexOf("e", StringComparison.OrdinalIgnoreCase)); // prints '1'
Console.WriteLine("r\u00E9sum\u00E9".IndexOf("e", StringComparison.OrdinalIgnoreCase)); // prints '-1'
Console.WriteLine("r\u00E9sume\u0301".IndexOf("e", StringComparison.OrdinalIgnoreCase)); // prints '5'
Console.WriteLine("re\u0301sum\u00E9".IndexOf("e", StringComparison.OrdinalIgnoreCase)); // prints '1'
Console.WriteLine("re\u0301sume\u0301".IndexOf("e", StringComparison.OrdinalIgnoreCase)); // prints '1'
Console.WriteLine("resume".IndexOf("E", StringComparison.OrdinalIgnoreCase)); // prints '1'
Console.WriteLine("r\u00E9sum\u00E9".IndexOf("E", StringComparison.OrdinalIgnoreCase)); // prints '-1'
Console.WriteLine("r\u00E9sume\u0301".IndexOf("E", StringComparison.OrdinalIgnoreCase)); // prints '5'
Console.WriteLine("re\u0301sum\u00E9".IndexOf("E", StringComparison.OrdinalIgnoreCase)); // prints '1'
Console.WriteLine("re\u0301sume\u0301".IndexOf("E", StringComparison.OrdinalIgnoreCase)); // prints '1'
```

Ordinal search and comparison routines are never affected by the current thread's culture setting.

Linguistic search and comparison routines decompose a string into *collation elements* and perform searches or comparisons on these elements. There's not necessarily a 1:1 mapping between a string's characters and its constituent collation elements. For example, a string of length 2 may consist of only a single collation element. When two strings are compared in a linguistic-aware fashion, the comparer checks whether the two strings' collation elements have the same semantic meaning, even if the string's literal characters are different.

Consider again the string "résumé" and its four different representations. The following table shows each representation broken down into its collation elements.

| String | As collation elements |
|--------------------|---|
| "r\u00E9sum\u00E9" | "r" + "\u00E9" + "s" + "u" + "m" + "\u00E9" |
| "r\u00E9sum\u0301" | "r" + "\u00E9" + "s" + "u" + "m" + "e\u0301" |
| "r\u0301sum\u00E9" | "r" + "e\u0301" + "s" + "u" + "m" + "\u00E9" |
| "r\u0301sum\u0301" | "r" + "e\u0301" + "s" + "u" + "m" + "e\u0301" |

A collation element corresponds loosely to what readers would think of as a single character or cluster of characters. It's conceptually similar to a [grapheme cluster](#) but encompasses a somewhat larger umbrella.

Under a linguistic comparer, exact matches aren't necessary. Collation elements are instead compared based on their semantic meaning. For example, a linguistic comparer treats the substrings "\u00E9" and "e\u0301" as equal since they both semantically mean "a lowercase e with an acute accent modifier." This allows the `IndexOf` method to match the substring "e\u0301" within a larger string that contains the semantically equivalent substring "\u00E9", as shown in the following code sample.

C#

```
Console.WriteLine("r\u00E9sum\u00E9.IndexOf("e")); // prints '-1' (not found)
Console.WriteLine("r\u00E9sum\u00E9.IndexOf("\u00E9")); // prints '1'
Console.WriteLine("\u00E9.IndexOf("e\u0301")); // prints '0'
```

As a consequence of this, two strings of different lengths may compare as equal if a linguistic comparison is used. Callers should take care not to special-case logic that deals with string length in such scenarios.

Culture-aware search and comparison routines are a special form of linguistic search and comparison routines. Under a culture-aware comparer, the concept of a collation element is extended to include information specific to the specified culture.

For example, [in the Hungarian alphabet](#), when the two characters <dz> appear back-to-back, they are considered their own unique letter distinct from either <d> or <z>. This means that when <dz> is seen in a string, a Hungarian culture-aware comparer treats it as a single collation element.

| String | As collation elements | Remarks |
|--------|-----------------------|--|
| "endz" | "e" + "n" + "d" + "z" | (using a standard linguistic comparer) |
| "endz" | "e" + "n" + "dz" | (using a Hungarian culture-aware comparer) |

When using a Hungarian culture-aware comparer, this means that the string "endz" *does not* end with the substring "z", as <dz> and <z> are considered collation elements with different semantic meaning.

C#

```
// Set thread culture to Hungarian
CultureInfo.CurrentCulture = CultureInfo.GetCultureInfo("hu-HU");
Console.WriteLine("endz".EndsWith("z")); // Prints 'False'

// Set thread culture to invariant culture
CultureInfo.CurrentCulture = CultureInfo.InvariantCulture;
Console.WriteLine("endz".EndsWith("z")); // Prints 'True'
```

ⓘ Note

- Behavior: Linguistic and culture-aware comparers can undergo behavioral adjustments from time to time. Both ICU and the older Windows NLS facility are updated to account for how world languages change. For more information, see the blog post [Locale \(culture\) data churn](#). The *Ordinal* comparer's behavior will never change since it performs exact bitwise searching and comparison. However, the *OrdinalIgnoreCase* comparer's behavior may change as Unicode grows to encompass more character sets and corrects omissions in existing casing data.
- Usage: The comparers `StringComparison.InvariantCulture` and `StringComparison.InvariantCultureIgnoreCase` are linguistic comparers that are not culture-aware. That is, these comparers understand concepts such as

the accented character é having multiple possible underlying representations, and that all such representations should be treated equal. But non-culture-aware linguistic comparers won't contain special handling for <dz> as distinct from <d> or <z>, as shown above. They also won't special-case characters like the German Eszett (ß).

.NET also offers the *invariant globalization mode*. This opt-in mode disables code paths that deal with linguistic search and comparison routines. In this mode, all operations use *Ordinal* or *OrdinalIgnoreCase* behaviors, regardless of what `CultureInfo` or `StringComparison` argument the caller provides. For more information, see [Runtime configuration options for globalization](#) and [.NET Core Globalization Invariant Mode](#).

For more information, see [Best practices for comparing strings in .NET](#).

Security implications

If your app uses an affected API for filtering, we recommend enabling the CA1307 and CA1309 code analysis rules to help locate places where a linguistic search may have inadvertently been used instead of an ordinal search. Code patterns like the following may be susceptible to security exploits.

C#

```
//  
// THIS SAMPLE CODE IS INCORRECT.  
// DO NOT USE IT IN PRODUCTION.  
  
public bool ContainsHtmlSensitiveCharacters(string input)  
{  
    if (input.IndexOf("<") >= 0) { return true; }  
    if (input.IndexOf("&") >= 0) { return true; }  
    return false;  
}
```

Because the `string.IndexOf(string)` method uses a linguistic search by default, it's possible for a string to contain a literal '`<`' or '`&`' character and for the `string.IndexOf(string)` routine to return `-1`, indicating that the search substring was not found. Code analysis rules CA1307 and CA1309 flag such call sites and alert the developer that there's a potential problem.

Default search and comparison types

The following table lists the default search and comparison types for various string and string-like APIs. If the caller provides an explicit `CultureInfo` or `StringComparison` parameter, that parameter will be honored over any default.

| API | Default behavior | Remarks |
|--------------------------------------|------------------|--|
| <code>string.Compare</code> | CurrentCulture | |
| <code>string.CompareTo</code> | CurrentCulture | |
| <code>string.Contains</code> | Ordinal | |
| <code>string.EndsWith</code> | Ordinal | (when the first parameter is a <code>char</code>) |
| <code>string.EndsWith</code> | CurrentCulture | (when the first parameter is a <code>string</code>) |
| <code>string.Equals</code> | Ordinal | |
| <code>string.GetHashCode</code> | Ordinal | |
| <code>string.IndexOf</code> | Ordinal | (when the first parameter is a <code>char</code>) |
| <code>string.IndexOf</code> | CurrentCulture | (when the first parameter is a <code>string</code>) |
| <code>string.IndexOfAny</code> | Ordinal | |
| <code>string.LastIndexOf</code> | Ordinal | (when the first parameter is a <code>char</code>) |
| <code>string.LastIndexOf</code> | CurrentCulture | (when the first parameter is a <code>string</code>) |
| <code>string.LastIndexOfAny</code> | Ordinal | |
| <code>string.Replace</code> | Ordinal | |
| <code>string.Split</code> | Ordinal | |
| <code>string.StartsWith</code> | Ordinal | (when the first parameter is a <code>char</code>) |
| <code>string.StartsWith</code> | CurrentCulture | (when the first parameter is a <code>string</code>) |
| <code>string.ToLower</code> | CurrentCulture | |
| <code>string.ToLowerInvariant</code> | InvariantCulture | |
| <code>string.ToUpper</code> | CurrentCulture | |
| <code>string.ToUpperInvariant</code> | InvariantCulture | |
| <code>string.Trim</code> | Ordinal | |
| <code>string.TrimEnd</code> | Ordinal | |

| API | Default behavior | Remarks |
|-------------------------------|------------------|---------|
| <code>string.TrimStart</code> | Ordinal | |
| <code>string == string</code> | Ordinal | |
| <code>string != string</code> | Ordinal | |

Unlike `string` APIs, all `MemoryExtensions` APIs perform *Ordinal* searches and comparisons by default, with the following exceptions.

| API | Default behavior | Remarks |
|--|-------------------------------|--|
| <code>MemoryExtensions.ToLower</code> | <code>CurrentCulture</code> | (when passed a null <code>CultureInfo</code> argument) |
| <code>MemoryExtensions.ToLowerInvariant</code> | <code>InvariantCulture</code> | |
| <code>MemoryExtensions.ToUpper</code> | <code>CurrentCulture</code> | (when passed a null <code>CultureInfo</code> argument) |
| <code>MemoryExtensions.ToUpperInvariant</code> | <code>InvariantCulture</code> | |

A consequence is that when converting code from consuming `string` to consuming `ReadOnlySpan<char>`, behavioral changes may be introduced inadvertently. An example of this follows.

```
C#
string str = GetString();
if (str.StartsWith("Hello")) { /* do something */ } // this is a CULTURE-AWARE (linguistic) comparison

ReadOnlySpan<char> span = s.AsSpan();
if (span.StartsWith("Hello")) { /* do something */ } // this is an ORDINAL (non-linguistic) comparison
```

The recommended way to address this is to pass an explicit `StringComparison` parameter to these APIs. The code analysis rules CA1307 and CA1309 can assist with this.

```
C#
string str = GetString();
if (str.StartsWith("Hello", StringComparison.OrdinalIgnoreCase)) { /* do something */ }
} // ordinal comparison
```

```
ReadOnlySpan<char> span = s.AsSpan();
if (span.StartsWith("Hello", StringComparison.Ordinal)) { /* do something */
} // ordinal comparison
```

Basic string operations in .NET

Article • 09/15/2021

Applications often respond to users by constructing messages based on user input. For example, it is not uncommon for websites to respond to a newly logged-on user with a specialized greeting that includes the user's name.

Several methods in the [System.String](#) and [System.Text.StringBuilder](#) classes allow you to dynamically construct custom strings to display in your user interface. These methods also help you perform a number of basic string operations like creating new strings from arrays of bytes, comparing the values of strings, and modifying existing strings.

Creating New Strings in .NET

Article • 09/15/2021

.NET allows strings to be created using simple assignment, and also overloads a class constructor to support string creation using a number of different parameters. .NET also provides several methods in the [System.String](#) class that create new string objects by combining several strings, arrays of strings, or objects.

Creating Strings Using Assignment

The easiest way to create a new [String](#) object is simply to assign a string literal to a [String](#) object.

Creating Strings Using a Class Constructor

You can use overloads of the [String](#) class constructor to create strings from character arrays. You can also create a new string by duplicating a particular character a specified number of times.

Methods that Return Strings

The following table lists several useful methods that return new string objects.

| Method | Use |
|-------------------------------|--|
| name | |
| String.Format | Builds a formatted string from a set of input objects. |
| String.Concat | Builds strings from two or more strings. |
| String.Join | Builds a new string by combining an array of strings. |
| String.Insert | Builds a new string by inserting a string into the specified index of an existing string. |
| String.CopyTo | Copies specified characters in a string into a specified position in an array of characters. |

Format

You can use the **String.Format** method to create formatted strings and concatenate strings representing multiple objects. This method automatically converts any passed object into a string. For example, if your application must display an **Int32** value and a **DateTime** value to the user, you can easily construct a string to represent these values using the **Format** method. For information about formatting conventions used with this method, see the section on [composite formatting](#).

The following example uses the **Format** method to create a string that uses an integer variable.

C#

```
int numberOfFleas = 12;
string miscInfo = String.Format("Your dog has {0} fleas. " +
                                 "It is time to get a flea collar. " +
                                 "The current universal date is: {1:u}.",
                                 numberOffleas, DateTime.Now);
Console.WriteLine(miscInfo);
// The example displays the following output:
//      Your dog has 12 fleas. It is time to get a flea collar.
//      The current universal date is: 2008-03-28 13:31:40Z.
```

In this example, **DateTime.Now** displays the current date and time in a manner specified by the culture associated with the current thread.

Concat

The **String.Concat** method can be used to easily create a new string object from two or more existing objects. It provides a language-independent way to concatenate strings. This method accepts any class that derives from **System.Object**. The following example creates a string from two existing string objects and a separating character.

C#

```
string helloString1 = "Hello";
string helloString2 = "World!";
Console.WriteLine(String.Concat(helloString1, ' ', helloString2));
// The example displays the following output:
//      Hello World!
```

Join

The **String.Join** method creates a new string from an array of strings and a separator string. This method is useful if you want to concatenate multiple strings together,

making a list perhaps separated by a comma.

The following example uses a space to bind a string array.

C#

```
string[] words = {"Hello", "and", "welcome", "to", "my" , "world!"};
Console.WriteLine(String.Join(" ", words));
// The example displays the following output:
//      Hello and welcome to my world!
```

Insert

The **String.Insert** method creates a new string by inserting a string into a specified position in another string. This method uses a zero-based index. The following example inserts a string into the fifth index position of `MyString` and creates a new string with this value.

C#

```
string sentence = "Once a time.";
Console.WriteLine(sentence.Insert(4, " upon"));
// The example displays the following output:
//      Once upon a time.
```

CopyTo

The **String.CopyTo** method copies portions of a string into an array of characters. You can specify both the beginning index of the string and the number of characters to be copied. This method takes the source index, an array of characters, the destination index, and the number of characters to copy. All indexes are zero-based.

The following example uses the **CopyTo** method to copy the characters of the word "Hello" from a string object to the first index position of an array of characters.

C#

```
string greeting = "Hello World!";
char[] charArray = {'W','h','e','r','e'};
Console.WriteLine("The original character array: {0}", new
string(charArray));
greeting.CopyTo(0, charArray,0 ,5);
Console.WriteLine("The new character array: {0}", new string(charArray));
// The example displays the following output:
```

```
//      The original character array: Where  
//      The new character array: Hello
```

Trim and remove characters from strings in .NET

Article • 10/04/2022

If you're parsing a sentence into individual words, you might end up with words that have blank spaces (also called white spaces) on either end of the word. In this situation, you can use one of the trim methods in the `System.String` class to remove any number of spaces or other characters from a specified position in the string. The following table describes the available trim methods:

| Method name | Use |
|-------------------------------|--|
| <code>String.Trim</code> | Removes white spaces or characters specified in an array of characters from the beginning and end of a string. |
| <code>String.TrimEnd</code> | Removes characters specified in an array of characters from the end of a string. |
| <code>String.TrimStart</code> | Removes characters specified in an array of characters from the beginning of a string. |
| <code>String.Remove</code> | Removes a specified number of characters from a specified index position in a string. |

Trim

You can easily remove white spaces from both ends of a string by using the `String.Trim` method, as shown in the following example:

C#

```
string MyString = " Big   ";
Console.WriteLine("Hello{0}World!", MyString);
string TrimString = MyString.Trim();
Console.WriteLine("Hello{0}World!", TrimString);
//      The example displays the following output:
//          Hello Big   World!
//          HelloBigWorld!
```

You can also remove characters that you specify in a character array from the beginning and end of a string. The following example removes white-space characters, periods, and asterisks:

C#

```
using System;

public class Example
{
    public static void Main()
    {
        String header = "* A Short String. *";
        Console.WriteLine(header);
        Console.WriteLine(header.Trim( new Char[] { ' ', '*', '.' } ));
    }
}

// The example displays the following output:
//      * A Short String. *
//      A Short String
```

TrimEnd

The `String.TrimEnd` method removes characters from the end of a string, creating a new string object. An array of characters is passed to this method to specify the characters to be removed. The order of the elements in the character array doesn't affect the trim operation. The trim stops when a character not specified in the array is found.

The following example removes the last letters of a string using the `TrimEnd` method. In this example, the position of the `'r'` character and the `'w'` character are reversed to illustrate that the order of characters in the array doesn't matter. Notice that this code removes the last word of `MyString` plus part of the first.

C#

```
string MyString = "Hello World!";
char[] MyChar = {'r','o','W','l','d','!', ' '};
string NewString = MyString.TrimEnd(MyChar);
Console.WriteLine(NewString);
```

This code displays `He` to the console.

The following example removes the last word of a string using the `TrimEnd` method. In this code, a comma follows the word `Hello` and because the comma isn't specified in the array of characters to trim, the trim ends at the comma.

C#

```
string MyString = "Hello, World!";
char[] MyChar = {'r','o','W','l','d','!', ' '};
```

```
string NewString = MyString.TrimEnd(MyChar);
Console.WriteLine(NewString);
```

This code displays `Hello,` to the console.

TrimStart

The `String.TrimStart` method is similar to the `String.TrimEnd` method except that it creates a new string by removing characters from the beginning of an existing string object. An array of characters is passed to the `TrimStart` method to specify the characters to be removed. As with the `TrimEnd` method, the order of the elements in the character array doesn't affect the trim operation. The trim stops when a character not specified in the array is found.

The following example removes the first word of a string. In this example, the position of the `'l'` character and the `'H'` character are reversed to illustrate that the order of characters in the array doesn't matter.

C#

```
string MyString = "Hello World!";
char[] MyChar = {'e', 'H', 'l', 'o', ' ' };
string NewString = MyString.TrimStart(MyChar);
Console.WriteLine(NewString);
```

This code displays `World!` to the console.

Remove

The `String.Remove` method removes a specified number of characters that begin at a specified position in an existing string. This method assumes a zero-based index.

The following example removes 10 characters from a string beginning at position five of a zero-based index of the string.

C#

```
string MyString = "Hello Beautiful World!";
Console.WriteLine(MyString.Remove(5,10));
// The example displays the following output:
//      Hello World!
```

Replace

You can also remove a specified character or substring from a string by calling the [String.Replace\(String, String\)](#) method and specifying an empty string ([String.Empty](#)) as the replacement. The following example removes all commas from a string:

C#

```
using System;

public class Example
{
    public static void Main()
    {
        String phrase = "a cold, dark night";
        Console.WriteLine("Before: {0}", phrase);
        phrase = phrase.Replace(",", "");
        Console.WriteLine("After: {0}", phrase);
    }
}

// The example displays the following output:
//      Before: a cold, dark night
//      After: a cold dark night
```

Padding Strings in .NET

Article • 09/15/2021

Use one of the following [String](#) methods to create a new string that consists of an original string that is padded with leading or trailing characters to a specified total length. The padding character can be a space or a specified character. The resulting string appears to be either right-aligned or left-aligned. If the original string's length is already equal to or greater than the desired total length, the padding methods return the original string unchanged; for more information, see the **Returns** sections of the two overloads of the [String.PadLeft](#) and [String.PadRight](#) methods.

| Method name | Use |
|---------------------------------|---|
| String.PadLeft | Pads a string with leading characters to a specified total length. |
| String.PadRight | Pads a string with trailing characters to a specified total length. |

PadLeft

The [String.PadLeft](#) method creates a new string by concatenating enough leading pad characters to an original string to achieve a specified total length. The [String.PadLeft\(Int32\)](#) method uses white space as the padding character and the [String.PadLeft\(Int32, Char\)](#) method enables you to specify your own padding character.

The following code example uses the [PadLeft](#) method to create a new string that is twenty characters long. The example displays "-----Hello World!" to the console.

C#

```
string MyString = "Hello World!";
Console.WriteLine(MyString.PadLeft(20, ' - '));
```

PadRight

The [String.PadRight](#) method creates a new string by concatenating enough trailing pad characters to an original string to achieve a specified total length. The [String.PadRight\(Int32\)](#) method uses white space as the padding character and the [String.PadRight\(Int32, Char\)](#) method enables you to specify your own padding character.

The following code example uses the [PadRight](#) method to create a new string that is twenty characters long. The example displays "Hello World!-----" to the console.

C#

```
string MyString = "Hello World!";
Console.WriteLine(MyString.PadRight(20, '-'));
```

Compare strings in .NET

Article • 09/15/2021

.NET provides several methods to compare the values of strings. The following table lists and describes the value-comparison methods.

| Method name | Use |
|---------------------------------------|---|
| String.Compare | Compares the values of two strings. Returns an integer value. |
| String.CompareOrdinal | Compares two strings without regard to local culture. Returns an integer value. |
| String.CompareTo | Compares the current string object to another string. Returns an integer value. |
| String.StartsWith | Determines whether a string begins with the string passed. Returns a Boolean value. |
| String.EndsWith | Determines whether a string ends with the string passed. Returns a Boolean value. |
| String.Contains | Determines whether a character or string occurs within another string. Returns a Boolean value. |
| String.Equals | Determines whether two strings are the same. Returns a Boolean value. |
| String.IndexOf | Returns the index position of a character or string, starting from the beginning of the string you are examining. Returns an integer value. |
| String.LastIndexOf | Returns the index position of a character or string, starting from the end of the string you are examining. Returns an integer value. |

Compare method

The static [String.Compare](#) method provides a thorough way of comparing two strings. This method is culturally aware. You can use this function to compare two strings or substrings of two strings. Additionally, overloads are provided that regard or disregard case and cultural variance. The following table shows the three integer values that this method might return.

| Return value | Condition |
|--------------------|--|
| A negative integer | The first string precedes the second string in the sort order. -or- |
| A positive integer | The first string follows the second string in the sort order. |

| Return value | Condition |
|--------------------|---|
| | The first string is <code>null</code> . |
| 0 | The first string and the second string are equal. -or- Both strings are <code>null</code> . |
| A positive integer | The first string follows the second string in the sort order. |
| -or- | -or- |
| 1 | The second string is <code>null</code> . |

ⓘ Important

The [String.Compare](#) method is primarily intended for use when ordering or sorting strings. You should not use the [String.Compare](#) method to test for equality (that is, to explicitly look for a return value of 0 with no regard for whether one string is less than or greater than the other). Instead, to determine whether two strings are equal, use the [String.Equals\(String, String, StringComparison\)](#) method.

The following example uses the [String.Compare](#) method to determine the relative values of two strings.

C#

```
string string1 = "Hello World!";
Console.WriteLine(String.Compare(string1, "Hello World?"));
```

This example displays `-1` to the console.

The preceding example is culture-sensitive by default. To perform a culture-insensitive string comparison, use an overload of the [String.Compare](#) method that allows you to specify the culture to use by supplying a *culture* parameter. For an example that demonstrates how to use the [String.Compare](#) method to perform a culture-insensitive comparison, see [Culture-insensitive string comparisons](#).

CompareOrdinal method

The `String.CompareOrdinal` method compares two string objects without considering the local culture. The return values of this method are identical to the values returned by the `Compare` method in the previous table.

ⓘ Important

The `String.CompareOrdinal` method is primarily intended for use when ordering or sorting strings. You should not use the `String.CompareOrdinal` method to test for equality (that is, to explicitly look for a return value of 0 with no regard for whether one string is less than or greater than the other). Instead, to determine whether two strings are equal, use the `String.Equals(String, String, StringComparison)` method.

The following example uses the `CompareOrdinal` method to compare the values of two strings.

C#

```
string string1 = "Hello World!";
Console.WriteLine(String.CompareOrdinal(string1, "hello world!"));
```

This example displays `-32` to the console.

CompareTo method

The `String.CompareTo` method compares the string that the current string object encapsulates to another string or object. The return values of this method are identical to the values returned by the `String.Compare` method in the previous table.

ⓘ Important

The `String.CompareTo` method is primarily intended for use when ordering or sorting strings. You should not use the `String.CompareTo` method to test for equality (that is, to explicitly look for a return value of 0 with no regard for whether one string is less than or greater than the other). Instead, to determine whether two strings are equal, use the `String.Equals(String, String, StringComparison)` method.

The following example uses the `String.CompareTo` method to compare the `string1` object to the `string2` object.

C#

```
string string1 = "Hello World";
string string2 = "Hello World!";
int MyInt = string1.CompareTo(string2);
Console.WriteLine( MyInt );
```

This example displays `-1` to the console.

All overloads of the [String.CompareTo](#) method perform culture-sensitive and case-sensitive comparisons by default. No overloads of this method are provided that allow you to perform a culture-insensitive comparison. For code clarity, we recommend that you use the [String.Compare](#) method instead, specifying [CultureInfo.CurrentCulture](#) for culture-sensitive operations or [CultureInfo.InvariantCulture](#) for culture-insensitive operations. For examples that demonstrate how to use the [String.Compare](#) method to perform both culture-sensitive and culture-insensitive comparisons, see [Performing Culture-Insensitive String Comparisons](#).

Equals method

The [String.Equals](#) method can easily determine if two strings are the same. This case-sensitive method returns a `true` or `false` Boolean value. It can be used from an existing class, as illustrated in the next example. The following example uses the [Equals](#) method to determine whether a string object contains the phrase "Hello World".

C#

```
string string1 = "Hello World";
Console.WriteLine(string1.Equals("Hello World"));
```

This example displays `True` to the console.

This method can also be used as a static method. The following example compares two string objects using a static method.

C#

```
string string1 = "Hello World";
string string2 = "Hello World";
Console.WriteLine(String.Equals(string1, string2));
```

This example displays `True` to the console.

StartsWith and EndsWith methods

You can use the [String.StartsWith](#) method to determine whether a string object begins with the same characters that encompass another string. This case-sensitive method returns `true` if the current string object begins with the passed string and `false` if it does not. The following example uses this method to determine if a string object begins with "Hello".

C#

```
string string1 = "Hello World";
Console.WriteLine(string1.StartsWith("Hello"));
```

This example displays `True` to the console.

The [String.EndsWith](#) method compares a passed string to the characters that exist at the end of the current string object. It also returns a Boolean value. The following example checks the end of a string using the `EndsWith` method.

C#

```
string string1 = "Hello World";
Console.WriteLine(string1.EndsWith("Hello"));
```

This example displays `False` to the console.

IndexOf and LastIndexOf methods

You can use the [String.IndexOf](#) method to determine the position of the first occurrence of a particular character within a string. This case-sensitive method starts counting from the beginning of a string and returns the position of a passed character using a zero-based index. If the character cannot be found, a value of `-1` is returned.

The following example uses the `IndexOf` method to search for the first occurrence of the '`l`' character in a string.

C#

```
string string1 = "Hello World";
Console.WriteLine(string1.IndexOf('l'));
```

This example displays `2` to the console.

The `String.LastIndexOf` method is similar to the `String.IndexOf` method except that it returns the position of the last occurrence of a particular character within a string. It is case-sensitive and uses a zero-based index.

The following example uses the `LastIndexOf` method to search for the last occurrence of the '`'l'`' character in a string.

C#

```
string string1 = "Hello World";
Console.WriteLine(string1.LastIndexOf('l'));
```

This example displays `9` to the console.

Both methods are useful when used in conjunction with the `String.Remove` method. You can use either the `IndexOf` or `LastIndexOf` methods to retrieve the position of a character, and then supply that position to the `Remove` method in order to remove a character or a word that begins with that character.

Change case in .NET

Article • 06/08/2022

If you write an application that accepts input from a user, you can never be sure what case (upper or lower) they will use to enter the data. Often, you want strings to be cased consistently, particularly if you are displaying them in the user interface. The following table describes three case-changing methods. The first two methods provide an overload that accepts a culture.

| Method name | Use |
|--------------------------------------|---|
| String.ToUpper | Converts all characters in a string to uppercase. |
| String.ToLower | Converts all characters in a string to lowercase. |
| TextInfo.ToTitleCase | Converts a string to title case. |

⚠ Warning

The [String.ToUpper](#) and [String.ToLower](#) methods should not be used to convert strings in order to compare them or test them for equality. For more information, see the [Compare strings of mixed case](#) section.

Compare strings of mixed case

To compare strings of mixed case to determine their ordering, call one of the overloads of the [String.CompareTo](#) method with a `comparisonType` parameter, and provide a value of either [StringComparison.CurrentCultureIgnoreCase](#), [StringComparison.InvariantCultureIgnoreCase](#), or [StringComparison.OrdinalIgnoreCase](#) for the `comparisonType` argument. For a comparison using a specific culture other than the current culture, call an overload of the [String.CompareTo](#) method with both a `culture` and `options` parameter, and provide a value of [CompareOptions.IgnoreCase](#) as the `options` argument.

To compare strings of mixed case to determine whether they're equal, call one of the overloads of the [String.Equals](#) method with a `comparisonType` parameter, and provide a value of either [StringComparison.CurrentCultureIgnoreCase](#), [StringComparison.InvariantCultureIgnoreCase](#), or [StringComparison.OrdinalIgnoreCase](#) for the `comparisonType` argument.

For more information, see [Best practices for using strings](#).

ToUpper method

The [String.ToUpper](#) method changes all characters in a string to uppercase. The following example converts the string "Hello World!" from mixed case to uppercase.

C#

```
string properString = "Hello World!";
Console.WriteLine(properString.ToUpper());
// This example displays the following output:
//      HELLO WORLD!
```

The preceding example is culture-sensitive by default; it applies the casing conventions of the current culture. To perform a culture-insensitive case change or to apply the casing conventions of a particular culture, use the [String.ToUpper\(CultureInfo\)](#) method overload and supply a value of [CultureInfo.InvariantCulture](#) or a [System.Globalization.CultureInfo](#) object that represents the specified culture to the `culture` parameter. For an example that demonstrates how to use the [ToUpper](#) method to perform a culture-insensitive case change, see [Perform culture-insensitive case changes](#).

ToLower method

The [String.ToLower](#) method is similar to the previous method, but instead converts all the characters in a string to lowercase. The following example converts the string "Hello World!" to lowercase.

C#

```
string properString = "Hello World!";
Console.WriteLine(properString.ToLower());
// This example displays the following output:
//      hello world!
```

The preceding example is culture-sensitive by default; it applies the casing conventions of the current culture. To perform a culture-insensitive case change or to apply the casing conventions of a particular culture, use the [String.ToLower\(CultureInfo\)](#) method overload and supply a value of [CultureInfo.InvariantCulture](#) or a [System.Globalization.CultureInfo](#) object that represents the specified culture to the `culture` parameter. For an example that demonstrates how to use the

[ToLower\(CultureInfo\)](#) method to perform a culture-insensitive case change, see [Perform culture-insensitive case changes](#).

ToTitleCase method

The [TextInfo.ToTitleCase](#) converts the first character of each word to uppercase and the remaining characters to lowercase. However, words that are entirely uppercase are assumed to be acronyms and are not converted.

The [TextInfo.ToTitleCase](#) method is culture-sensitive; that is, it uses the casing conventions of a particular culture. In order to call the method, you first retrieve the [TextInfo](#) object that represents the casing conventions of the particular culture from the [CultureInfo.TextInfo](#) property of a particular culture.

The following example passes each string in an array to the [TextInfo.ToTitleCase](#) method. The strings include proper title strings as well as acronyms. The strings are converted to title case by using the casing conventions of the English (United States) culture.

C#

```
using System;
using System.Globalization;

public class Example
{
    public static void Main()
    {
        string[] values = { "a tale of two cities", "gROWL to the rescue",
                           "inside the US government", "sports and MLB
baseball",
                           "The Return of Sherlock Holmes", "UNICEF and
children"};

        TextInfo ti = CultureInfo.CurrentCulture.TextInfo;
        foreach (var value in values)
            Console.WriteLine("{0} --> {1}", value, ti.ToTitleCase(value));
    }
}

// The example displays the following output:
//   a tale of two cities --> A Tale Of Two Cities
//   gROWL to the rescue --> Growl To The Rescue
//   inside the US government --> Inside The US Government
//   sports and MLB baseball --> Sports And MLB Baseball
//   The Return of Sherlock Holmes --> The Return Of Sherlock Holmes
//   UNICEF and children --> UNICEF And Children
```

Note that although it is culture-sensitive, the `TextInfo.ToTitleCase` method does not provide linguistically correct casing rules. For instance, in the previous example, the method converts "a tale of two cities" to "A Tale Of Two Cities". However, the linguistically correct title casing for the en-US culture is "A Tale of Two Cities."

Extract substrings from a string

Article • 09/15/2021

This article covers some different techniques for extracting parts of a string.

- Use the [Split method](#) when the substrings you want are separated by a known delimiting character (or characters).
- [Regular expressions](#) are useful when the string conforms to a fixed pattern.
- Use the [IndexOf](#) and [Substring methods](#) in conjunction when you don't want to extract *all* of the substrings in a string.

String.Split method

[String.Split](#) provides a handful of overloads to help you break up a string into a group of substrings based on one or more delimiting characters that you specify. You can choose to limit the total number of substrings in the final result, trim white-space characters from substrings, or exclude empty substrings.

The following examples show three different overloads of `String.Split()`. The first example calls the [Split\(Char\[\]\)](#) overload without passing any separator characters. When you don't specify any delimiting characters, `String.Split()` uses default delimiters, which are white-space characters, to split up the string.

C#

```
string s = "You win some. You lose some.";  
  
string[] subs = s.Split();  
  
foreach (string sub in subs)  
{  
    Console.WriteLine($"Substring: {sub}");  
}  
  
// This example produces the following output:  
//  
// Substring: You  
// Substring: win  
// Substring: some.  
// Substring: You  
// Substring: lose  
// Substring: some.
```

As you can see, the period characters (.) are included in two of the substrings. If you want to exclude the period characters, you can add the period character as an additional delimiting character. The next example shows how to do this.

C#

```
string s = "You win some. You lose some.";  
  
string[] subs = s.Split(' ', '.');  
  
foreach (string sub in subs)  
{  
    Console.WriteLine($"Substring: {sub}");  
}  
  
// This example produces the following output:  
//  
// Substring: You  
// Substring: win  
// Substring: some  
// Substring:  
// Substring: You  
// Substring: lose  
// Substring: some  
// Substring:
```

The periods are gone from the substrings, but now two extra empty substrings have been included. These empty substring represent the substring between the word and the period that follows it. To omit empty substrings from the resulting array, you can call the [Split\(Char\[\], StringSplitOptions\)](#) overload and specify [StringSplitOptions.RemoveEmptyEntries](#) for the `options` parameter.

C#

```
string s = "You win some. You lose some.";  
char[] separators = new char[] { ' ', '.' };  
  
string[] subs = s.Split(separators, StringSplitOptions.RemoveEmptyEntries);  
  
foreach (string sub in subs)  
{  
    Console.WriteLine($"Substring: {sub}");  
}  
  
// This example produces the following output:  
//  
// Substring: You  
// Substring: win  
// Substring: some  
// Substring: You
```

```
// Substring: lose  
// Substring: some
```

Regular expressions

If your string conforms to a fixed pattern, you can use a regular expression to extract and handle its elements. For example, if strings take the form "*number operand number*", you can use a [regular expression](#) to extract and handle the string's elements. Here's an example:

C#

```
String[] expressions = { "16 + 21", "31 * 3", "28 / 3",  
                        "42 - 18", "12 * 7",  
                        "2, 4, 6, 8" };  
String pattern = @"(\d+)\s+([-*/])\s+(\d+)";  
  
foreach (string expression in expressions)  
{  
    foreach (System.Text.RegularExpressions.Match m in  
        System.Text.RegularExpressions.Regex.Matches(expression, pattern))  
    {  
        int value1 = Int32.Parse(m.Groups[1].Value);  
        int value2 = Int32.Parse(m.Groups[3].Value);  
        switch (m.Groups[2].Value)  
        {  
            case "+":  
                Console.WriteLine("{0} = {1}", m.Value, value1 + value2);  
                break;  
            case "-":  
                Console.WriteLine("{0} = {1}", m.Value, value1 - value2);  
                break;  
            case "*":  
                Console.WriteLine("{0} = {1}", m.Value, value1 * value2);  
                break;  
            case "/":  
                Console.WriteLine("{0} = {1:N2}", m.Value, value1 / value2);  
                break;  
        }  
    }  
}  
  
// The example displays the following output:  
//      16 + 21 = 37  
//      31 * 3 = 93  
//      28 / 3 = 9.33  
//      42 - 18 = 24  
//      12 * 7 = 84
```

The regular expression pattern `(\d+)\s+([-+*/])\s+(\d+)` is defined like this:

| Pattern | Description |
|-----------------------|--|
| <code>(\d+)</code> | Match one or more decimal digits. This is the first capturing group. |
| <code>\s+</code> | Match one or more white-space characters. |
| <code>([-+*/])</code> | Match an arithmetic operator sign (+, -, *, or /). This is the second capturing group. |
| <code>\s+</code> | Match one or more white-space characters. |
| <code>(\d+)</code> | Match one or more decimal digits. This is the third capturing group. |

You can also use a regular expression to extract substrings from a string based on a pattern rather than a fixed set of characters. This is a common scenario when either of these conditions occurs:

- One or more of the delimiter characters does not *always* serve as a delimiter in the [String](#) instance.
- The sequence and number of delimiter characters is variable or unknown.

For example, the [Split](#) method cannot be used to split the following string, because the number of `\n` (newline) characters is variable, and they don't always serve as delimiters.

```
text

[This is captured\n{text.}]\n\n[\n[This is more captured text.]\n]
\n[Some more captured text:\n    Option1\n    Option2][Terse text.]
```

A regular expression can split this string easily, as the following example shows.

```
C#

String input = "[This is captured\n{text.}]\n\n[\n[This is more captured text.]\n]
\n[Some more captured text:\n    Option1" +
    "\n    Option2][Terse text.]";
String pattern = @"\[(^\[\]]+)\]";
int ctr = 0;

foreach (System.Text.RegularExpressions.Match m in
    System.Text.RegularExpressions.Regex.Matches(input, pattern))
{
    Console.WriteLine("{0}: {1}", ++ctr, m.Groups[1].Value);
}

// The example displays the following output:
```

```
//      1: This is captured
//      text.
//      2: This is more captured text.
//      3: Some more captured text:
//          Option1
//          Option2
//      4: Terse text.
```

The regular expression pattern `\[(\[^[\]]+\)]` is defined like this:

| Pattern | Description |
|---------------------------|--|
| <code>\[</code> | Match an opening bracket. |
| <code>([^\\[\\]]+)</code> | Match any character that is not an opening or a closing bracket one or more times. This is the first capturing group. |
| <code>\]</code> | Match a closing bracket. |

The [Regex.Split](#) method is almost identical to [String.Split](#), except that it splits a string based on a regular expression pattern instead of a fixed character set. For example, the following example uses the [Regex.Split](#) method to split a string that contains substrings delimited by various combinations of hyphens and other characters.

C#

```
String input = "abacus -- alabaster - * - atrium -+- " +
              "any -* - actual - + - armoire - - alarm";
String pattern = @"\s-\s?[*]? \s?- \s";
String[] elements = System.Text.RegularExpressions.Regex.Split(input,
pattern);

foreach (string element in elements)
    Console.WriteLine(element);

// The example displays the following output:
//      abacus
//      alabaster
//      atrium
//      any
//      actual
//      armoire
//      alarm
```

The regular expression pattern `\s-\s?[*]? \s?- \s` is defined like this:

| Pattern | Description |
|------------------|---|
| <code>\s-</code> | Match a white-space character followed by a hyphen. |

| Pattern | Description |
|---------|--|
| \s? | Match zero or one white-space character. |
| [+*]? | Match zero or one occurrence of either the + or * character. |
| \s? | Match zero or one white-space character. |
| -\s | Match a hyphen followed by a white-space character. |

String.IndexOf and String.Substring methods

If you aren't interested in all of the substrings in a string, you might prefer to work with one of the string comparison methods that returns the index at which the match begins. You can then call the [Substring](#) method to extract the substring that you want. The string comparison methods include:

- [IndexOf](#), which returns the zero-based index of the first occurrence of a character or string in a string instance.
- [IndexOfAny](#), which returns the zero-based index in the current string instance of the first occurrence of any character in a character array.
- [LastIndexOf](#), which returns the zero-based index of the last occurrence of a character or string in a string instance.
- [LastIndexOfAny](#), which returns a zero-based index in the current string instance of the last occurrence of any character in a character array.

The following example uses the [IndexOf](#) method to find the periods in a string. It then uses the [Substring](#) method to return full sentences.

C#

```
String s = "This is the first sentence in a string. " +
           "More sentences will follow. For example, " +
           "this is the third sentence. This is the " +
           "fourth. And this is the fifth and final " +
           "sentence.";
var sentences = new List<String>();
int start = 0;
int position;

// Extract sentences from the string.
do
{
    position = s.IndexOf('.', start);
```

```
if (position >= 0)
{
    sentences.Add(s.Substring(start, position - start + 1).Trim());
    start = position + 1;
}
} while (position > 0);

// Display the sentences.
foreach (var sentence in sentences)
    Console.WriteLine(sentence);

// The example displays the following output:
//      This is the first sentence in a string.
//      More sentences will follow.
//      For example, this is the third sentence.
//      This is the fourth.
//      And this is the fifth and final sentence.
```

Using the StringBuilder Class in .NET

Article • 09/15/2021

The [String](#) object is immutable. Every time you use one of the methods in the [System.String](#) class, you create a new string object in memory, which requires a new allocation of space for that new object. In situations where you need to perform repeated modifications to a string, the overhead associated with creating a new [String](#) object can be costly. The [System.Text.StringBuilder](#) class can be used when you want to modify a string without creating a new object. For example, using the [StringBuilder](#) class can boost performance when concatenating many strings together in a loop.

Importing the System.Text Namespace

The [StringBuilder](#) class is found in the [System.Text](#) namespace. To avoid having to provide a fully qualified type name in your code, you can import the [System.Text](#) namespace:

```
C#
```

```
using System;
using System.Text;
```

Instantiating a StringBuilder Object

You can create a new instance of the [StringBuilder](#) class by initializing your variable with one of the overloaded constructor methods, as illustrated in the following example.

```
C#
```

```
StringBuilder myStringBuilder = new StringBuilder("Hello World!");
```

Setting the Capacity and Length

Although the [StringBuilder](#) is a dynamic object that allows you to expand the number of characters in the string that it encapsulates, you can specify a value for the maximum number of characters that it can hold. This value is called the capacity of the object and should not be confused with the length of the string that the current [StringBuilder](#) holds. For example, you might create a new instance of the [StringBuilder](#) class with the string "Hello", which has a length of 5, and you might specify that the object has a

maximum capacity of 25. When you modify the [StringBuilder](#), it does not reallocate size for itself until the capacity is reached. When this occurs, the new space is allocated automatically and the capacity is doubled. You can specify the capacity of the [StringBuilder](#) class using one of the overloaded constructors. The following example specifies that the `myStringBuilder` object can be expanded to a maximum of 25 spaces.

C#

```
StringBuilder myStringBuilder = new StringBuilder("Hello World!", 25);
```

Additionally, you can use the read/write [Capacity](#) property to set the maximum length of your object. The following example uses the [Capacity](#) property to define the maximum object length.

C#

```
myStringBuilder.Capacity = 25;
```

The [EnsureCapacity](#) method can be used to check the capacity of the current [StringBuilder](#). If the capacity is greater than the passed value, no change is made; however, if the capacity is smaller than the passed value, the current capacity is changed to match the passed value.

The [Length](#) property can also be viewed or set. If you set the [Length](#) property to a value that is greater than the [Capacity](#) property, the [Capacity](#) property is automatically changed to the same value as the [Length](#) property. Setting the [Length](#) property to a value that is less than the length of the string within the current [StringBuilder](#) shortens the string.

Modifying the [StringBuilder](#) String

The following table lists the methods you can use to modify the contents of a [StringBuilder](#).

| Method name | Use |
|--|--|
| StringBuilder.Append | Appends information to the end of the current StringBuilder . |
| StringBuilder.AppendFormat | Replaces a format specifier passed in a string with formatted text. |
| StringBuilder.Insert | Inserts a string or object into the specified index of the current StringBuilder . |

| Method name | Use |
|---------------------------------------|---|
| StringBuilder.Remove | Removes a specified number of characters from the current StringBuilder . |
| StringBuilder.Replace | Replaces all occurrences of a specified character or string in the current StringBuilder with another specified character or string. |

Append

The **Append** method can be used to add text or a string representation of an object to the end of a string represented by the current **StringBuilder**. The following example initializes a **StringBuilder** to "Hello World" and then appends some text to the end of the object. Space is allocated automatically as needed.

C#

```
StringBuilder myStringBuilder = new StringBuilder("Hello World!");
myStringBuilder.Append(" What a beautiful day.");
Console.WriteLine(myStringBuilder);
// The example displays the following output:
//      Hello World! What a beautiful day.
```

AppendFormat

The [StringBuilder.AppendFormat](#) method adds text to the end of the **StringBuilder** object. It supports the composite formatting feature (for more information, see [Composite Formatting](#)) by calling the [IFormattable](#) implementation of the object or objects to be formatted. Therefore, it accepts the standard format strings for numeric, date and time, and enumeration values, the custom format strings for numeric and date and time values, and the format strings defined for custom types. (For information about formatting, see [Formatting Types](#).) You can use this method to customize the format of variables and append those values to a **StringBuilder**. The following example uses the [AppendFormat](#) method to place an integer value formatted as a currency value at the end of a **StringBuilder** object.

C#

```
int MyInt = 25;
StringBuilder myStringBuilder = new StringBuilder("Your total is ");
myStringBuilder.AppendFormat("{0:C} ", MyInt);
Console.WriteLine(myStringBuilder);
// The example displays the following output:
//      Your total is $25.00
```

Insert

The [Insert](#) method adds a string or object to a specified position in the current [StringBuilder](#) object. The following example uses this method to insert a word into the sixth position of a [StringBuilder](#) object.

C#

```
StringBuilder myStringBuilder = new StringBuilder("Hello World!");
myStringBuilder.Insert(6,"Beautiful ");
Console.WriteLine(myStringBuilder);
// The example displays the following output:
//      Hello Beautiful World!
```

Remove

You can use the [Remove](#) method to remove a specified number of characters from the current [StringBuilder](#) object, beginning at a specified zero-based index. The following example uses the [Remove](#) method to shorten a [StringBuilder](#) object.

C#

```
StringBuilder myStringBuilder = new StringBuilder("Hello World!");
myStringBuilder.Remove(5,7);
Console.WriteLine(myStringBuilder);
// The example displays the following output:
//      Hello
```

Replace

The [Replace](#) method can be used to replace characters within the [StringBuilder](#) object with another specified character. The following example uses the [Replace](#) method to search a [StringBuilder](#) object for all instances of the exclamation point character (!) and replace them with the question mark character (?).

C#

```
StringBuilder myStringBuilder = new StringBuilder("Hello World!");
myStringBuilder.Replace('!', '?');
Console.WriteLine(myStringBuilder);
// The example displays the following output:
//      Hello World?
```

Converting a `StringBuilder` Object to a `String`

You must convert the `StringBuilder` object to a `String` object before you can pass the string represented by the `StringBuilder` object to a method that has a `String` parameter or display it in the user interface. You do this conversion by calling the `StringBuilder.ToString` method. The following example calls a number of `StringBuilder` methods and then calls the `StringBuilder.ToString()` method to display the string.

C#

```
using System;
using System.Text;

public class Example
{
    public static void Main()
    {
        StringBuilder sb = new StringBuilder();
        bool flag = true;
        string[] spellings = { "recieve", "receeve", "receive" };
        sb.AppendFormat("Which of the following spellings is {0}:", flag);
        sb.AppendLine();
        for (int ctr = 0; ctr <= spellings.GetUpperBound(0); ctr++) {
            sb.AppendFormat(" {0}. {1}", ctr, spellings[ctr]);
            sb.AppendLine();
        }
        sb.AppendLine();
        Console.WriteLine(sb.ToString());
    }
}
// The example displays the following output:
//      Which of the following spellings is True:
//          0. recieve
//          1. receeve
//          2. receive
```

How to: Perform Basic String Manipulations in .NET

Article • 09/15/2021

The following example uses some of the methods discussed in the [Basic String Operations](#) topics to construct a class that performs string manipulations in a manner that might be found in a real-world application. The `MailToData` class stores the name and address of an individual in separate properties and provides a way to combine the `City`, `State`, and `Zip` fields into a single string for display to the user. Furthermore, the class allows the user to enter the city, state, and zip code information as a single string. The application automatically parses the single string and enters the proper information into the corresponding property.

For simplicity, this example uses a console application with a command-line interface.

Example

C#

```
using System;

class MainClass
{
    static void Main()
    {
        MailToData MyData = new MailToData();

        Console.Write("Enter Your Name: ");
        MyData.Name = Console.ReadLine();
        Console.Write("Enter Your Address: ");
        MyData.Address = Console.ReadLine();
        Console.Write("Enter Your City, State, and ZIP Code separated by
spaces: ");
        MyData.CityStateZip = Console.ReadLine();
        Console.WriteLine();

        if (MyData.Validated) {
            Console.WriteLine("Name: {0}", MyData.Name);
            Console.WriteLine("Address: {0}", MyData.Address);
            Console.WriteLine("City: {0}", MyData.City);
            Console.WriteLine("State: {0}", MyData.State);
            Console.WriteLine("Zip: {0}", MyData.Zip);

            Console.WriteLine("\nThe following address will be used:");
            Console.WriteLine(MyData.Address);
            Console.WriteLine(MyData.CityStateZip);
```

```
        }
    }

public class MailToData
{
    string name = "";
    string address = "";
    string citystatezip = "";
    string city = "";
    string state = "";
    string zip = "";
    bool parseSucceeded = false;

    public string Name
    {
        get{return name;}
        set{name = value;}
    }

    public string Address
    {
        get{return address;}
        set{address = value;}
    }

    public string CityStateZip
    {
        get {
            return String.Format("{0}, {1} {2}", city, state, zip);
        }
        set {
            citystatezip = value.Trim();
            ParseCityStateZip();
        }
    }

    public string City
    {
        get{return city;}
        set{city = value;}
    }

    public string State
    {
        get{return state;}
        set{state = value;}
    }

    public string Zip
    {
        get{return zip;}
        set{zip = value;}
    }
}
```

```

public bool Validated
{
    get { return parseSucceeded; }
}

private void ParseCityStateZip()
{
    string msg = "";
    const string msgEnd = "\nYou must enter spaces between city, state,
and zip code.\n";

    // Throw a FormatException if the user did not enter the necessary
    // spaces
    // between elements.
    try
    {
        // City may consist of multiple words, so we'll have to parse the
        // string from right to left starting with the zip code.
        int zipIndex = citystatezip.LastIndexOf(" ");
        if (zipIndex == -1) {
            msg = "\nCannot identify a zip code." + msgEnd;
            throw new FormatException(msg);
        }
        zip = citystatezip.Substring(zipIndex + 1);

        int stateIndex = citystatezip.LastIndexOf(" ", zipIndex - 1);
        if (stateIndex == -1) {
            msg = "\nCannot identify a state." + msgEnd;
            throw new FormatException(msg);
        }
        state = citystatezip.Substring(stateIndex + 1, zipIndex -
stateIndex - 1);
        state = state.ToUpper();

        city = citystatezip.Substring(0, stateIndex);
        if (city.Length == 0) {
            msg = "\nCannot identify a city." + msgEnd;
            throw new FormatException(msg);
        }
        parseSucceeded = true;
    }
    catch (FormatException ex)
    {
        Console.WriteLine(ex.Message);
    }
}

private string ReturnCityStateZip()
{
    // Make state uppercase.
    state = state.ToUpper();

    // Put the value of city, state, and zip together in the proper
    // manner.
    string MyCityStateZip = String.Concat(city, " ", state, " ", zip);
}

```

```
        return MyCityStateZip;  
    }  
}
```

When the preceding code is executed, the user is asked to enter their name and address. The application places the information in the appropriate properties and displays the information back to the user, creating a single string that displays the city, state, and zip code information.

Parse strings in .NET

Article • 09/15/2021

A *parsing* operation converts a string that represents a .NET base type into that base type. For example, a parsing operation is used to convert a string to a floating-point number or to a date-and-time value. The method most commonly used to perform a parsing operation is the `Parse` method. Because parsing is the reverse operation of formatting (which involves converting a base type into its string representation), many of the same rules and conventions apply. Just as formatting uses an object that implements the `IFormatProvider` interface to provide culture-sensitive formatting information, parsing also uses an object that implements the `IFormatProvider` interface to determine how to interpret a string representation. For more information, see [Format types](#).

Parsing numeric strings in .NET

Article • 10/04/2022

All numeric types have two static parsing methods, `Parse` and `TryParse`, that you can use to convert the string representation of a number into a numeric type. These methods enable you to parse strings that were produced by using the format strings documented in [Standard Numeric Format Strings](#) and [Custom Numeric Format Strings](#). By default, the `Parse` and `TryParse` methods can successfully convert strings that contain integral decimal digits only to integer values. They can successfully convert strings that contain integral and fractional decimal digits, group separators, and a decimal separator to floating-point values. The `Parse` method throws an exception if the operation fails, whereas the `TryParse` method returns `false`.

ⓘ Note

Starting in .NET 7, the numeric types in .NET also implement the `System.IParseable<TSelf>` interface, which defines the `IParsable<TSelf>.Parse` and `IParsable<TSelf>.TryParse` methods.

Parsing and format providers

Typically, the string representations of numeric values differ by culture. Elements of numeric strings, such as currency symbols, group (or thousands) separators, and decimal separators, all vary by culture. Parsing methods either implicitly or explicitly use a format provider that recognizes these culture-specific variations. If no format provider is specified in a call to the `Parse` or `TryParse` method, the format provider associated with the current culture (the `NumberFormatInfo` object returned by the `NumberFormatInfo.CurrentInfo` property) is used.

A format provider is represented by an `IFormatProvider` implementation. This interface has a single member, the `GetFormat` method, whose single parameter is a `Type` object that represents the type to be formatted. This method returns the object that provides formatting information. .NET supports the following two `IFormatProvider` implementations for parsing numeric strings:

- A `CultureInfo` object whose `CultureInfo.GetFormat` method returns a `NumberFormatInfo` object that provides culture-specific formatting information.

- A [NumberFormatInfo](#) object whose [NumberFormatInfo.GetFormat](#) method returns itself.

The following example tries to convert each string in an array to a [Double](#) value. It first tries to parse the string by using a format provider that reflects the conventions of the English (United States) culture. If this operation throws a [FormatException](#), it tries to parse the string by using a format provider that reflects the conventions of the French (France) culture.

C#

```
using System;
using System.Globalization;

public class Example
{
    public static void Main()
    {
        string[] values = { "1,304.16", "$1,456.78", "1,094", "152",
                            "123,45 €", "1 304,16", "Ae9f" };
        double number;
        CultureInfo culture = null;

        foreach (string value in values) {
            try {
                culture = CultureInfo.CreateSpecificCulture("en-US");
                number = Double.Parse(value, culture);
                Console.WriteLine("{0}: {1} --> {2}", culture.Name, value,
number);
            }
            catch (FormatException) {
                Console.WriteLine("{0}: Unable to parse '{1}'.",
culture.Name, value);
                culture = CultureInfo.CreateSpecificCulture("fr-FR");
                try {
                    number = Double.Parse(value, culture);
                    Console.WriteLine("{0}: {1} --> {2}", culture.Name, value,
number);
                }
                catch (FormatException) {
                    Console.WriteLine("{0}: Unable to parse '{1}'.",
culture.Name, value);
                }
            }
            Console.WriteLine();
        }
    }
}

// The example displays the following output:
//      en-US: 1,304.16 --> 1304.16
//
//      en-US: Unable to parse '$1,456.78'.
```

```
//    fr-FR: Unable to parse '$1,456.78'.
//
//    en-US: 1,094 --> 1094
//
//    en-US: 152 --> 152
//
//    en-US: Unable to parse '123,45 €'.
//    fr-FR: Unable to parse '123,45 €'.
//
//    en-US: Unable to parse '1 304,16'.
//    fr-FR: 1 304,16 --> 1304.16
//
//    en-US: Unable to parse 'Ae9f'.
//    fr-FR: Unable to parse 'Ae9f'.
```

Parsing and NumberStyles Values

The style elements (such as white space, group separators, and decimal separator) that the parse operation can handle are defined by a [NumberStyles](#) enumeration value. By default, strings that represent integer values are parsed by using the [NumberStyles.Integer](#) value, which permits only numeric digits, leading and trailing white space, and a leading sign. Strings that represent floating-point values are parsed using a combination of the [NumberStyles.Float](#) and [NumberStyles.AllowThousands](#) values; this composite style permits decimal digits along with leading and trailing white space, a leading sign, a decimal separator, a group separator, and an exponent. By calling an overload of the [Parse](#) or [TryParse](#) method that includes a parameter of type [NumberStyles](#) and setting one or more [NumberStyles](#) flags, you can control the style elements that can be present in the string for the parse operation to succeed.

For example, a string that contains a group separator can't be converted to an [Int32](#) value by using the [Int32.Parse\(String\)](#) method. However, the conversion succeeds if you use the [NumberStyles.AllowThousands](#) flag, as the following example illustrates.

C#

```
using System;
using System.Globalization;

public class Example
{
    public static void Main()
    {
        string value = "1,304";
        int number;
        IFormatProvider provider = CultureInfo.CreateSpecificCulture("en-US");
        if (Int32.TryParse(value, out number))
            Console.WriteLine("{0} --> {1}", value, number);
```

```

        else
            Console.WriteLine("Unable to convert '{0}'", value);

        if (Int32.TryParse(value, NumberStyles.Integer |
NumberStyles.AllowThousands,
                    provider, out number))
            Console.WriteLine("{0} --> {1}", value, number);
        else
            Console.WriteLine("Unable to convert '{0}'", value);
    }
}

// The example displays the following output:
//      Unable to convert '1,304'
//      1,304 --> 1304

```

Warning

The parse operation always uses the formatting conventions of a particular culture. If you do not specify a culture by passing a [CultureInfo](#) or [NumberFormatInfo](#) object, the culture associated with the current thread is used.

The following table lists the members of the [NumberStyles](#) enumeration and describes the effect that they have on the parsing operation.

| NumberStyles value | Effect on the string to be parsed |
|---|--|
| NumberStyles.None | Only numeric digits are permitted. |
| NumberStyles.AllowDecimalPoint | The decimal separator and fractional digits are permitted. For integer values, only zero is permitted as a fractional digit. Valid decimal separators are determined by the NumberFormatInfo.NumberDecimalSeparator or NumberFormatInfo.CurrencyDecimalSeparator property. |
| NumberStyles.AllowExponent | The "e" or "E" character can be used to indicate exponential notation. For more information, see NumberStyles . |
| NumberStyles.AllowLeadingWhite | Leading white space is permitted. |
| NumberStyles.AllowTrailingWhite | Trailing white space is permitted. |
| NumberStyles.AllowLeadingSign | A positive or negative sign can precede numeric digits. |
| NumberStyles.AllowTrailingSign | A positive or negative sign can follow numeric digits. |
| NumberStyles.AllowParentheses | Parentheses can be used to indicate negative values. |

| NumberStyles value | Effect on the string to be parsed |
|----------------------------------|---|
| NumberStyles.AllowThousands | The group separator is permitted. The group separator character is determined by the NumberFormatInfo.NumberGroupSeparator or NumberFormatInfo.CurrencyGroupSeparator property. |
| NumberStyles.AllowCurrencySymbol | The currency symbol is permitted. The currency symbol is defined by the NumberFormatInfo.CurrencySymbol property. |
| NumberStyles.AllowHexSpecifier | The string to be parsed is interpreted as a hexadecimal number. It can include the hexadecimal digits 0-9, A-F, and a-f. This flag can be used only to parse integer values. |

In addition, the [NumberStyles](#) enumeration provides the following composite styles, which include multiple [NumberStyles](#) flags.

| Composite NumberStyles value | Includes members |
|------------------------------|---|
| NumberStyles.Integer | Includes the NumberStyles.AllowLeadingWhite , NumberStyles.AllowTrailingWhite , and NumberStyles.AllowLeadingSign styles. This is the default style used to parse integer values. |
| NumberStyles.Number | Includes the NumberStyles.AllowLeadingWhite , NumberStyles.AllowTrailingWhite , NumberStyles.AllowLeadingSign , NumberStyles.AllowTrailingSign , NumberStyles.AllowDecimalPoint , and NumberStyles.AllowThousands styles. |
| NumberStyles.Float | Includes the NumberStyles.AllowLeadingWhite , NumberStyles.AllowTrailingWhite , NumberStyles.AllowLeadingSign , NumberStyles.AllowDecimalPoint , and NumberStyles.AllowExponent styles. |
| NumberStyles.Currency | Includes all styles except NumberStyles.AllowExponent and NumberStyles.AllowHexSpecifier . |
| NumberStyles.Any | Includes all styles except NumberStyles.AllowHexSpecifier . |
| NumberStyles.HexNumber | Includes the NumberStyles.AllowLeadingWhite , NumberStyles.AllowTrailingWhite , and NumberStyles.AllowHexSpecifier styles. |

Parsing and Unicode Digits

The Unicode standard defines code points for digits in various writing systems. For example, code points from U+0030 to U+0039 represent the basic Latin digits 0 through 9, code points from U+09E6 to U+09EF represent the Bangla digits 0 through 9, and code points from U+FF10 to U+FF19 represent the Fullwidth digits 0 through 9. However, the only numeric digits recognized by parsing methods are the basic Latin digits 0-9 with code points from U+0030 to U+0039. If a numeric parsing method is passed a string that contains any other digits, the method throws a [FormatException](#).

The following example uses the [Int32.Parse](#) method to parse strings that consist of digits in different writing systems. As the output from the example shows, the attempt to parse the basic Latin digits succeeds, but the attempt to parse the Fullwidth, Arabic-Indic, and Bangla digits fails.

C#

```
using System;

public class Example
{
    public static void Main()
    {
        string value;
        // Define a string of basic Latin digits 1-5.
        value = "\u0031\u0032\u0033\u0034\u0035";
        ParseDigits(value);

        // Define a string of Fullwidth digits 1-5.
        value = "\uFF11\uFF12\uFF13\uFF14\uFF15";
        ParseDigits(value);

        // Define a string of Arabic-Indic digits 1-5.
        value = "\u0661\u0662\u0663\u0664\u0665";
        ParseDigits(value);

        // Define a string of Bangla digits 1-5.
        value = "\u09e7\u09e8\u09e9\u09ea\u09eb";
        ParseDigits(value);
    }

    static void ParseDigits(string value)
    {
        try {
            int number = Int32.Parse(value);
            Console.WriteLine("{0} --> {1}", value, number);
        }
        catch (FormatException) {
            Console.WriteLine("Unable to parse '{0}'.", value);
        }
    }
}

// The example displays the following output:
```

```
//      '12345' --> 12345
//      Unable to parse '1 2 3 4 5'.
//      Unable to parse '۱۲۳۴۵'.
//      Unable to parse '۱۲۳۸۶'.
```

Parse date and time strings in .NET

Article • 10/04/2022

Parsing strings to convert them to [DateTime](#) objects requires you to specify information about how the dates and times are represented as text. Different cultures use different orders for day, month, and year. Some time representations use a 24-hour clock, others specify "AM" and "PM." Some applications need only the date. Others need only the time. Still others need to specify both the date and time. The methods that convert strings to [DateTime](#) objects enable you to provide detailed information about the formats you expect and the elements of a date and time your application needs. There are three subtasks to correctly converting text into a [DateTime](#):

1. You must specify the expected format of the text representing a date and time.
2. You can specify the culture for the format of a date time.
3. You can specify how missing components in the text representation are set in the date and time.

The [Parse](#) and [TryParse](#) methods convert many common representations of a date and time. The [ParseExact](#) and [TryParseExact](#) methods convert a string representation that conforms to the pattern specified by a date and time format string. For more information, see the articles on [standard date and time format strings](#) and [custom date and time format strings](#).

The current [DateTimeFormatInfo](#) object provides more control over how text should be interpreted as a date and time. Properties of a [DateTimeFormatInfo](#) describe the date and time separators, the names of months, days, and eras, and the format for the "AM" and "PM" designations. The [CultureInfo](#) returned by [CultureInfo.CurrentCulture](#) has a [CultureInfo.DateTimeFormat](#) property that represents the current culture. If you want a specific culture or custom settings, you specify the [IFormatProvider](#) parameter of a parsing method. For the [IFormatProvider](#) parameter, specify a [CultureInfo](#) object, which represents a culture, or a [DateTimeFormatInfo](#) object.

The text representing a date or time might be missing some information. For example, most people would assume the date "March 12" represents the current year. Similarly, "March 2018" represents the month of March in the year 2018. Text representing time often does only include hours, minutes, and an AM/PM designation. Parsing methods handle this missing information by using reasonable defaults:

- When only the time is present, the date portion uses the current date.
- When only the date is present, the time portion is midnight.
- When the year isn't specified in a date, the current year is used.

- When the day of the month isn't specified, the first day of the month is used.

If the date is present in the string, it must include the month and one of the day or year. If the time is present, it must include the hour, and either the minutes or the AM/PM designator.

You can specify the [NoCurrentDateDefault](#) constant to override these defaults. When you use that constant, any missing year, month, or day properties are set to the value `1`. The [last example](#) using [Parse](#) demonstrates this behavior.

In addition to a date and a time component, the string representation of a date and time can include an offset that indicates how much the time differs from Coordinated Universal Time (UTC). For example, the string "2/14/2007 5:32:00 -7:00" defines a time that is seven hours earlier than UTC. If an offset is omitted from the string representation of a time, parsing returns a [DateTime](#) object with its [Kind](#) property set to [DateTimeKind.Unspecified](#). If an offset is specified, parsing returns a [DateTime](#) object with its [Kind](#) property set to [DateTimeKind.Local](#). Its value is also adjusted to the local time zone of your machine. You can modify this behavior by using a [DateTimeStyles](#) value with the parsing method.

The format provider is also used to interpret an ambiguous numeric date. It's unclear which components of the date represented by the string "02/03/04" are the month, day, and year. The components are interpreted according to the order of similar date formats in the format provider.

Parse

The following example illustrates the use of the [DateTime.Parse](#) method to convert a `string` into a [DateTime](#). This example uses the culture associated with the current thread. If the [CultureInfo](#) associated with the current culture can't parse the input string, a [FormatException](#) is thrown.

Tip

All the C# samples in this article run in your browser. Press the **Run** button to see the output. You can also edit them to experiment yourself.

Note

These examples are available in the GitHub docs repo for both [C#](#) and [Visual Basic](#).

C#

```
string dateInput = "Jan 1, 2009";
var parsedDate = DateTime.Parse(dateInput);
Console.WriteLine(parsedDate);
// Displays the following output on a system whose culture is en-US:
//      1/1/2009 00:00:00
```

You can also explicitly define the culture whose formatting conventions are used when you parse a string. You specify one of the standard [DateTimeFormatInfo](#) objects returned by the [CultureInfo.DateTimeFormat](#) property. The following example uses a format provider to parse a German string into a [DateTime](#). It creates a [CultureInfo](#) representing the `de-DE` culture. That [CultureInfo](#) object ensures successful parsing of this particular string. This process precludes whatever setting is in the [CurrentCulture](#) of the [CurrentThread](#).

C#

```
var cultureInfo = new CultureInfo("de-DE");
string dateString = "12 Juni 2008";
var dateTime = DateTime.Parse(dateString, cultureInfo);
Console.WriteLine(dateTime);
// The example displays the following output:
//      6/12/2008 00:00:00
```

However, you can use overloads of the [Parse](#) method to specify custom format providers. The [Parse](#) method doesn't support parsing non-standard formats. To parse a date and time expressed in a non-standard format, use the [ParseExact](#) method instead.

The following example uses the [DateTimeStyles](#) enumeration to specify that the current date and time information shouldn't be added to the [DateTime](#) for unspecified fields.

C#

```
var cultureInfo = new CultureInfo("de-DE");
string dateString = "12 Juni 2008";
var dateTime = DateTime.Parse(dateString, cultureInfo,
                             DateTimeStyles.NoCurrentDateDefault);
Console.WriteLine(dateTime);
// The example displays the following output if the current culture is en-US:
//      6/12/2008 00:00:00
```

ParseExact

The [DateTime.ParseExact](#) method converts a string to a [DateTime](#) object if it conforms to one of the specified string patterns. When a string that isn't one of the forms specified is passed to this method, a [FormatException](#) is thrown. You can specify one of the standard date and time format specifiers or a combination of the custom format specifiers. Using the custom format specifiers, it's possible for you to construct a custom recognition string. For an explanation of the specifiers, see the articles on [standard date and time format strings](#) and [custom date and time format strings](#).

In the following example, the [DateTime.ParseExact](#) method is passed a string object to parse, followed by a format specifier, followed by a [CultureInfo](#) object. This [ParseExact](#) method can only parse strings that follow the long date pattern in the `en-US` culture.

C#

```
var cultureInfo = new CultureInfo("en-US");
string[] dateStrings = { " Friday, April 10, 2009", "Friday, April 10, 2009"
};
foreach (string dateString in dateStrings)
{
    try
    {
        var dateTime = DateTime.ParseExact(dateString, "D", cultureInfo);
        Console.WriteLine(dateTime);
    }
    catch (FormatException)
    {
        Console.WriteLine("Unable to parse '{0}'", dateString);
    }
}
// The example displays the following output:
//      Unable to parse ' Friday, April 10, 2009'
//      4/10/2009 00:00:00
```

Each overload of the [Parse](#) and [ParseExact](#) methods also has an [IFormatProvider](#) parameter that provides culture-specific information about the formatting of the string. The [IFormatProvider](#) object is a [CultureInfo](#) object that represents a standard culture or a [DateTimeFormatInfo](#) object that is returned by the [CultureInfo.DateTimeFormat](#) property. [ParseExact](#) also uses an additional string or string array argument that defines one or more custom date and time formats.

Parsing Other Strings in .NET

Article • 03/11/2022

In addition to numeric and [DateTime](#) strings, you can also parse strings that represent the types [Char](#), [Boolean](#), and [Enum](#) into data types.

Char

The static `parse` method associated with the **Char** data type is useful for converting a string that contains a single character into its Unicode value. The following code example parses a string into a Unicode character.

C#

```
string MyString1 = "A";
char MyChar = Char.Parse(MyString1);
// MyChar now contains a Unicode "A" character.
```

Boolean

The **Boolean** data type contains a `Parse` method that you can use to convert a string that represents a Boolean value into an actual **Boolean** type. This method is not case-sensitive and can successfully parse a string containing "True" or "False." The `Parse` method associated with the **Boolean** type can also parse strings that are surrounded by white spaces. If any other string is passed, a [FormatException](#) is thrown.

The following code example uses the `Parse` method to convert a string into a Boolean value.

C#

```
string MyString2 = "True";
bool MyBool = bool.Parse(MyString2);
// MyBool now contains a True Boolean value.
```

Enumeration

You can use the static `Parse` method to initialize an enumeration type to the value of a string. This method accepts the enumeration type you are parsing, the string to parse, and an optional Boolean flag indicating whether or not the parse is case-sensitive. The

string you are parsing can contain several values separated by commas, which can be preceded or followed by one or more empty spaces (also called white spaces). When the string contains multiple values, the value of the returned object is the value of all specified values combined with a bitwise OR operation.

The following example uses the `Parse` method to convert a string representation into an enumeration value. The `DayOfWeek` enumeration is initialized to `Thursday` from a string.

C#

```
string MyString3 = "Thursday";
DayOfWeek MyDays = (DayOfWeek)Enum.Parse(typeof(DayOfWeek), MyString3);
Console.WriteLine(MyDays);
// The result is Thursday.
```

System.String class

Article • 01/08/2024

This article provides supplementary remarks to the reference documentation for this API.

A string is a sequential collection of characters that's used to represent text. A [String](#) object is a sequential collection of [System.Char](#) objects that represent a string; a [System.Char](#) object corresponds to a UTF-16 code unit. The value of the [String](#) object is the content of the sequential collection of [System.Char](#) objects, and that value is immutable (that is, it is read-only). For more information about the immutability of strings, see the [Immutability and the StringBuilder class](#) section. The maximum size of a [String](#) object in memory is 2-GB, or about 1 billion characters.

For more information about Unicode, UTF-16, code units, code points, and the [Char](#) and [Rune](#) types, see [Introduction to character encoding in .NET](#).

Instantiate a String object

You can instantiate a [String](#) object in the following ways:

- By assigning a string literal to a [String](#) variable. This is the most commonly used method for creating a string. The following example uses assignment to create several strings. Note that in C# and F#, because the backslash (\) is an escape character, literal backslashes in a string must be escaped or the entire string must be @-quoted.

C#

```
string string1 = "This is a string created by assignment.";
Console.WriteLine(string1);
string string2a = "The path is C:\\PublicDocuments\\Report1.doc";
Console.WriteLine(string2a);
string string2b = @"/The path is C:\\PublicDocuments\\Report1.doc";
Console.WriteLine(string2b);
// The example displays the following output:
//      This is a string created by assignment.
//      The path is C:\\PublicDocuments\\Report1.doc
//      The path is C:\\PublicDocuments\\Report1.doc
```

- By calling a [String](#) class constructor. The following example instantiates strings by calling several class constructors. Note that some of the constructors include pointers to character arrays or signed byte arrays as parameters. Visual Basic does

not support calls to these constructors. For detailed information about [String](#) constructors, see the [String constructor summary](#).

```
C#  
  
char[] chars = { 'w', 'o', 'r', 'd' };  
sbyte[] bytes = { 0x41, 0x42, 0x43, 0x44, 0x45, 0x00 };  
  
// Create a string from a character array.  
string string1 = new string(chars);  
Console.WriteLine(string1);  
  
// Create a string that consists of a character repeated 20 times.  
string string2 = new string('c', 20);  
Console.WriteLine(string2);  
  
string stringFromBytes = null;  
string stringFromChars = null;  
unsafe  
{  
    fixed (sbyte* pbytes = bytes)  
    {  
        // Create a string from a pointer to a signed byte array.  
        stringFromBytes = new string(pbytes);  
    }  
    fixed (char* pchars = chars)  
    {  
        // Create a string from a pointer to a character array.  
        stringFromChars = new string(pchars);  
    }  
}  
Console.WriteLine(stringFromBytes);  
Console.WriteLine(stringFromChars);  
// The example displays the following output:  
//      word  
//      ccccccccccccccccccc  
//      ABCDE  
//      word
```

- By using the string concatenation operator (+ in C# and F#, and & or + in Visual Basic) to create a single string from any combination of [String](#) instances and string literals. The following example illustrates the use of the string concatenation operator.

```
C#  
  
string string1 = "Today is " + DateTime.Now.ToString("D") + ".";  
Console.WriteLine(string1);  
  
string string2 = "This is one sentence. " + "This is a second. ";  
string2 += "This is a third sentence.";
```

```
Console.WriteLine(string2);
// The example displays output like the following:
//     Today is Tuesday, July 06, 2011.
//     This is one sentence. This is a second. This is a third sentence.
```

- By retrieving a property or calling a method that returns a string. The following example uses the methods of the [String](#) class to extract a substring from a larger string.

C#

```
string sentence = "This sentence has five words.";
// Extract the second word.
int startPosition = sentence.IndexOf(" ") + 1;
string word2 = sentence.Substring(startPosition,
                                  sentence.IndexOf(" ", startPosition)
                                  - startPosition);
Console.WriteLine("Second word: " + word2);
// The example displays the following output:
//     Second word: sentence
```

- By calling a formatting method to convert a value or object to its string representation. The following example uses the [composite formatting](#) feature to embed the string representation of two objects into a string.

C#

```
DateTime dateAndTime = new DateTime(2011, 7, 6, 7, 32, 0);
double temperature = 68.3;
string result = String.Format("At {0:t} on {0:D}, the temperature was
{1:F1} degrees Fahrenheit.", 
                               dateAndTime, temperature);
Console.WriteLine(result);
// The example displays the following output:
//     At 7:32 AM on Wednesday, July 06, 2011, the temperature was
//     68.3 degrees Fahrenheit.
```

Char objects and Unicode characters

Each character in a string is defined by a Unicode scalar value, also called a Unicode code point or the ordinal (numeric) value of the Unicode character. Each code point is encoded by using UTF-16 encoding, and the numeric value of each element of the encoding is represented by a [Char](#) object.

 Note

Note that, because a `String` instance consists of a sequential collection of UTF-16 code units, it is possible to create a `String` object that is not a well-formed Unicode string. For example, it is possible to create a string that has a low surrogate without a corresponding high surrogate. Although some methods, such as the methods of encoding and decoding objects in the `System.Text` namespace, may perform checks to ensure that strings are well-formed, `String` class members don't ensure that a string is well-formed.

A single `Char` object usually represents a single code point; that is, the numeric value of the `Char` equals the code point. For example, the code point for the character "a" is U+0061. However, a code point might require more than one encoded element (more than one `Char` object). The Unicode standard defines two types of characters that correspond to multiple `Char` objects: graphemes, and Unicode supplementary code points that correspond to characters in the Unicode supplementary planes.

- A grapheme is represented by a base character followed by one or more combining characters. For example, the character ä is represented by a `Char` object whose code point is U+0061 followed by a `Char` object whose code point is U+0308. This character can also be defined by a single `Char` object that has a code point of U+00E4. As the following example shows, a culture-sensitive comparison for equality indicates that these two representations are equal, although an ordinary ordinal comparison does not. However, if the two strings are normalized, an ordinal comparison also indicates that they are equal. (For more information on normalizing strings, see the [Normalization](#) section.)

C#

```
using System;
using System.Globalization;
using System.IO;

public class Example5
{
    public static void Main()
    {
        StreamWriter sw = new StreamWriter(@".\graphemes.txt");
        string grapheme = "\u0061\u0308";
        sw.WriteLine(grapheme);

        string singleChar = "\u00e4";
        sw.WriteLine(singleChar);

        sw.WriteLine("{0} = {1} (Culture-sensitive): {2}", grapheme,
singleChar,
            String.Equals(grapheme, singleChar,
StringComparison.CurrentCulture));
```

```

        sw.WriteLine("{0} = {1} (Ordinal): {2}", grapheme, singleChar,
                    String.Equals(grapheme, singleChar,
                                  StringComparison.OrdinalIgnoreCase));
        sw.WriteLine("{0} = {1} (Normalized Ordinal): {2}", grapheme,
                    singleChar,
                    String.Equals(grapheme.Normalize(),
                                  singleChar.Normalize(),
                                  StringComparison.OrdinalIgnoreCase));
    sw.Close();
}
}

// The example produces the following output:
//      ä
//      ä
//      ä = ä (Culture-sensitive): True
//      ä = ä (Ordinal): False
//      ä = ä (Normalized Ordinal): True

```

- A Unicode supplementary code point (a surrogate pair) is represented by a [Char](#) object whose code point is a high surrogate followed by a [Char](#) object whose code point is a low surrogate. The code units of high surrogates range from U+D800 to U+DBFF. The code units of low surrogates range from U+DC00 to U+DFFF. Surrogate pairs are used to represent characters in the 16 Unicode supplementary planes. The following example creates a surrogate character and passes it to the [Char.IsSurrogatePair\(Char, Char\)](#) method to determine whether it is a surrogate pair.

C#

```

string surrogate = "\uD800\uDC03";
for (int ctr = 0; ctr < surrogate.Length; ctr++)
    Console.Write($"U+{(ushort)surrogate[ctr]:X2} ");

Console.WriteLine();
Console.WriteLine("  Is Surrogate Pair: {0}",
                Char.IsSurrogatePair(surrogate[0], surrogate[1]));
// The example displays the following output:
//      U+D800 U+DC03
//      Is Surrogate Pair: True

```

The Unicode standard

Characters in a string are represented by UTF-16 encoded code units, which correspond to [Char](#) values.

Each character in a string has an associated Unicode character category, which is represented in .NET by the [UnicodeCategory](#) enumeration. The category of a character

or a surrogate pair can be determined by calling the [CharUnicodeInfo.GetUnicodeCategory](#) method.

.NET maintains its own table of characters and their corresponding categories, which ensures that a specific version of a .NET implementation running on different platforms returns identical character category information. On all .NET versions and across all OS platforms, character category information is provided by the [Unicode Character Database](#).

The following table lists .NET versions and the versions of the Unicode Standard on which their character categories are based.

[\[+\] Expand table](#)

| .NET version | Version of the Unicode Standard |
|---|--|
| .NET Framework 1.1 | The Unicode Standard, Version 4.0.0 |
| .NET Framework 2.0 | The Unicode Standard, Version 5.0.0 |
| .NET Framework 3.5 | The Unicode Standard, Version 5.0.0 |
| .NET Framework 4 | The Unicode Standard, Version 5.0.0 |
| .NET Framework 4.5 | The Unicode Standard, Version 6.3.0 |
| .NET Framework 4.5.1 | The Unicode Standard, Version 6.3.0 |
| .NET Framework 4.5.2 | The Unicode Standard, Version 6.3.0 |
| .NET Framework 4.6 | The Unicode Standard, Version 6.3.0 |
| .NET Framework 4.6.1 | The Unicode Standard, Version 6.3.0 |
| .NET Framework 4.6.2 and later versions | The Unicode Standard, Version 8.0.0 |
| .NET Core 2.1 | The Unicode Standard, Version 8.0.0 |
| .NET Core 3.1 | The Unicode Standard, Version 11.0.0 |
| .NET 5 | The Unicode Standard, Version 13.0.0 |

In addition, .NET supports string comparison and sorting based on the Unicode standard. .NET Framework 4 and previous versions maintain their own table of string data. This is also true of versions of .NET Framework starting with .NET Framework 4.5 running on Windows 7. Starting with .NET Framework 4.5 running on Windows 8 and later versions of the Windows operating system, the runtime delegates string comparison and sorting operations to the operating system. On .NET Core and .NET 5+,

String comparison and sorting information is provided by [International Components for Unicode](#) libraries (except on Windows versions prior to Windows 10 May 2019 Update). The following table lists the versions of .NET and the versions of the Unicode Standard on which character comparison and sorting are based.

 [Expand table](#)

| .NET version | Version of the Unicode Standard |
|---|--|
| .NET Framework 1.1 | The Unicode Standard, Version 4.0.0 |
| .NET Framework 2.0 | The Unicode Standard, Version 5.0.0 |
| .NET Framework 3.5 | The Unicode Standard, Version 5.0.0 |
| .NET Framework 4 | The Unicode Standard, Version 5.0.0 |
| .NET Framework 4.5 and later on Windows 7 | The Unicode Standard, Version 5.0.0 |
| .NET Framework 4.5 and later on Windows 8 and later Windows operating systems | The Unicode Standard, Version 6.3.0 |
| .NET Core and .NET 5+ | Depends on the version of the Unicode Standard supported by the underlying operating system. |

Embedded null characters

In .NET, a [String](#) object can include embedded null characters, which count as a part of the string's length. However, in some languages such as C and C++, a null character indicates the end of a string; it is not considered a part of the string and is not counted as part of the string's length. This means that the following common assumptions that C and C++ programmers or libraries written in C or C++ might make about strings are not necessarily valid when applied to [String](#) objects:

- The value returned by the `strlen` or `wcslen` functions does not necessarily equal [String.Length](#).
- The string created by the `strcpy_s` or `wcsncpy_s` functions is not necessarily identical to the string created by the [String.Copy](#) method.

You should ensure that native C and C++ code that instantiates [String](#) objects, and code that is passed [String](#) objects through platform invoke, don't assume that an embedded null character marks the end of the string.

Embedded null characters in a string are also treated differently when a string is sorted (or compared) and when a string is searched. Null characters are ignored when performing culture-sensitive comparisons between two strings, including comparisons using the invariant culture. They are considered only for ordinal or case-insensitive ordinal comparisons. On the other hand, embedded null characters are always considered when searching a string with methods such as [Contains](#), [StartsWith](#), and [IndexOf](#).

Strings and indexes

An index is the position of a [Char](#) object (not a Unicode character) in a [String](#). An index is a zero-based, nonnegative number that starts from the first position in the string, which is index position zero. A number of search methods, such as [IndexOf](#) and [LastIndexOf](#), return the index of a character or substring in the string instance.

The [Chars\[\]](#) property lets you access individual [Char](#) objects by their index position in the string. Because the [Chars\[\]](#) property is the default property (in Visual Basic) or the indexer (in C# and F#), you can access the individual [Char](#) objects in a string by using code such as the following. This code looks for white space or punctuation characters in a string to determine how many words the string contains.

C#

```
string s1 = "This string consists of a single short sentence.";
int nWords = 0;

s1 = s1.Trim();
for (int ctr = 0; ctr < s1.Length; ctr++) {
    if (Char.IsPunctuation(s1[ctr]) | Char.IsWhiteSpace(s1[ctr]))
        nWords++;
}
Console.WriteLine("The sentence\n  {0}\nhas {1} words.",
                  s1, nWords);
// The example displays the following output:
//      The sentence
//      This string consists of a single short sentence.
//      has 8 words.
```

Because the [String](#) class implements the [IEnumerable](#) interface, you can also iterate through the [Char](#) objects in a string by using a [foreach](#) construct, as the following example shows.

C#

```

string s1 = "This string consists of a single short sentence.";
int nWords = 0;

s1 = s1.Trim();
foreach (var ch in s1) {
    if (Char.IsPunctuation(ch) | Char.IsWhiteSpace(ch))
        nWords++;
}
Console.WriteLine("The sentence\n  {0}\nhas {1} words.",
                  s1, nWords);
// The example displays the following output:
//      The sentence
//      This string consists of a single short sentence.
//      has 8 words.

```

Consecutive index values might not correspond to consecutive Unicode characters, because a Unicode character might be encoded as more than one [Char](#) object. In particular, a string may contain multi-character units of text that are formed by a base character followed by one or more combining characters or by surrogate pairs. To work with Unicode characters instead of [Char](#) objects, use the [System.Globalization.StringInfo](#) and [TextElementEnumerator](#) classes, or the [String.EnumerateRunes](#) method and the [Rune](#) struct. The following example illustrates the difference between code that works with [Char](#) objects and code that works with Unicode characters. It compares the number of characters or text elements in each word of a sentence. The string includes two sequences of a base character followed by a combining character.

C#

```

// First sentence of The Mystery of the Yellow Room, by Leroux.
string opening = "Ce n'est pas sans une certaine émotion que "+
                 "je commence à raconter ici les aventures " +
                 "extraordinaires de Joseph Rouletabille.';

// Character counters.
int nChars = 0;
// Objects to store word count.
List<int> chars = new List<int>();
List<int> elements = new List<int>();

foreach (var ch in opening) {
    // Skip the ' character.
    if (ch == '\u0027') continue;

    if (Char.IsWhiteSpace(ch) | (Char.IsPunctuation(ch))) {
        chars.Add(nChars);
        nChars = 0;
    }
    else {
        nChars++;
    }
}

```

```

}

System.Globalization.TextElementEnumerator te =
    System.Globalization.StringInfo.GetTextElementEnumerator(opening);
while (te.MoveNext()) {
    string s = te.GetTextElement();
    // Skip the ' character.
    if (s == "\u0027") continue;
    if (String.IsNullOrEmpty(s.Trim()) | (s.Length == 1 &&
Char.IsPunctuation(Convert.ToChar(s)))) {
        elements.Add(nChars);
        nChars = 0;
    }
    else {
        nChars++;
    }
}

// Display character counts.
Console.WriteLine("{0,6} {1,20} {2,20}",
    "Word #", "Char Objects", "Characters");
for (int ctr = 0; ctr < chars.Count; ctr++)
    Console.WriteLine("{0,6} {1,20} {2,20}",
        ctr, chars[ctr], elements[ctr]);
// The example displays the following output:
//      Word #      Char Objects      Characters
//          0                  2                  2
//          1                  4                  4
//          2                  3                  3
//          3                  4                  4
//          4                  3                  3
//          5                  8                  8
//          6                  8                  7
//          7                  3                  3
//          8                  2                  2
//          9                  8                  8
//         10                  2                  1
//         11                  8                  8
//         12                  3                  3
//         13                  3                  3
//         14                  9                  9
//         15                 15                 15
//         16                  2                  2
//         17                  6                  6
//         18                 12                 12

```

This example works with text elements by using the [StringInfo.GetTextElementEnumerator](#) method and the [TextElementEnumerator](#) class to enumerate all the text elements in a string. You can also retrieve an array that contains the starting index of each text element by calling the [StringInfo.ParseCombiningCharacters](#) method.

For more information about working with units of text rather than individual `Char` values, see [Introduction to character encoding in .NET](#).

Null strings and empty strings

A string that has been declared but has not been assigned a value is `null`. Attempting to call methods on that string throws a `NullReferenceException`. A null string is different from an empty string, which is a string whose value is `""` or `String.Empty`. In some cases, passing either a null string or an empty string as an argument in a method call throws an exception. For example, passing a null string to the `Int32.Parse` method throws an `ArgumentNullException`, and passing an empty string throws a `FormatException`. In other cases, a method argument can be either a null string or an empty string. For example, if you are providing an `IFormattable` implementation for a class, you want to equate both a null string and an empty string with the general ("G") format specifier.

The `String` class includes the following two convenience methods that enable you to test whether a string is `null` or empty:

- `IsNullOrEmpty`, which indicates whether a string is either `null` or is equal to `String.Empty`. This method eliminates the need to use code such as the following:

```
C#  
  
if (str == null || str.Equals(String.Empty))
```

- `IsNullOrWhiteSpace`, which indicates whether a string is `null`, equals `String.Empty`, or consists exclusively of white-space characters. This method eliminates the need to use code such as the following:

```
C#  
  
if (str == null || str.Equals(String.Empty) ||  
str.Trim().Equals(String.Empty))
```

The following example uses the `IsNullOrEmpty` method in the `IFormattable.ToString` implementation of a custom `Temperature` class. The method supports the "G", "C", "F", and "K" format strings. If an empty format string or a format string whose value is `null` is passed to the method, its value is changed to the "G" format string.

```
C#
```

```

public string ToString(string format, IFormatProvider provider)
{
    if (String.IsNullOrEmpty(format)) format = "G";
    if (provider == null) provider = CultureInfo.CurrentCulture;

    switch (format.ToUpperInvariant())
    {
        // Return degrees in Celsius.
        case "G":
        case "C":
            return temp.ToString("F2", provider) + "°C";
        // Return degrees in Fahrenheit.
        case "F":
            return (temp * 9 / 5 + 32).ToString("F2", provider) + "°F";
        // Return degrees in Kelvin.
        case "K":
            return (temp + 273.15).ToString();
        default:
            throw new FormatException(
                String.Format("The {0} format string is not supported.", 
                format));
    }
}

```

Immutability and the StringBuilder class

A [String](#) object is called immutable (read-only), because its value cannot be modified after it has been created. Methods that appear to modify a [String](#) object actually return a new [String](#) object that contains the modification.

Because strings are immutable, string manipulation routines that perform repeated additions or deletions to what appears to be a single string can exact a significant performance penalty. For example, the following code uses a random number generator to create a string with 1000 characters in the range 0x0001 to 0x052F. Although the code appears to use string concatenation to append a new character to the existing string named `str`, it actually creates a new [String](#) object for each concatenation operation.

C#

```

using System;
using System.IO;
using System.Text;

public class Example6
{
    public static void Main()
    {

```

```

Random rnd = new Random();

string str = String.Empty;
StreamWriter sw = new StreamWriter(@".\StringFile.txt",
                                false, Encoding.Unicode);

for (int ctr = 0; ctr <= 1000; ctr++) {
    str += (char)rnd.Next(1, 0x0530);
    if (str.Length % 60 == 0)
        str += Environment.NewLine;
}
sw.Write(str);
sw.Close();
}
}

```

You can use the [StringBuilder](#) class instead of the [String](#) class for operations that make multiple changes to the value of a string. Unlike instances of the [String](#) class, [StringBuilder](#) objects are mutable; when you concatenate, append, or delete substrings from a string, the operations are performed on a single string. When you have finished modifying the value of a [StringBuilder](#) object, you can call its [StringBuilder.ToString](#) method to convert it to a string. The following example replaces the [String](#) used in the previous example to concatenate 1000 random characters in the range to 0x0001 to 0x052F with a [StringBuilder](#) object.

C#

```

using System;
using System.IO;
using System.Text;

public class Example10
{
    public static void Main()
    {
        Random rnd = new Random();
        StringBuilder sb = new StringBuilder();
        StreamWriter sw = new StreamWriter(@".\StringFile.txt",
                                         false, Encoding.Unicode);

        for (int ctr = 0; ctr <= 1000; ctr++) {
            sb.Append((char)rnd.Next(1, 0x0530));
            if (sb.Length % 60 == 0)
                sb.AppendLine();
        }
        sw.Write(sb.ToString());
        sw.Close();
    }
}

```

Ordinal vs. culture-sensitive operations

Members of the [String](#) class perform either ordinal or culture-sensitive (linguistic) operations on a [String](#) object. An ordinal operation acts on the numeric value of each [Char](#) object. A culture-sensitive operation acts on the value of the [String](#) object, and takes culture-specific casing, sorting, formatting, and parsing rules into account. Culture-sensitive operations execute in the context of an explicitly declared culture or the implicit current culture. The two kinds of operations can produce very different results when they are performed on the same string.

.NET also supports culture-insensitive linguistic string operations by using the invariant culture ([CultureInfo.InvariantCulture](#)), which is loosely based on the culture settings of the English language independent of region. Unlike other [System.Globalization.CultureInfo](#) settings, the settings of the invariant culture are guaranteed to remain consistent on a single computer, from system to system, and across versions of .NET. The invariant culture can be seen as a kind of black box that ensures stability of string comparisons and ordering across all cultures.

Important

If your application makes a security decision about a symbolic identifier such as a file name or named pipe, or about persisted data such as the text-based data in an XML file, the operation should use an ordinal comparison instead of a culture-sensitive comparison. This is because a culture-sensitive comparison can yield different results depending on the culture in effect, whereas an ordinal comparison depends solely on the binary value of the compared characters.

Important

Most methods that perform string operations include an overload that has a parameter of type [StringComparison](#), which enables you to specify whether the method performs an ordinal or culture-sensitive operation. In general, you should call this overload to make the intent of your method call clear. For best practices and guidance for using ordinal and culture-sensitive operations on strings, see [Best Practices for Using Strings](#).

Operations for casing, parsing and formatting, comparison and sorting, and testing for equality can be either ordinal or culture-sensitive. The following sections discuss each category of operation.

💡 Tip

You should always call a method overload that makes the intent of your method call clear. For example, instead of calling the `Compare(String, String)` method to perform a culture-sensitive comparison of two strings by using the conventions of the current culture, you should call the `Compare(String, String, StringComparison)` method with a value of `StringComparison.CurrentCulture` for the `comparisonType` argument. For more information, see [Best Practices for Using Strings](#).

You can download the sorting weight tables, a set of text files that contain information on the character weights used in sorting and comparison operations, from the following links:

- Windows (.NET Framework and .NET Core): [Sorting Weight Tables ↗](#)
- Windows 10 May 2019 Update or later (.NET 5+) and Linux and macOS (.NET Core and .NET 5+): [Default Unicode Collation Element Table ↗](#)

Casing

Casing rules determine how to change the capitalization of a Unicode character; for example, from lowercase to uppercase. Often, a casing operation is performed before a string comparison. For example, a string might be converted to uppercase so that it can be compared with another uppercase string. You can convert the characters in a string to lowercase by calling the `ToLower` or `ToLowerInvariant` method, and you can convert them to uppercase by calling the `ToUpper` or `ToUpperInvariant` method. In addition, you can use the `TextInfo.ToTitleCase` method to convert a string to title case.

ⓘ Note

.NET Core running on Linux and macOS systems only: The collation behavior for the C and Posix cultures is always case-sensitive because these cultures do not use the expected Unicode collation order. We recommend that you use a culture other than C or Posix for performing culture-sensitive, case-insensitive sorting operations.

Casing operations can be based on the rules of the current culture, a specified culture, or the invariant culture. Because case mappings can vary depending on the culture used, the result of casing operations can vary based on culture. The actual differences in casing are of three kinds:

- Differences in the case mapping of LATIN CAPITAL LETTER I (U+0049), LATIN SMALL LETTER I (U+0069), LATIN CAPITAL LETTER I WITH DOT ABOVE (U+0130), and LATIN SMALL LETTER DOTLESS I (U+0131). In the tr-TR (Turkish (Turkey)) and az-Latn-AZ (Azerbaijan, Latin) cultures, and in the tr, az, and az-Latn neutral cultures, the lowercase equivalent of LATIN CAPITAL LETTER I is LATIN SMALL LETTER DOTLESS I, and the uppercase equivalent of LATIN SMALL LETTER I is LATIN CAPITAL LETTER I WITH DOT ABOVE. In all other cultures, including the invariant culture, LATIN SMALL LETTER I and LATIN CAPITAL LETTER I are lowercase and uppercase equivalents.

The following example demonstrates how a string comparison designed to prevent file system access can fail if it relies on a culture-sensitive casing comparison. (The casing conventions of the invariant culture should have been used.)

C#

```
using System;
using System.Globalization;
using System.Threading;

public class Example1
{
    const string disallowed = "file";

    public static void Main()
    {

        IsAccessAllowed(@"FILE:\\\\c:\\users\\user001\\documents\\FinancialInfo.txt");
    }

    private static void IsAccessAllowed(String resource)
    {
        CultureInfo[] cultures = { CultureInfo.CreateSpecificCulture("en-US"),
                                    CultureInfo.CreateSpecificCulture("tr-TR") };
        String scheme = null;
        int index = resource.IndexOfAny( new Char[] { '\\', '/' } );
        if (index > 0)
            scheme = resource.Substring(0, index - 1);

        // Change the current culture and perform the comparison.
        foreach (var culture in cultures) {
            Thread.CurrentThread.CurrentCulture = culture;
            Console.WriteLine("Culture: {0}",
                CultureInfo.CurrentCulture.DisplayName);
            Console.WriteLine(resource);
            Console.WriteLine("Access allowed: {0}",
                ! String.Equals(disallowed, scheme,

```

```

        StringComparison.CurrentCultureIgnoreCase));
        Console.WriteLine();
    }
}
// The example displays the following output:
//      Culture: English (United States)
//      FILE:\\\\c:\\users\\user001\\documents\\FinancialInfo.txt
//      Access allowed: False
//
//      Culture: Turkish (Turkey)
//      FILE:\\\\c:\\users\\user001\\documents\\FinancialInfo.txt
//      Access allowed: True

```

- Differences in case mappings between the invariant culture and all other cultures. In these cases, using the casing rules of the invariant culture to change a character to uppercase or lowercase returns the same character. For all other cultures, it returns a different character. Some of the affected characters are listed in the following table.

[\[+\] Expand table](#)

| Character | If changed to | Returns |
|--|---------------|---|
| MICRON SIGN (U+00B5) | Uppercase | GREEK CAPITAL LETTER MU (U+-39C) |
| LATIN CAPITAL LETTER I WITH DOT ABOVE (U+0130) | Lowercase | LATIN SMALL LETTER I (U+0069) |
| LATIN SMALL LETTER DOTLESS I (U+0131) | Uppercase | LATIN CAPITAL LETTER I (U+0049) |
| LATIN SMALL LETTER LONG S (U+017F) | Uppercase | LATIN CAPITAL LETTER S (U+0053) |
| LATIN CAPITAL LETTER D WITH SMALL LETTER Z WITH CARON (U+01C5) | Lowercase | LATIN SMALL LETTER DZ WITH CARON (U+01C6) |
| COMBINING GREEK YPOGEGRAMMENI (U+0345) | Uppercase | GREEK CAPITAL LETTER IOTA (U+0399) |

- Differences in case mappings of two-letter mixed-case pairs in the ASCII character range. In most cultures, a two-letter mixed-case pair is equal to the equivalent two-letter uppercase or lowercase pair. This is not true for the following two-letter pairs in the following cultures, because in each case they are compared to a digraph:

- "IJ" and "nJ" in the hr-HR (Croatian (Croatia)) culture.
- "cH" in the cs-CZ (Czech (Czech Republic)) and sk-SK (Slovak (Slovakia)) cultures.
- "aA" in the da-DK (Danish (Denmark)) culture.
- "cS", "dZ", "dZS", "nY", "sZ", "tY", and "zS" in the hu-HU (Hungarian (Hungary)) culture.
- "cH" and "IL" in the es-ES_tradnl (Spanish (Spain, Traditional Sort)) culture.
- "cH", "gl", "kH", "nG" "nH", "pH", "qU", "tH", and "tR" in the vi-VN (Vietnamese (Vietnam)) culture.

However, it is unusual to encounter a situation in which a culture-sensitive comparison of these pairs creates problems, because these pairs are uncommon in fixed strings or identifiers.

The following example illustrates some of the differences in casing rules between cultures when converting strings to uppercase.

C#

```
using System;
using System.Globalization;
using System.IO;

public class Example
{
    public static void Main()
    {
        StreamWriter sw = new StreamWriter(@".\case.txt");
        string[] words = { "file", "sifir", "ßenana" };
        CultureInfo[] cultures = { CultureInfo.InvariantCulture,
                                   new CultureInfo("en-US"),
                                   new CultureInfo("tr-TR") };

        foreach (var word in words) {
            sw.WriteLine("{0}:", word);
            foreach (var culture in cultures) {
                string name = String.IsNullOrEmpty(culture.Name) ?
                    "Invariant" : culture.Name;
                string upperWord = word.ToUpper(culture);
                sw.WriteLine("  {0,10}: {1,7} {2, 38}", name,
                           upperWord, ShowHexValue(upperWord));
            }
            sw.WriteLine();
        }
        sw.Close();
    }

    private static string ShowHexValue(string s)
    {
        string retval = null;
        foreach (var ch in s) {
```

```

        byte[] bytes = BitConverter.GetBytes(ch);
        retval += String.Format("{0:X2} {1:X2} ", bytes[1], bytes[0]);
    }
    return retval;
}
// The example displays the following output:
//   file:
//       Invariant: FILE          00 46 00 49 00 4C 00 45
//       en-US:     FILE          00 46 00 49 00 4C 00 45
//       tr-TR:     FILE          00 46 01 30 00 4C 00 45
//
//   sıfır:
//       Invariant: SıFıR        00 53 01 31 00 46 01 31 00 52
//       en-US:     SIFIR         00 53 00 49 00 46 00 49 00 52
//       tr-TR:     SIFIR         00 53 00 49 00 46 00 49 00 52
//
//   Đenana:
//       Invariant: ĐENANA      01 C5 00 45 00 4E 00 41 00 4E 00 41
//       en-US:     ĐENANA      01 C4 00 45 00 4E 00 41 00 4E 00 41
//       tr-TR:     ĐENANA      01 C4 00 45 00 4E 00 41 00 4E 00 41

```

Parsing and formatting

Formatting and parsing are inverse operations. Formatting rules determine how to convert a value, such as a date and time or a number, to its string representation, whereas parsing rules determine how to convert a string representation to a value such as a date and time. Both formatting and parsing rules are dependent on cultural conventions. The following example illustrates the ambiguity that can arise when interpreting a culture-specific date string. Without knowing the conventions of the culture that was used to produce a date string, it is not possible to know whether 03/01/2011, 3/1/2011, and 01/03/2011 represent January 3, 2011 or March 1, 2011.

C#

```

using System;
using System.Globalization;

public class Example9
{
    public static void Main()
    {
        DateTime date = new DateTime(2011, 3, 1);
        CultureInfo[] cultures = { CultureInfo.InvariantCulture,
                                  new CultureInfo("en-US"),
                                  new CultureInfo("fr-FR") };

        foreach (var culture in cultures)
            Console.WriteLine("{0,-12} {1}", String.IsNullOrEmpty(culture.Name)

```

```

    ?
        "Invariant" : culture.Name,
        date.ToString("d", culture));
    }
}
// The example displays the following output:
//      Invariant      03/01/2011
//      en-US          3/1/2011
//      fr-FR          01/03/2011

```

Similarly, as the following example shows, a single string can produce different dates depending on the culture whose conventions are used in the parsing operation.

C#

```

using System;
using System.Globalization;

public class Example15
{
    public static void Main()
    {
        string dateString = "07/10/2011";
        CultureInfo[] cultures = { CultureInfo.InvariantCulture,
                                   CultureInfo.CreateSpecificCulture("en-GB"),
                                   CultureInfo.CreateSpecificCulture("en-US") };
        Console.WriteLine("{0,-12} {1,10} {2,8} {3,8}\n", "Date String",
"Culture",
                           "Month", "Day");
        foreach (var culture in cultures) {
            DateTime date = DateTime.Parse(dateString, culture);
            Console.WriteLine("{0,-12} {1,10} {2,8} {3,8}", dateString,
                           String.IsNullOrEmpty(culture.Name) ?
                           "Invariant" : culture.Name,
                           date.Month, date.Day);
        }
    }
}
// The example displays the following output:
//      Date String      Culture      Month      Day
//
//      07/10/2011      Invariant      7          10
//      07/10/2011      en-GB         10         7
//      07/10/2011      en-US         7          10

```

String comparison and sorting

Conventions for comparing and sorting strings vary from culture to culture. For example, the sort order may be based on phonetics or on the visual representation of characters.

In East Asian languages, characters are sorted by the stroke and radical of ideographs. Sorting also depends on the order languages and cultures use for the alphabet. For example, the Danish language has an "Æ" character that it sorts after "Z" in the alphabet. In addition, comparisons can be case-sensitive or case-insensitive, and casing rules might differ by culture. Ordinal comparison, on the other hand, uses the Unicode code points of individual characters in a string when comparing and sorting strings.

Sort rules determine the alphabetic order of Unicode characters and how two strings compare to each other. For example, the [String.Compare\(String, String, StringComparison\)](#) method compares two strings based on the [StringComparison](#) parameter. If the parameter value is [StringComparison.CurrentCulture](#), the method performs a linguistic comparison that uses the conventions of the current culture; if the parameter value is [StringComparison.OrdinalIgnoreCase](#), the method performs an ordinal comparison. Consequently, as the following example shows, if the current culture is U.S. English, the first call to the [String.Compare\(String, String, StringComparison\)](#) method (using culture-sensitive comparison) considers "a" less than "A", but the second call to the same method (using ordinal comparison) considers "a" greater than "A".

C#

```
using System;
using System.Globalization;
using System.Threading;

public class Example2
{
    public static void Main()
    {
        Thread.CurrentThread.CurrentCulture =
CultureInfo.CreateSpecificCulture("en-US");
        Console.WriteLine(String.Compare("A", "a",
StringComparison.CurrentCulture));
        Console.WriteLine(String.Compare("A", "a", StringComparison.OrdinalIgnoreCase));
    }
}
// The example displays the following output:
//      1
//     -32
```

.NET supports word, string, and ordinal sort rules:

- A word sort performs a culture-sensitive comparison of strings in which certain nonalphanumeric Unicode characters might have special weights assigned to them. For example, the hyphen (-) might have a very small weight assigned to it so that "coop" and "co-op" appear next to each other in a sorted list. For a list of the

[String methods that compare two strings using word sort rules, see the String operations by category section.](#)

- A string sort also performs a culture-sensitive comparison. It is similar to a word sort, except that there are no special cases, and all nonalphanumeric symbols come before all alphanumeric Unicode characters. Two strings can be compared using string sort rules by calling the [CompareInfo.Compare](#) method overloads that have an `options` parameter that is supplied a value of [CompareOptions.StringSort](#). Note that this is the only method that .NET provides to compare two strings using string sort rules.
- An ordinal sort compares strings based on the numeric value of each [Char](#) object in the string. An ordinal comparison is automatically case-sensitive because the lowercase and uppercase versions of a character have different code points. However, if case is not important, you can specify an ordinal comparison that ignores case. This is equivalent to converting the string to uppercase by using the invariant culture and then performing an ordinal comparison on the result. For a list of the [String](#) methods that compare two strings using ordinal sort rules, see the [String operations by category section](#).

A culture-sensitive comparison is any comparison that explicitly or implicitly uses a [CultureInfo](#) object, including the invariant culture that is specified by the [CultureInfo.InvariantCulture](#) property. The implicit culture is the current culture, which is specified by the [Thread.CurrentCulture](#) and [CultureInfo.CurrentCulture](#) properties. There is considerable variation in the sort order of alphabetic characters (that is, characters for which the [Char.IsLetter](#) property returns `true`) across cultures. You can specify a culture-sensitive comparison that uses the conventions of a specific culture by supplying a [CultureInfo](#) object to a string comparison method such as [Compare\(String, String, CultureInfo, CompareOptions\)](#). You can specify a culture-sensitive comparison that uses the conventions of the current culture by supplying [StringComparison.CurrentCulture](#), [StringComparison.CurrentCultureIgnoreCase](#), or any member of the [CompareOptions](#) enumeration other than [CompareOptions.Ordinal](#) or [CompareOptions.OrdinalIgnoreCase](#) to an appropriate overload of the [Compare](#) method. A culture-sensitive comparison is generally appropriate for sorting whereas an ordinal comparison is not. An ordinal comparison is generally appropriate for determining whether two strings are equal (that is, for determining identity) whereas a culture-sensitive comparison is not.

The following example illustrates the difference between culture-sensitive and ordinal comparison. The example evaluates three strings, "Apple", "Æble", and "AEble", using ordinal comparison and the conventions of the da-DK and en-US cultures (each of which is the default culture at the time the [Compare](#) method is called). Because the

Danish language treats the character "Æ" as an individual letter and sorts it after "Z" in the alphabet, the string "Æble" is greater than "Apple". However, "Æble" is not considered equivalent to "AEble", so "Æble" is also greater than "AEble". The en-US culture doesn't include the letter "Æ" but treats it as equivalent to "AE", which explains why "Æble" is less than "Apple" but equal to "AEble". Ordinal comparison, on the other hand, considers "Apple" to be less than "Æble", and "Æble" to be greater than "AEble".

C#

```
using System;
using System.Globalization;
using System.Threading;

public class CompareStringSample
{
    public static void Main()
    {
        string str1 = "Apple";
        string str2 = "Æble";
        string str3 = "AEble";

        // Set the current culture to Danish in Denmark.
        Thread.CurrentCulture = new CultureInfo("da-DK");
        Console.WriteLine("Current culture: {0}",
                          CultureInfo.CurrentCulture.Name);
        Console.WriteLine("Comparison of {0} with {1}: {2}",
                          str1, str2, String.Compare(str1, str2));
        Console.WriteLine("Comparison of {0} with {1}: {2}\n",
                          str2, str3, String.Compare(str2, str3));

        // Set the current culture to English in the U.S.
        Thread.CurrentCulture = new CultureInfo("en-US");
        Console.WriteLine("Current culture: {0}",
                          CultureInfo.CurrentCulture.Name);
        Console.WriteLine("Comparison of {0} with {1}: {2}",
                          str1, str2, String.Compare(str1, str2));
        Console.WriteLine("Comparison of {0} with {1}: {2}\n",
                          str2, str3, String.Compare(str2, str3));

        // Perform an ordinal comparison.
        Console.WriteLine("Ordinal comparison");
        Console.WriteLine("Comparison of {0} with {1}: {2}",
                          str1, str2,
                          String.Compare(str1, str2,
                                         StringComparison.Ordinal));
        Console.WriteLine("Comparison of {0} with {1}: {2}",
                          str2, str3,
                          String.Compare(str2, str3,
                                         StringComparison.Ordinal));
    }
}

// The example displays the following output:
```

```
//      Current culture: da-DK
//      Comparison of Apple with Äble: -1
//      Comparison of Äble with AEble: 1
//
//      Current culture: en-US
//      Comparison of Apple with Äble: 1
//      Comparison of Äble with AEble: 0
//
//      Ordinal comparison
//      Comparison of Apple with Äble: -133
//      Comparison of Äble with AEble: 133
```

Use the following general guidelines to choose an appropriate sorting or string comparison method:

- If you want the strings to be ordered based on the user's culture, you should order them based on the conventions of the current culture. If the user's culture changes, the order of sorted strings will also change accordingly. For example, a thesaurus application should always sort words based on the user's culture.
- If you want the strings to be ordered based on the conventions of a specific culture, you should order them by supplying a [CultureInfo](#) object that represents that culture to a comparison method. For example, in an application designed to teach students a particular language, you want strings to be ordered based on the conventions of one of the cultures that speaks that language.
- If you want the order of strings to remain unchanged across cultures, you should order them based on the conventions of the invariant culture or use an ordinal comparison. For example, you would use an ordinal sort to organize the names of files, processes, mutexes, or named pipes.
- For a comparison that involves a security decision (such as whether a username is valid), you should always perform an ordinal test for equality by calling an overload of the [Equals](#) method.

Note

The culture-sensitive sorting and casing rules used in string comparison depend on the version of the .NET. On .NET Core, string comparison depends on the version of the Unicode Standard supported by the underlying operating system. In .NET Framework 4.5 and later versions running on Windows 8 or later, sorting, casing, normalization, and Unicode character information conform to the Unicode 6.0 standard. On other Windows operating systems, they conform to the Unicode 5.0 standard.

For more information about word, string, and ordinal sort rules, see the [System.Globalization.CompareOptions](#) topic. For additional recommendations on when to use each rule, see [Best Practices for Using Strings](#).

Ordinarily, you don't call string comparison methods such as [Compare](#) directly to determine the sort order of strings. Instead, comparison methods are called by sorting methods such as [Array.Sort](#) or [List<T>.Sort](#). The following example performs four different sorting operations (word sort using the current culture, word sort using the invariant culture, ordinal sort, and string sort using the invariant culture) without explicitly calling a string comparison method, although they do specify the type of comparison to use. Note that each type of sort produces a unique ordering of strings in its array.

C#

```
using System;
using System.Collections;
using System.Collections.Generic;
using System.Globalization;

public class Example3
{
    public static void Main()
    {
        string[] strings = { "coop", "co-op", "cooperative",
                             "co\u00e2operative", "cœur", "coeur" };

        // Perform a word sort using the current (en-US) culture.
        string[] current = new string[strings.Length];
        strings.CopyTo(current, 0);
        Array.Sort(current, StringComparer.CurrentCulture);

        // Perform a word sort using the invariant culture.
        string[] invariant = new string[strings.Length];
        strings.CopyTo(invariant, 0);
        Array.Sort(invariant, StringComparer.InvariantCulture);

        // Perform an ordinal sort.
        string[] ordinal = new string[strings.Length];
        strings.CopyTo(ordinal, 0);
        Array.Sort(ordinal, StringComparer.Ordinal);

        // Perform a string sort using the current culture.
        string[] stringSort = new string[strings.Length];
        strings.CopyTo(stringSort, 0);
        Array.Sort(stringSort, new SCompare());

        // Display array values
        Console.WriteLine("{0,13} {1,13} {2,15} {3,13} {4,13}\n",
                         "Original", "Word Sort", "Invariant Word",
                         "Ordinal Sort", "String Sort");
    }
}
```

```

        for (int ctr = 0; ctr < strings.Length; ctr++)
            Console.WriteLine("{0,13} {1,13} {2,15} {3,13} {4,13}",
                strings[ctr], current[ctr], invariant[ctr],
                ordinal[ctr], stringSort[ctr] );
    }
}

// IComparer<String> implementation to perform string sort.
internal class SCompare : IComparer<String>
{
    public int Compare(string x, string y)
    {
        return CultureInfo.CurrentCulture.CompareInfo.Compare(x, y,
CompareOptions.StringSort);
    }
}
// The example displays the following output:
//          Original      Word Sort  Invariant Word  Ordinal Sort  String
Sort
//
//          coop           cœur          cœur          co-op         co-
op
//
//          co-op          cœur          cœur          cœur
cœur
//
//          cooperative     coop          coop          coop
coeur
//
//          cooperative     co-op          co-op        cooperative       coop
//
//          cœur          cooperative   cooperative  cooperative  cooperative
//
//          cœur          cooperative   cooperative  cœur        cooperative

```

Tip

Internally, .NET uses sort keys to support culturally sensitive string comparison. Each character in a string is given several categories of sort weights, including alphabetic, case, and diacritic. A sort key, represented by the **SortKey** class, provides a repository of these weights for a particular string. If your app performs a large number of searching or sorting operations on the same set of strings, you can improve its performance by generating and storing sort keys for all the strings that it uses. When a sort or comparison operation is required, you use the sort keys instead of the strings. For more information, see the **SortKey** class.

If you don't specify a string comparison convention, sorting methods such as [Array.Sort\(Array\)](#) perform a culture-sensitive, case-sensitive sort on strings. The following example illustrates how changing the current culture affects the order of sorted strings in an array. It creates an array of three strings. First, it sets the [System.Threading.Thread.CurrentCulture](#) property to en-US and calls the [Array.Sort\(Array\)](#) method. The resulting sort order is based on sorting conventions for

the English (United States) culture. Next, the example sets the `System.Threading.Thread.CurrentCulture` property to da-DK and calls the `Array.Sort` method again. Notice how the resulting sort order differs from the en-US results because it uses the sorting conventions for Danish (Denmark).

C#

```
using System;
using System.Globalization;
using System.Threading;

public class ArraySort
{
    public static void Main(String[] args)
    {
        // Create and initialize a new array to store the strings.
        string[] stringArray = { "Apple", "Æble", "Zebra" };

        // Display the values of the array.
        Console.WriteLine( "The original string array:");
        PrintIndexAndValues(stringArray);

        // Set the CurrentCulture to "en-US".
        Thread.CurrentCulture = new CultureInfo("en-US");
        // Sort the values of the array.
        Array.Sort(stringArray);

        // Display the values of the array.
        Console.WriteLine("After sorting for the culture \"en-US\":");
        PrintIndexAndValues(stringArray);

        // Set the CurrentCulture to "da-DK".
        Thread.CurrentCulture = new CultureInfo("da-DK");
        // Sort the values of the Array.
        Array.Sort(stringArray);

        // Display the values of the array.
        Console.WriteLine("After sorting for the culture \"da-DK\":");
        PrintIndexAndValues(stringArray);
    }

    public static void PrintIndexAndValues(string[] myArray)
    {
        for (int i = myArray.GetLowerBound(0); i <=
             myArray.GetUpperBound(0); i++ )
            Console.WriteLine("[{0}]: {1}", i, myArray[i]);
        Console.WriteLine();
    }
}

// The example displays the following output:
//      The original string array:
//      [0]: Apple
//      [1]: Æble
//      [2]: Zebra
```

```
//      After sorting for the "en-US" culture:  
//      [0]: Åble  
//      [1]: Apple  
//      [2]: Zebra  
  
//      After sorting for the culture "da-DK":  
//      [0]: Apple  
//      [1]: Zebra  
//      [2]: Åble
```

⚠ Warning

If your primary purpose in comparing strings is to determine whether they are equal, you should call the [String.Equals](#) method. Typically, you should use [Equals](#) to perform an ordinal comparison. The [String.Compare](#) method is intended primarily to sort strings.

String search methods, such as [String.StartsWith](#) and [String.IndexOf](#), also can perform culture-sensitive or ordinal string comparisons. The following example illustrates the differences between ordinal and culture-sensitive comparisons using the [IndexOf](#) method. A culture-sensitive search in which the current culture is English (United States) considers the substring "oe" to match the ligature "œ". Because a soft hyphen (U+00AD) is a zero-width character, the search treats the soft hyphen as equivalent to [String.Empty](#) and finds a match at the beginning of the string. An ordinal search, on the other hand, does not find a match in either case.

C#

```
using System;  
  
public class Example8  
{  
    public static void Main()  
    {  
        // Search for "oe" and "œu" in "œufs" and "oeufs".  
        string s1 = "œufs";  
        string s2 = "oeufs";  
        FindInString(s1, "oe", StringComparison.CurrentCulture);  
        FindInString(s1, "oe", StringComparison.Ordinal);  
        FindInString(s2, "œu", StringComparison.CurrentCulture);  
        FindInString(s2, "œu", StringComparison.Ordinal);  
        Console.WriteLine();  
  
        string s3 = "co\u00ADoperative";  
        FindInString(s3, "\u00AD", StringComparison.CurrentCulture);  
        FindInString(s3, "\u00AD", StringComparison.Ordinal);  
    }  
}
```

```

private static void FindInString(string s, string substring,
 StringComparison options)
{
    int result = s.IndexOf(substring, options);
    if (result != -1)
        Console.WriteLine("'{}' found in {} at position {}",
                         substring, s, result);
    else
        Console.WriteLine("'{}' not found in {}", substring, s);
}
// The example displays the following output:
//      'oe' found in œufs at position 0
//      'oe' not found in œufs
//      'œu' found in œufs at position 0
//      'œu' not found in œufs
//
//      '' found in cooperative at position 0
//      '' found in cooperative at position 2

```

Search in strings

String search methods, such as [String.StartsWith](#) and [String.IndexOf](#), also can perform culture-sensitive or ordinal string comparisons to determine whether a character or substring is found in a specified string.

The search methods in the [String](#) class that search for an individual character, such as the [IndexOf](#) method, or one of a set of characters, such as the [IndexOfAny](#) method, all perform an ordinal search. To perform a culture-sensitive search for a character, you must call a [CompareInfo](#) method such as [CompareInfo.IndexOf\(String, Char\)](#) or [CompareInfo.LastIndexOf\(String, Char\)](#). Note that the results of searching for a character using ordinal and culture-sensitive comparison can be very different. For example, a search for a precomposed Unicode character such as the ligature "Æ" (U+00C6) might match any occurrence of its components in the correct sequence, such as "AE" (U+041U+0045), depending on the culture. The following example illustrates the difference between the [String.IndexOf\(Char\)](#) and [CompareInfo.IndexOf\(String, Char\)](#) methods when searching for an individual character. The ligature "æ" (U+00E6) is found in the string "aerial" when using the conventions of the en-US culture, but not when using the conventions of the da-DK culture or when performing an ordinal comparison.

C#

```

using System;
using System.Globalization;

```

```

public class Example17
{
    public static void Main()
    {
        String[] cultureNames = { "da-DK", "en-US" };
        CompareInfo ci;
        String str = "aerial";
        Char ch = 'æ'; // U+00E6

        Console.Write("Ordinal comparison -- ");
        Console.WriteLine("Position of '{0}' in {1}: {2}", ch, str,
                         str.IndexOf(ch));

        foreach (var cultureName in cultureNames) {
            ci = CultureInfo.CreateSpecificCulture(cultureName).CompareInfo;
            Console.Write("{0} cultural comparison -- ", cultureName);
            Console.WriteLine("Position of '{0}' in {1}: {2}", ch, str,
                             ci.IndexOf(str, ch));
        }
    }
}

// The example displays the following output:
//      Ordinal comparison -- Position of 'æ' in aerial: -1
//      da-DK cultural comparison -- Position of 'æ' in aerial: -1
//      en-US cultural comparison -- Position of 'æ' in aerial: 0

```

On the other hand, [String](#) class methods that search for a string rather than a character perform a culture-sensitive search if search options are not explicitly specified by a parameter of type [StringComparison](#). The sole exception is [Contains](#), which performs an ordinal search.

Test for equality

Use the [String.Compare](#) method to determine the relationship of two strings in the sort order. Typically, this is a culture-sensitive operation. In contrast, call the [String.Equals](#) method to test for equality. Because the test for equality usually compares user input with some known string, such as a valid user name, a password, or a file system path, it is typically an ordinal operation.

Warning

It is possible to test for equality by calling the [String.Compare](#) method and determining whether the return value is zero. However, this practice is not recommended. To determine whether two strings are equal, you should call one of the overloads of the [String.Equals](#) method. The preferred overload to call is either the instance [Equals\(String, StringComparison\)](#) method or the static [Equals\(String, String, StringComparison\)](#) method, because both methods include a

System.StringComparison parameter that explicitly specifies the type of comparison.

The following example illustrates the danger of performing a culture-sensitive comparison for equality when an ordinal one should be used instead. In this case, the intent of the code is to prohibit file system access from URLs that begin with "FILE://" or "file://" by performing a case-insensitive comparison of the beginning of a URL with the string "FILE://". However, if a culture-sensitive comparison is performed using the Turkish (Turkey) culture on a URL that begins with "file://", the comparison for equality fails, because the Turkish uppercase equivalent of the lowercase "i" is "İ" instead of "I". As a result, file system access is inadvertently permitted. On the other hand, if an ordinal comparison is performed, the comparison for equality succeeds, and file system access is denied.

C#

```
using System;
using System.Globalization;
using System.Threading;

public class Example4
{
    public static void Main()
    {
        Thread.CurrentThread.CurrentCulture =
CultureInfo.CreateSpecificCulture("tr-TR");

        string filePath = "file:///c:/notes.txt";

        Console.WriteLine("Culture-sensitive test for equality:");
        if (! TestForEquality(filePath,
StringComparison.CurrentCultureIgnoreCase))
            Console.WriteLine("Access to {0} is allowed.", filePath);
        else
            Console.WriteLine("Access to {0} is not allowed.", filePath);

        Console.WriteLine("\nOrdinal test for equality:");
        if (! TestForEquality(filePath, StringComparison.OrdinalIgnoreCase))
            Console.WriteLine("Access to {0} is allowed.", filePath);
        else
            Console.WriteLine("Access to {0} is not allowed.", filePath);
    }

    private static bool TestForEquality(string str, StringComparison cmp)
    {
        int position = str.IndexOf(":/");
        if (position < 0) return false;

        string substring = str.Substring(0, position);
```

```
        return substring.Equals("FILE", cmp);
    }
}
// The example displays the following output:
//     Culture-sensitive test for equality:
//         Access to file:///c:/notes.txt is allowed.
//
//     Ordinal test for equality:
//         Access to file:///c:/notes.txt is not allowed.
```

Normalization

Some Unicode characters have multiple representations. For example, any of the following code points can represent the letter "å":

- U+1EAF
- U+0103 U+0301
- U+0061 U+0306 U+0301

Multiple representations for a single character complicate searching, sorting, matching, and other string operations.

The Unicode standard defines a process called normalization that returns one binary representation of a Unicode character for any of its equivalent binary representations. Normalization can use several algorithms, called normalization forms, that follow different rules. .NET supports Unicode normalization forms C, D, KC, and KD. When strings have been normalized to the same normalization form, they can be compared by using ordinal comparison.

An ordinal comparison is a binary comparison of the Unicode scalar value of corresponding [Char](#) objects in each string. The [String](#) class includes a number of methods that can perform an ordinal comparison, including the following:

- Any overload of the [Compare](#), [Equals](#), [StartsWith](#), [EndsWith](#), [IndexOf](#), and [LastIndexOf](#) methods that includes a [StringComparison](#) parameter. The method performs an ordinal comparison if you supply a value of [StringComparison.Ordinal](#) or [StringComparison.OrdinalIgnoreCase](#) for this parameter.
- The overloads of the [CompareOrdinal](#) method.
- Methods that use ordinal comparison by default, such as [Contains](#), [Replace](#), and [Split](#).
- Methods that search for a [Char](#) value or for the elements in a [Char](#) array in a string instance. Such methods include [IndexOf\(Char\)](#) and [Split\(Char\[\]\)](#).

You can determine whether a string is normalized to normalization form C by calling the [String.IsNormalized\(\)](#) method, or you can call the [String.IsNormalized\(NormalizationForm\)](#) method to determine whether a string is normalized to a specified normalization form. You can also call the [String.Normalize\(\)](#) method to convert a string to normalization form C, or you can call the [String.Normalize\(NormalizationForm\)](#) method to convert a string to a specified normalization form. For step-by-step information about normalizing and comparing strings, see the [Normalize\(\)](#) and [Normalize\(NormalizationForm\)](#) methods.

The following simple example illustrates string normalization. It defines the letter "ő" in three different ways in three different strings, and uses an ordinal comparison for equality to determine that each string differs from the other two strings. It then converts each string to the supported normalization forms, and again performs an ordinal comparison of each string in a specified normalization form. In each case, the second test for equality shows that the strings are equal.

C#

```
using System;
using System.Globalization;
using System.IO;
using System.Text;

public class Example13
{
    private static StreamWriter sw;

    public static void Main()
    {
        sw = new StreamWriter(@".\TestNorm1.txt");

        // Define three versions of the same word.
        string s1 = "sőng";           // create word with U+1ED1
        string s2 = "s\u00F4ng";
        string s3 = "s\u0302ng";

        TestForEquality(s1, s2, s3);
        sw.WriteLine();

        // Normalize and compare strings using each normalization form.
        foreach (string formName in Enum.GetNames(typeof(NormalizationForm)))
        {
            sw.WriteLine("Normalization {0}:\n", formName);
            NormalizationForm nf = (NormalizationForm)
                Enum.Parse(typeof(NormalizationForm), formName);
            string[] sn = NormalizeStrings(nf, s1, s2, s3);
            TestForEquality(sn);
            sw.WriteLine("\n");
        }
    }

    private void TestForEquality(string[] strings)
    {
        for (int i = 0; i < strings.Length - 1; i++)
        {
            if (strings[i] != strings[i + 1])
            {
                sw.WriteLine("The strings are not equal.");
                return;
            }
        }
        sw.WriteLine("The strings are equal.");
    }

    private string[] NormalizeStrings(NormalizationForm nf, string s1, string s2, string s3)
    {
        string[] result = new string[3];
        result[0] = String.Normalize(nf, s1);
        result[1] = String.Normalize(nf, s2);
        result[2] = String.Normalize(nf, s3);
        return result;
    }
}
```

```

        sw.Close();
    }

private static void TestForEquality(params string[] words)
{
    for (int ctr = 0; ctr <= words.Length - 2; ctr++)
        for (int ctr2 = ctr + 1; ctr2 <= words.Length - 1; ctr2++)
            sw.WriteLine("{0} ({1}) = {2} ({3}): {4}",
                        words[ctr], ShowBytes(words[ctr]),
                        words[ctr2], ShowBytes(words[ctr2]),
                        words[ctr].Equals(words[ctr2],
StringComparison.OrdinalIgnoreCase));
}

private static string ShowBytes(string str)
{
    string result = null;
    foreach (var ch in str)
        result += $"{(ushort)ch:X4} ";
    return result.Trim();
}

private static string[] NormalizeStrings(NormalizationForm nf, params
string[] words)
{
    for (int ctr = 0; ctr < words.Length; ctr++)
        if (!words[ctr].IsNormalized(nf))
            words[ctr] = words[ctr].Normalize(nf);
    return words;
}

// The example displays the following output:
//      sông (0073 1ED1 006E 0067) = sông (0073 00F4 0301 006E 0067): False

```

For more information about normalization and normalization forms, see [System.Text.NormalizationForm](#), as well as [Unicode Standard Annex #15: Unicode Normalization Forms](#) and the [Normalization FAQ](#) on the unicode.org website.

String operations by category

The [String](#) class provides members for comparing strings, testing strings for equality, finding characters or substrings in a string, modifying a string, extracting substrings from a string, combining strings, formatting values, copying a string, and normalizing a string.

Compare strings

You can compare strings to determine their relative position in the sort order by using the following [String](#) methods:

- [Compare](#) returns an integer that indicates the relationship of one string to a second string in the sort order.
- [CompareOrdinal](#) returns an integer that indicates the relationship of one string to a second string based on a comparison of their code points.
- [CompareTo](#) returns an integer that indicates the relationship of the current string instance to a second string in the sort order. The [CompareTo\(String\)](#) method provides the [IComparable](#) and [IComparable<T>](#) implementations for the [String](#) class.

Test strings for equality

You call the [Equals](#) method to determine whether two strings are equal. The instance [Equals\(String, String, StringComparison\)](#) and the static [Equals\(String, StringComparison\)](#) overloads let you specify whether the comparison is culture-sensitive or ordinal, and whether case is considered or ignored. Most tests for equality are ordinal, and comparisons for equality that determine access to a system resource (such as a file system object) should always be ordinal.

Find characters in a string

The [String](#) class includes two kinds of search methods:

- Methods that return a [Boolean](#) value to indicate whether a particular substring is present in a string instance. These include the [Contains](#), [EndsWith](#), and [StartsWith](#) methods.
- Methods that indicate the starting position of a substring in a string instance. These include the [IndexOf](#), [IndexOfAny](#), [LastIndexOf](#), and [LastIndexOfAny](#) methods.

Warning

If you want to search a string for a particular pattern rather than a specific substring, you should use regular expressions. For more information, see [.NET Regular Expressions](#).

Modify a string

The [String](#) class includes the following methods that appear to modify the value of a string:

- [Insert](#) inserts a string into the current [String](#) instance.
- [PadLeft](#) inserts one or more occurrences of a specified character at the beginning of a string.
- [PadRight](#) inserts one or more occurrences of a specified character at the end of a string.
- [Remove](#) deletes a substring from the current [String](#) instance.
- [Replace](#) replaces a substring with another substring in the current [String](#) instance.
- [ToLower](#) and [ToLowerInvariant](#) convert all the characters in a string to lowercase.

- [ToUpper](#) and [ToUpperInvariant](#) convert all the characters in a string to uppercase.
- [Trim](#) removes all occurrences of a character from the beginning and end of a string.
- [TrimEnd](#) removes all occurrences of a character from the end of a string.
- [TrimStart](#) removes all occurrences of a character from the beginning of a string.

Important

All string modification methods return a new [String](#) object. They don't modify the value of the current instance.

Extract substrings from a string

The [String.Split](#) method separates a single string into multiple strings. Overloads of the method allow you to specify multiple delimiters, to limit the number of substrings that the method extracts, to trim white space from substrings, and to specify whether empty strings (which occur when delimiters are adjacent) are included among the returned strings.

Combine strings

The following [String](#) methods can be used for string concatenation:

- [Concat](#) combines one or more substrings into a single string.
- [Join](#) concatenates one or more substrings into a single element and adds a separator between each substring.

Format values

The [String.Format](#) method uses the composite formatting feature to replace one or more placeholders in a string with the string representation of some object or value. The [Format](#) method is often used to do the following:

- To embed the string representation of a numeric value in a string.
- To embed the string representation of a date and time value in a string.
- To embed the string representation of an enumeration value in a string.
- To embed the string representation of some object that supports the [IFormattable](#) interface in a string.
- To right-justify or left-justify a substring in a field within a larger string.

For detailed information about formatting operations and examples, see the [Format](#) overload summary.

Copy a string

You can call the following [String](#) methods to make a copy of a string:

- [Clone](#) returns a reference to an existing [String](#) object.
- [Copy](#) creates a copy of an existing string.
- [CopyTo](#) copies a portion of a string to a character array.

Normalize a string

In Unicode, a single character can have multiple code points. Normalization converts these equivalent characters into the same binary representation. The [String.Normalize](#) method performs the normalization, and the [String.IsNormalized](#) method determines whether a string is normalized.

For more information and an example, see the [Normalization](#) section earlier in this article.

System.Char struct

Article • 01/08/2024

This article provides supplementary remarks to the reference documentation for this API.

The [Char](#) structure represents Unicode code points by using UTF-16 encoding. The value of a [Char](#) object is its 16-bit numeric (ordinal) value.

If you aren't familiar with Unicode, scalar values, code points, surrogate pairs, UTF-16, and the [Rune](#) type, see [Introduction to character encoding in .NET](#).

This article examines the relationship between a [Char](#) object and a character and discuss some common tasks performed with [Char](#) instances. We recommend that you consider the [Rune](#) type, introduced in .NET Core 3.0, as an alternative to [Char](#) for performing some of these tasks.

Char objects, Unicode characters, and strings

A [String](#) object is a sequential collection of [Char](#) structures that represents a string of text. Most Unicode characters can be represented by a single [Char](#) object, but a character that is encoded as a base character, surrogate pair, and/or combining character sequence is represented by multiple [Char](#) objects. For this reason, a [Char](#) structure in a [String](#) object is not necessarily equivalent to a single Unicode character.

Multiple 16-bit code units are used to represent single Unicode characters in the following cases:

- Glyphs, which may consist of a single character or of a base character followed by one or more combining characters. For example, the character ä is represented by a [Char](#) object whose code unit is U+0061 followed by a [Char](#) object whose code unit is U+0308. (The character ä can also be defined by a single [Char](#) object that has a code unit of U+00E4.) The following example illustrates that the character ä consists of two [Char](#) objects.

C#

```
using System;
using System.IO;

public class Example1
{
    public static void Main()
```

```

    }
    StreamWriter sw = new StreamWriter("chars1.txt");
    char[] chars = { '\u0061', '\u0308' };
    string strng = new String(chars);
    sw.WriteLine(strng);
    sw.Close();
}
}

// The example produces the following output:
//      ä

```

- Characters outside the Unicode Basic Multilingual Plane (BMP). Unicode supports sixteen planes in addition to the BMP, which represents plane 0. A Unicode code point is represented in UTF-32 by a 21-bit value that includes the plane. For example, U+1D160 represents the MUSICAL SYMBOL EIGHTH NOTE character. Because UTF-16 encoding has only 16 bits, characters outside the BMP are represented by surrogate pairs in UTF-16. The following example illustrates that the UTF-32 equivalent of U+1D160, the MUSICAL SYMBOL EIGHTH NOTE character, is U+D834 U+DD60. U+D834 is the high surrogate; high surrogates range from U+D800 through U+DBFF. U+DD60 is the low surrogate; low surrogates range from U+DC00 through U+DFFF.

C#

```

using System;
using System.IO;

public class Example3
{
    public static void Main()
    {
        StreamWriter sw = new StreamWriter(@".\chars2.txt");
        int utf32 = 0x1D160;
        string surrogate = Char.ConvertFromUtf32(utf32);
        sw.WriteLine("U+{0:X6} UTF-32 = {1} ({2}) UTF-16",
                    utf32, surrogate, ShowCodePoints(surrogate));
        sw.Close();
    }

    private static string ShowCodePoints(string value)
    {
        string retval = null;
        foreach (var ch in value)
            retval += String.Format("U+{0:X4} ", Convert.ToInt16(ch));

        return retval.Trim();
    }
}

```

```
// The example produces the following output:  
//      U+01D160 UTF-32 = δ (U+D834 U+DD60) UTF-16
```

Characters and character categories

Each Unicode character or valid surrogate pair belongs to a Unicode category. In .NET, Unicode categories are represented by members of the [UnicodeCategory](#) enumeration and include values such as [UnicodeCategory.CurrencySymbol](#), [UnicodeCategory.LowercaseLetter](#), and [UnicodeCategory.SpaceSeparator](#), for example.

To determine the Unicode category of a character, call the [GetUnicodeCategory](#) method. For example, the following example calls the [GetUnicodeCategory](#) to display the Unicode category of each character in a string. The example works correctly only if there are no surrogate pairs in the [String](#) instance.

C#

```
using System;  
using System.Globalization;  
  
class Example  
{  
    public static void Main()  
    {  
        // Define a string with a variety of character categories.  
        String s = "The red car drove down the long, narrow, secluded road.";  
        // Determine the category of each character.  
        foreach (var ch in s)  
            Console.WriteLine("{0}': {1}", ch, Char.GetUnicodeCategory(ch));  
    }  
}  
// The example displays the following output:  
//      'T': UppercaseLetter  
//      'h': LowercaseLetter  
//      'e': LowercaseLetter  
//      ' ': SpaceSeparator  
//      'r': LowercaseLetter  
//      'e': LowercaseLetter  
//      'd': LowercaseLetter  
//      ' ': SpaceSeparator  
//      'c': LowercaseLetter  
//      'a': LowercaseLetter  
//      'r': LowercaseLetter  
//      ' ': SpaceSeparator  
//      'd': LowercaseLetter  
//      'r': LowercaseLetter  
//      'o': LowercaseLetter  
//      'v': LowercaseLetter  
//      'e': LowercaseLetter
```

```
//      ' ': SpaceSeparator
//      'd': LowercaseLetter
//      'o': LowercaseLetter
//      'w': LowercaseLetter
//      'n': LowercaseLetter
//      ' ': SpaceSeparator
//      't': LowercaseLetter
//      'h': LowercaseLetter
//      'e': LowercaseLetter
//      ' ': SpaceSeparator
//      'l': LowercaseLetter
//      'o': LowercaseLetter
//      'n': LowercaseLetter
//      'g': LowercaseLetter
//      ',': OtherPunctuation
//      ' ': SpaceSeparator
//      'n': LowercaseLetter
//      'a': LowercaseLetter
//      'r': LowercaseLetter
//      'r': LowercaseLetter
//      'o': LowercaseLetter
//      'w': LowercaseLetter
//      ',': OtherPunctuation
//      ' ': SpaceSeparator
//      's': LowercaseLetter
//      'e': LowercaseLetter
//      'c': LowercaseLetter
//      'l': LowercaseLetter
//      'u': LowercaseLetter
//      'd': LowercaseLetter
//      'e': LowercaseLetter
//      'd': LowercaseLetter
//      ' ': SpaceSeparator
//      'r': LowercaseLetter
//      'o': LowercaseLetter
//      'a': LowercaseLetter
//      'd': LowercaseLetter
//      '.': OtherPunctuation
```

Internally, for characters outside the ASCII range (U+0000 through U+00FF), the [GetUnicodeCategory](#) method depends on Unicode categories reported by the [CharUnicodeInfo](#) class. Starting with .NET Framework 4.6.2, Unicode characters are classified based on [The Unicode Standard, Version 8.0.0](#). In versions of the .NET Framework from .NET Framework 4 to .NET Framework 4.6.1, they are classified based on [The Unicode Standard, Version 6.3.0](#).

Characters and text elements

Because a single character can be represented by multiple [Char](#) objects, it is not always meaningful to work with individual [Char](#) objects. For instance, the following example

converts the Unicode code points that represent the Aegean numbers zero through 9 to UTF-16 encoded code units. Because it erroneously equates [Char](#) objects with characters, it inaccurately reports that the resulting string has 20 characters.

C#

```
using System;

public class Example5
{
    public static void Main()
    {
        string result = String.Empty;
        for (int ctr = 0x10107; ctr <= 0x10110; ctr++) // Range of Aegean
numbers.
            result += Char.ConvertFromUtf32(ctr);

        Console.WriteLine("The string contains {0} characters.", result.Length);
    }
}
// The example displays the following output:
//      The string contains 20 characters.
```

You can do the following to avoid the assumption that a [Char](#) object represents a single character:

- You can work with a [String](#) object in its entirety instead of working with its individual characters to represent and analyze linguistic content.
- You can use [String.EnumerateRunes](#) as shown in the following example:

C#

```
int CountLetters(string s)
{
    int letterCount = 0;

    foreach (Rune rune in s.EnumerateRunes())
    {
        if (Rune.IsLetter(rune))
            { letterCount++; }
    }

    return letterCount;
}
```

- You can use the [StringInfo](#) class to work with text elements instead of individual [Char](#) objects. The following example uses the [StringInfo](#) object to count the

number of text elements in a string that consists of the Aegean numbers zero through nine. Because it considers a surrogate pair a single character, it correctly reports that the string contains ten characters.

```
C#  
  
using System;  
using System.Globalization;  
  
public class Example4  
{  
    public static void Main()  
    {  
        string result = String.Empty;  
        for (int ctr = 0x10107; ctr <= 0x10110; ctr++) // Range of Aegean numbers.  
            result += Char.ConvertFromUtf32(ctr);  
  
        StringInfo si = new StringInfo(result);  
        Console.WriteLine("The string contains {0} characters.",  
                          si.LengthInTextElements);  
    }  
}  
// The example displays the following output:  
//     The string contains 10 characters.
```

- If a string contains a base character that has one or more combining characters, you can call the `String.Normalize` method to convert the substring to a single UTF-16 encoded code unit. The following example calls the `String.Normalize` method to convert the base character U+0061 (LATIN SMALL LETTER A) and combining character U+0308 (COMBINING DIAERESIS) to U+00E4 (LATIN SMALL LETTER A WITH DIAERESIS).

```
C#  
  
using System;  
  
public class Example2  
{  
    public static void Main()  
    {  
        string combining = "\u0061\u0308";  
        ShowString(combining);  
  
        string normalized = combining.Normalize();  
        ShowString(normalized);  
    }  
  
    private static void ShowString(string s)  
    {
```

```

        Console.WriteLine("Length of string: {0} ({", s.Length);
        for (int ctr = 0; ctr < s.Length; ctr++)
        {
            Console.Write("U+{0:X4}", Convert.ToInt16(s[ctr]));
            if (ctr != s.Length - 1) Console.Write(" ");
        }
        Console.WriteLine(")\n");
    }
}

// The example displays the following output:
//      Length of string: 2 (U+0061 U+0308)
//
//      Length of string: 1 (U+00E4)

```

Common operations

The [Char](#) structure provides methods to compare [Char](#) objects, convert the value of the current [Char](#) object to an object of another type, and determine the Unicode category of a [Char](#) object:

[Expand table](#)

| To do this | Use these <code>System.Char</code> methods |
|--|--|
| Compare Char objects | CompareTo and Equals |
| Convert a code point to a string | ConvertFromUtf32 See also the Rune type. |
| Convert a Char object or a surrogate pair of Char objects to a code point | For a single character: Convert.ToInt32(Char) For a surrogate pair or a character in a string: Char.ConvertToUtf32 See also the Rune type. |
| Get the Unicode category of a character | GetUnicodeCategory See also Rune.GetUnicodeCategory . |
| Determine whether a character is in a particular Unicode category such as digit, letter, punctuation, control character, and so on | IsControl , IsDigit , IsHighSurrogate , IsLetter , IsLetterOrDigit , IsLower , IsLowSurrogate , IsNumber , IsPunctuation , IsSeparator , IsSurrogate , IsSurrogatePair , IsSymbol , IsUpper , and IsWhiteSpace See also corresponding methods on the Rune type. |

| To do this | Use these <code>System.Char</code> methods |
|---|--|
| Convert a <code>Char</code> object that represents a number to a numeric value type | <code>GetNumericValue</code> See also Rune.GetNumericValue . |
| Convert a character in a string into a <code>Char</code> object | <code>Parse</code> and <code>TryParse</code> |
| Convert a <code>Char</code> object to a <code>String</code> object | <code>ToString</code> |
| Change the case of a <code>Char</code> object | <code>ToLower</code> , <code>ToLowerInvariant</code> , <code>ToUpper</code> , and <code>ToUpperInvariant</code> See also corresponding methods on the <code>Rune</code> type. |

Char values and interop

When a managed `Char` type, which is represented as a Unicode UTF-16 encoded code unit, is passed to unmanaged code, the interop marshaller converts the character set to ANSI by default. You can apply the `DllImportAttribute` attribute to platform invoke declarations and the `StructLayoutAttribute` attribute to a COM interop declaration to control which character set a marshaled `Char` type uses.

System.StringComparer class

Article • 01/08/2024

This article provides supplementary remarks to the reference documentation for this API.

An object derived from the [StringComparer](#) class embodies string-based comparison, equality, and hash code operations that take into account both case and culture-specific comparison rules. You can use the [StringComparer](#) class to create a type-specific comparison to sort the elements in a generic collection. Classes such as [Hashtable](#), [Dictionary<TKey,TValue>](#), [SortedList](#), and [SortedList<TKey,TValue>](#) use the [StringComparer](#) class for sorting purposes.

A comparison operation that is represented by the [StringComparer](#) class is defined to be either case-sensitive or case-insensitive, and use either word (culture-sensitive) or ordinal (culture-insensitive) comparison rules. For more information about word and ordinal comparison rules, see [System.Globalization.CompareOptions](#).

ⓘ Note

You can download the [Default Unicode Collation Element Table](#), the latest version of the sort weight table. The specific version of the sort weight table depends on the version of the [International Components for Unicode](#) libraries installed on the system. For information on ICU versions and the Unicode versions that they implement, see [Downloading ICU](#).

For .NET Framework on Windows, you can download the [Sorting Weight Tables](#), a set of text files that contain information on the character weights used in sorting and comparison operations.

Implemented properties

You might be confused about how to use the [StringComparer](#) class properties because of a seeming contradiction. The [StringComparer](#) class is declared `abstract` (`MustInherit` in Visual Basic), which means its members can be invoked only on an object of a class derived from the [StringComparer](#) class. The contradiction is that each property of the [StringComparer](#) class is declared `static` (`Shared` in Visual Basic), which means the property can be invoked without first creating a derived class.

You can call a [StringComparer](#) property directly because each property actually returns an instance of an anonymous class that is derived from the [StringComparer](#) class. Consequently, the type of each property value is [StringComparer](#), which is the base class of the anonymous class, not the type of the anonymous class itself. Each [StringComparer](#) class property returns a [StringComparer](#) object that supports predefined case and comparison rules.

System.Text.Encoding class

Article • 01/08/2024

This article provides supplementary remarks to the reference documentation for this API.

The [Encoding](#) class represents a character encoding.

Encoding is the process of transforming a set of Unicode characters into a sequence of bytes. In contrast, decoding is the process of transforming a sequence of encoded bytes into a set of Unicode characters. For information about the Unicode Transformation Formats (UTFs) and other encodings supported by [Encoding](#), see [Character Encoding in .NET](#).

[Encoding](#) is intended to operate on Unicode characters instead of arbitrary binary data, such as byte arrays. If you must encode arbitrary binary data into text, you should use a protocol such as uuencode, which is implemented by methods such as [Convert.ToBase64CharArray](#).

.NET provides the following implementations of the [Encoding](#) class to support current Unicode encodings and other encodings:

- [ASCIIEncoding](#) encodes Unicode characters as single 7-bit ASCII characters. This encoding only supports character values between U+0000 and U+007F. Code page 20127. Also available through the [ASCII](#) property.
- [UTF7Encoding](#) encodes Unicode characters using the UTF-7 encoding. This encoding supports all Unicode character values. Code page 65000. Also available through the [UTF7](#) property.
- [UTF8Encoding](#) encodes Unicode characters using the UTF-8 encoding. This encoding supports all Unicode character values. Code page 65001. Also available through the [UTF8](#) property.
- [UnicodeEncoding](#) encodes Unicode characters using the UTF-16 encoding. Both little endian and big endian byte orders are supported. Also available through the [Unicode](#) property and the [BigEndianUnicode](#) property.
- [UTF32Encoding](#) encodes Unicode characters using the UTF-32 encoding. Both little endian (code page 12000) and big endian (code page 12001) byte orders are supported. Also available through the [UTF32](#) property.

The [Encoding](#) class is primarily intended to convert between different encodings and Unicode. Often one of the derived Unicode classes is the correct choice for your app.

Use the [GetEncoding](#) method to obtain other encodings, and call the [GetEncodings](#) method to get a list of all encodings.

List of encodings

The following table lists the encodings supported by .NET. It lists each encoding's code page number and the values of the encoding's [EncodingInfo.Name](#) and [EncodingInfo.DisplayName](#) properties. A check mark in the [.NET Framework support](#), [.NET Core support](#), or [.NET 5 and later support](#) column indicates that the code page is natively supported by that .NET implementation, regardless of the underlying platform. For .NET Framework, the availability of other encodings listed in the table depends on the operating system. For .NET Core and .NET 5 and later versions, other encodings are available by using the [System.Text.CodePagesEncodingProvider](#) class or by deriving from the [System.Text.EncodingProvider](#) class.

 **Note**

Code pages whose [EncodingInfo.Name](#) property corresponds to an international standard do not necessarily comply in full with that standard.

The following example calls the [GetEncoding\(Int32\)](#) and [GetEncoding\(String\)](#) methods to get the Greek (Windows) code page encoding. It compares the [Encoding](#) objects returned by the method calls to show that they are equal, and then maps displays the Unicode code point and the corresponding code page value for each character in the Greek alphabet.

C#

```

using System;
using System.Text;

public class Example
{
    public static void Main()
    {
        Encoding enc = Encoding.GetEncoding(1253);
        Encoding altEnc = Encoding.GetEncoding("windows-1253");
        Console.WriteLine("{0} = Code Page {1}: {2}", enc.EncodingName,
                           altEnc.CodePage, enc.Equals(altEnc));
        string greekAlphabet = "Α α Β β Γ γ Δ δ Ε ε Ζ ζ Η η " +
                               "Θ θ Ι ι Κ κ Λ λ Μ μ Ν ν Ξ ξ " +
                               "Ο ο Π π Ρ ρ Σ σ Σ σ Τ τ Υ υ " +
                               "Φ φ Χ χ Ψ ψ Ω ω";
        Console.OutputEncoding = Encoding.UTF8;
        byte[] bytes = enc.GetBytes(greekAlphabet);
        Console.WriteLine("{0,-12} {1,20} {2,20:X2}", "Character",
                           "Unicode Code Point", "Code Page 1253");
        for (int ctr = 0; ctr < bytes.Length; ctr++) {
            if (greekAlphabet[ctr].Equals(' '))
                continue;

            Console.WriteLine("{0,-12} {1,20} {2,20:X2}", greekAlphabet[ctr],
                             GetCodePoint(greekAlphabet[ctr]), bytes[ctr]);
        }
    }

    private static string GetCodePoint(char ch)
    {
        string retVal = "u+";
        byte[] bytes = Encoding.Unicode.GetBytes(ch.ToString());
        for (int ctr = bytes.Length - 1; ctr >= 0; ctr--)
            retVal += bytes[ctr].ToString("X2");

        return retVal;
    }
}

// The example displays the following output:
//      Character      Unicode Code Point      Code Page 1253
//      A                  u+0391                 C1
//      α                  u+03B1                 E1
//      Β                  u+0392                 C2
//      β                  u+03B2                 E2
//      Γ                  u+0393                 C3
//      γ                  u+03B3                 E3
//      Δ                  u+0394                 C4
//      δ                  u+03B4                 E4
//      Ε                  u+0395                 C5
//      ε                  u+03B5                 E5
//      Ζ                  u+0396                 C6
//      ζ                  u+03B6                 E6
//      Η                  u+0397                 C7
//      η                  u+03B7                 E7

```

| | | | |
|----|---|--------|----|
| // | Θ | u+0398 | C8 |
| // | θ | u+03B8 | E8 |
| // | Ι | u+0399 | C9 |
| // | ι | u+03B9 | E9 |
| // | Κ | u+039A | CA |
| // | κ | u+03BA | EA |
| // | Λ | u+039B | CB |

| // | Ρ | u+03A1 | D1 |
| // | ρ | u+03C1 | F1 |
| // | Σ | u+03A3 | D3 |
| // | σ | u+03C3 | F3 |
| // | ς | u+03C2 | F2 |
| // | Τ | u+03A4 | D4 |
| // | τ | u+03C4 | F4 |
| // | Υ | u+03A5 | D5 |
| // | υ | u+03C5 | F5 |
| // | Φ | u+03A6 | D6 |
| // | φ | u+03C6 | F6 |
| // | Χ | u+03A7 | D7 |
| // | χ | u+03C7 | F7 |
| // | Ψ | u+03A8 | D8 |
| // | ψ | u+03C8 | F8 |
| // | Ω | u+03A9 | D9 |
| // | ω | u+03C9 | F9 |

If the data to be converted is available only in sequential blocks (such as data read from a stream) or if the amount of data is so large that it needs to be divided into smaller blocks, you should use the [Decoder](#) or the [Encoder](#) provided by the [GetDecoder](#) method or the [GetEncoder](#) method, respectively, of a derived class.

The UTF-16 and the UTF-32 encoders can use the big endian byte order (most significant byte first) or the little endian byte order (least significant byte first). For example, the Latin Capital Letter A (U+0041) is serialized as follows (in hexadecimal):

- UTF-16 big endian byte order: 00 41
- UTF-16 little endian byte order: 41 00
- UTF-32 big endian byte order: 00 00 00 41
- UTF-32 little endian byte order: 41 00 00 00

It is generally more efficient to store Unicode characters using the native byte order. For example, it is better to use the little endian byte order on little endian platforms, such as Intel computers.

The [GetPreamble](#) method retrieves an array of bytes that includes the byte order mark (BOM). If this byte array is prefixed to an encoded stream, it helps the decoder to identify the encoding format used.

For more information on byte order and the byte order mark, see The Unicode Standard at the [Unicode home page](#).

Note that the encoding classes allow errors to:

- Silently change to a "?" character.
- Use a "best fit" character.
- Change to an application-specific behavior through use of the [EncoderFallback](#) and [DecoderFallback](#) classes with the U+FFFD Unicode replacement character.

You should throw an exception on any data stream error. An app either uses a "throwonerror" flag when applicable or uses the [EncoderExceptionFallback](#) and [DecoderExceptionFallback](#) classes. Best fit fallback is often not recommended because it can cause data loss or confusion and is slower than simple character replacements. For ANSI encodings, the best fit behavior is the default.

System.Text.RegularExpressions.Regex class

Article • 01/08/2024

This article provides supplementary remarks to the reference documentation for this API.

The [Regex](#) class represents .NET's regular expression engine. It can be used to quickly parse large amounts of text to find specific character patterns; to extract, edit, replace, or delete text substrings; and to add the extracted strings to a collection to generate a report.

Note

If you want to validate a string by determining whether it conforms to a particular pattern, you can use the [System.Configuration.RegexStringValidator](#) class.

To use regular expressions, you define the pattern that you want to identify in a text stream by using the syntax documented in [Regular Expression Language - Quick Reference](#). Next, you can optionally instantiate a [Regex](#) object. Finally, you call a method that performs some operation, such as replacing text that matches the regular expression pattern, or identifying a pattern match.

Note

For some common regular expression patterns, see [Regular Expression Examples](#). There are also a number of online libraries of regular expression patterns, such as the one at [Regular-Expressions.info](#).

For more information about the regular expression language, see [Regular Expression Language - Quick Reference](#) or download and print one of these brochures:

[Quick Reference in Word \(.docx\) format](#)  [Quick Reference in PDF \(.pdf\) format](#) 

Regex vs. String methods

The [System.String](#) class includes several search and comparison methods that you can use to perform pattern matching with text. For example, the [String.Contains](#), [String.EndsWith](#), and [String.StartsWith](#) methods determine whether a string instance

contains a specified substring; and the [String.IndexOf](#), [String.IndexOfAny](#), [String.LastIndexOf](#), and [String.LastIndexOfAny](#) methods return the starting position of a specified substring in a string. Use the methods of the [System.String](#) class when you are searching for a specific string. Use the [Regex](#) class when you are searching for a specific pattern in a string. For more information and examples, see [.NET Regular Expressions](#).

Static vs. instance methods

After you define a regular expression pattern, you can provide it to the regular expression engine in either of two ways:

- By instantiating a [Regex](#) object that represents the regular expression. To do this, you pass the regular expression pattern to a [Regex](#) constructor. A [Regex](#) object is immutable; when you instantiate a [Regex](#) object with a regular expression, that object's regular expression cannot be changed.
- By supplying both the regular expression and the text to search to a `static` (`Shared` in Visual Basic) [Regex](#) method. This enables you to use a regular expression without explicitly creating a [Regex](#) object.

All [Regex](#) pattern identification methods include both static and instance overloads.

The regular expression engine must compile a particular pattern before the pattern can be used. Because [Regex](#) objects are immutable, this is a one-time procedure that occurs when a [Regex](#) class constructor or a static method is called. To eliminate the need to repeatedly compile a single regular expression, the regular expression engine caches the compiled regular expressions used in static method calls. As a result, regular expression pattern-matching methods offer comparable performance for static and instance methods. However, caching can adversely affect performance in the following two cases:

- When you use static method calls with a large number of regular expressions. By default, the regular expression engine caches the 15 most recently used static regular expressions. If your application uses more than 15 static regular expressions, some regular expressions must be recompiled. To prevent this recompilation, you can increase the [Regex.CacheSize](#) property.
- When you instantiate new [Regex](#) objects with regular expressions that have previously been compiled. For example, the following code defines a regular expression to locate duplicated words in a text stream. Although the example uses a single regular expression, it instantiates a new [Regex](#) object to process each line of text. This results in the recompilation of the regular expression with each iteration of the loop.

C#

```
StreamReader sr = new StreamReader(filename);
string input;
string pattern = @"\b(\w+)\s\1\b";
while (sr.Peek() >= 0)
{
    input = sr.ReadLine();
    Regex rgx = new Regex(pattern, RegexOptions.IgnoreCase);
    MatchCollection matches = rgx.Matches(input);
    if (matches.Count > 0)
    {
        Console.WriteLine("{0} ({1} matches):", input, matches.Count);
        foreach (Match match in matches)
            Console.WriteLine("    " + match.Value);
    }
}
sr.Close();
```

To prevent recompilation, you should instantiate a single [Regex](#) object that is accessible to all code that requires it, as shown in the following rewritten example.

C#

```
StreamReader sr = new StreamReader(filename);
string input;
string pattern = @"\b(\w+)\s\1\b";
Regex rgx = new Regex(pattern, RegexOptions.IgnoreCase);

while (sr.Peek() >= 0)
{
    input = sr.ReadLine();
    MatchCollection matches = rgx.Matches(input);
    if (matches.Count > 0)
    {
        Console.WriteLine("{0} ({1} matches):", input, matches.Count);
        foreach (Match match in matches)
            Console.WriteLine("    " + match.Value);
    }
}
sr.Close();
```

Perform regular expression operations

Whether you decide to instantiate a [Regex](#) object and call its methods or call static methods, the [Regex](#) class offers the following pattern-matching functionality:

- Validation of a match. You call the [IsMatch](#) method to determine whether a match is present.

- Retrieval of a single match. You call the [Match](#) method to retrieve a [Match](#) object that represents the first match in a string or in part of a string. Subsequent matches can be retrieved by calling the [Match.NextMatch](#) method.
- Retrieval of all matches. You call the [Matches](#) method to retrieve a [System.Text.RegularExpressions.MatchCollection](#) object that represents all the matches found in a string or in part of a string.
- Replacement of matched text. You call the [Replace](#) method to replace matched text. The replacement text can also be defined by a regular expression. In addition, some of the [Replace](#) methods include a [MatchEvaluator](#) parameter that enables you to programmatically define the replacement text.
- Creation of a string array that is formed from parts of an input string. You call the [Split](#) method to split an input string at positions that are defined by the regular expression.

In addition to its pattern-matching methods, the [Regex](#) class includes several special-purpose methods:

- The [Escape](#) method escapes any characters that may be interpreted as regular expression operators in a regular expression or input string.
- The [Unescape](#) method removes these escape characters.
- The [CompileToAssembly](#) method creates an assembly that contains predefined regular expressions. .NET contains examples of these special-purpose assemblies in the [System.Web.RegularExpressions](#) namespace.

Define a time-out value

.NET supports a full-featured regular expression language that provides substantial power and flexibility in pattern matching. However, the power and flexibility come at a cost: the risk of poor performance. Regular expressions that perform poorly are surprisingly easy to create. In some cases, regular expression operations that rely on excessive backtracking can appear to stop responding when they process text that nearly matches the regular expression pattern. For more information about the .NET Regular Expression engine, see [Details of Regular Expression Behavior](#). For more information about excessive backtracking, see [Backtracking](#).

Starting with .NET Framework 4.5, you can define a time-out interval for regular expression matches to limit excessive backtracking. Depending on the regular expression pattern and the input text, the execution time may exceed the specified

time-out interval, but it will not spend more time backtracking than the specified time-out interval. If the regular expression engine times out, it throws a [RegexMatchTimeoutException](#) exception. In most cases, this prevents the regular expression engine from wasting processing power by trying to match text that nearly matches the regular expression pattern. It also could indicate, however, that the time-out interval has been set too low, or that the current machine load has caused an overall degradation in performance.

How you handle the exception depends on the cause of the exception. If the exception occurs because the time-out interval is set too low or because of excessive machine load, you can increase the time-out interval and retry the matching operation. If the exception occurs because the regular expression relies on excessive backtracking, you can assume that a match does not exist, and, optionally, you can log information that will help you modify the regular expression pattern.

You can set a time-out interval by calling the [Regex\(String, RegexOptions, TimeSpan\)](#) constructor when you instantiate a regular expression object. For static methods, you can set a time-out interval by calling an overload of a matching method that has a `matchTimeout` parameter. If you do not set a time-out value explicitly, the default time-out value is determined as follows:

- By using the application-wide time-out value, if one exists. This can be any time-out value that applies to the application domain in which the [Regex](#) object is instantiated or the static method call is made. You can set the application-wide time-out value by calling the [AppDomain.SetData](#) method to assign the string representation of a [TimeSpan](#) value to the "REGEX_DEFAULT_MATCH_TIMEOUT" property.
- By using the value [InfiniteMatchTimeout](#), if no application-wide time-out value has been set.

Important

We recommend that you set a time-out value in all regular expression pattern-matching operations. For more information, see [Best Practices for Regular Expressions](#).

Examples

The following example uses a regular expression to check for repeated occurrences of words in a string. The regular expression `\b(?<word>\w+)\s+(\k<word>)\b` can be

interpreted as shown in the following table.

[\[\] Expand table](#)

| Pattern | Description |
|------------------|---|
| \b | Start the match at a word boundary. |
| (? <word>\w+) | Match one or more word characters up to a word boundary. Name this captured group <code>word</code> . |
| \s+ | Match one or more white-space characters. |
| (\k<word>) | Match the captured group that is named <code>word</code> . |
| \b | Match a word boundary. |

C#

```
using System;
using System.Text.RegularExpressions;

public class Test
{
    public static void Main ()
    {
        // Define a regular expression for repeated words.
        Regex rx = new Regex(@"\b(?<word>\w+)\s+(\k<word>)\b",
            RegexOptions.Compiled | RegexOptions.IgnoreCase);

        // Define a test string.
        string text = "The the quick brown fox  fox jumps over the lazy dog
dog.";

        // Find matches.
        MatchCollection matches = rx.Matches(text);

        // Report the number of matches found.
        Console.WriteLine("{0} matches found in:\n {1}",
            matches.Count,
            text);

        // Report on each match.
        foreach (Match match in matches)
        {
            GroupCollection groups = match.Groups;
            Console.WriteLine('{0}' repeated at positions {1} and {2},
                groups["word"].Value,
                groups[0].Index,
                groups[1].Index);
        }
    }
}
```

```

}

// The example produces the following output to the console:
//      3 matches found in:
//          The the quick brown fox fox jumps over the lazy dog dog.
//          'The' repeated at positions 0 and 4
//          'fox' repeated at positions 20 and 25
//          'dog' repeated at positions 49 and 53

```

The following example illustrates the use of a regular expression to check whether a string either represents a currency value or has the correct format to represent a currency value. In this case, the regular expression is built dynamically from the [NumberFormatInfo.CurrencyDecimalSeparator](#), [CurrencyDecimalDigits](#), [NumberFormatInfo.CurrencySymbol](#), [NumberFormatInfo.NegativeSign](#), and [NumberFormatInfo.PositiveSign](#) properties for the en-US culture. The resulting regular expression is `^\s*[+-]?\s?\$?\s?(\d*\.\?\d{2}){1}\$`. This regular expression can be interpreted as shown in the following table.

[+] Expand table

| Pattern | Description |
|--|--|
| <code>^</code> | Start at the beginning of the string. |
| <code>\s*</code> | Match zero or more white-space characters. |
| <code>[+-]?</code> | Match zero or one occurrence of either the positive sign or the negative sign. |
| <code>\s?</code> | Match zero or one white-space character. |
| <code>\\$?</code> | Match zero or one occurrence of the dollar sign. |
| <code>\s?</code> | Match zero or one white-space character. |
| <code>\d*</code> | Match zero or more decimal digits. |
| <code>\.?</code> | Match zero or one decimal point symbol. |
| <code>(\d{2})?</code> | Capturing group 1: Match two decimal digits zero or one time. |
| <code>(\d*\.\?(\d{2})?) {1}</code> | Match the pattern of integral and fractional digits separated by a decimal point symbol at least one time. |
| <code>\$</code> | Match the end of the string. |

In this case, the regular expression assumes that a valid currency string does not contain group separator symbols, and that it has either no fractional digits or the number of fractional digits defined by the specified culture's [CurrencyDecimalDigits](#) property.

C#

```
using System;
using System.Globalization;
using System.Text.RegularExpressions;

public class Example
{
    public static void Main()
    {
        // Get the en-US NumberFormatInfo object to build the regular
        // expression pattern dynamically.
        NumberFormatInfo nfi = CultureInfo.GetCultureInfo("en-
US").NumberFormat;

        // Define the regular expression pattern.
        string pattern;
        pattern = @"\s*[";
        // Get the positive and negative sign symbols.
        pattern += Regex.Escape(nfi.PositiveSign + nfi.NegativeSign) + @"]?";
        pattern += @"\s?"; // Get the currency symbol.
        pattern += Regex.Escape(nfi.CurrencySymbol) + @"?\s?"; // Add integral digits to the pattern.
        pattern += @"(\d*"; // Add the decimal separator.
        pattern += Regex.Escape(nfi.CurrencyDecimalSeparator) + "?"; // Add the fractional digits.
        pattern += @"(\d{"; // Determine the number of fractional digits in currency values.
        pattern += nfi.CurrencyDecimalDigits.ToString() + "})?)\{1}\$"; // Check each test string against the regular expression.
        foreach (string test in tests)
        {
            if (rgx.IsMatch(test))
                Console.WriteLine($"{test} is a currency value.");
            else
                Console.WriteLine($"{test} is not a currency value.");
        }
    }
}

// The example displays the following output:
//      Pattern is ^\s*[+-]?\s?\$?\s?(\d*\.\?(\d{2}))?\{1}\$
```

```
//      -42 is a currency value.  
//      19.99 is a currency value.  
//      0.001 is not a currency value.  
//      100 USD is not a currency value.  
//      .34 is a currency value.  
//      0.34 is a currency value.  
//      1,052.21 is not a currency value.  
//      $10.62 is a currency value.  
//      +1.43 is a currency value.  
//      -$0.23 is a currency value.
```

Because the regular expression in this example is built dynamically, you don't know at design time whether the currency symbol, decimal sign, or positive and negative signs of the specified culture (en-US in this example) might be misinterpreted by the regular expression engine as regular expression language operators. To prevent any misinterpretation, the example passes each dynamically generated string to the [Escape](#) method.

System.Text.Rune struct

Article • 01/08/2024

This article provides supplementary remarks to the reference documentation for this API.

A [Rune](#) instance represents a Unicode scalar value, which means any code point excluding the surrogate range (U+D800..U+DFFF). The type's constructors and conversion operators validate the input, so consumers can call the APIs assuming that the underlying [Rune](#) instance is well formed.

If you aren't familiar with the terms Unicode scalar value, code point, surrogate range, and well-formed, see [Introduction to character encoding in .NET](#).

When to use the Rune type

Consider using the `Rune` type if your code:

- Calls APIs that require Unicode scalar values
- Explicitly handles surrogate pairs

APIs that require Unicode scalar values

If your code iterates through the `char` instances in a `string` or a `ReadOnlySpan<char>`, some of the `char` methods won't work correctly on `char` instances that are in the surrogate range. For example, the following APIs require a scalar value `char` to work correctly:

- [Char.GetNumericValue](#)
- [Char.GetUnicodeCategory](#)
- [Char.IsDigit](#)
- [Char.IsLetter](#)
- [Char.IsLetterOrDigit](#)
- [Char.IsLower](#)
- [Char.IsNumber](#)
- [Char.IsPunctuation](#)
- [Char.IsSymbol](#)
- [Char.IsUpper](#)

The following example shows code that won't work correctly if any of the `char` instances are surrogate code points:

C#

```
// THE FOLLOWING METHOD SHOWS INCORRECT CODE.  
// DO NOT DO THIS IN A PRODUCTION APPLICATION.  
int CountLettersBadExample(string s)  
{  
    int letterCount = 0;  
  
    foreach (char ch in s)  
    {  
        if (char.IsLetter(ch))  
        { letterCount++; }  
    }  
  
    return letterCount;  
}
```

Here's equivalent code that works with a `ReadOnlySpan<char>`:

C#

```
// THE FOLLOWING METHOD SHOWS INCORRECT CODE.  
// DO NOT DO THIS IN A PRODUCTION APPLICATION.  
static int CountLettersBadExample(ReadOnlySpan<char> span)  
{  
    int letterCount = 0;  
  
    foreach (char ch in span)  
    {  
        if (char.IsLetter(ch))  
        { letterCount++; }  
    }  
  
    return letterCount;  
}
```

The preceding code works correctly with some languages such as English:

C#

```
CountLettersInString("Hello")  
// Returns 5
```

But it won't work correctly for languages outside the Basic Multilingual Plane, such as Osage:

C#

```
CountLettersInString("հԱՀԶՅԱ ՈԱ")
// Returns 0
```

The reason this method returns incorrect results for Osage text is that the `char` instances for Osage letters are surrogate code points. No single surrogate code point has enough information to determine if it's a letter.

If you change this code to use `Rune` instead of `char`, the method works correctly with code points outside the Basic Multilingual Plane:

C#

```
int CountLetters(string s)
{
    int letterCount = 0;

    foreach (Rune rune in s.EnumerateRunes())
    {
        if (Rune.IsLetter(rune))
        { letterCount++; }

    }

    return letterCount;
}
```

Here's equivalent code that works with a `ReadOnlySpan<char>`:

C#

```
static int CountLetters(ReadOnlySpan<char> span)
{
    int letterCount = 0;

    foreach (Rune rune in span.EnumerateRunes())
    {
        if (Rune.IsLetter(rune))
        { letterCount++; }

    }

    return letterCount;
}
```

The preceding code counts Osage letters correctly:

C#

```
CountLettersInString("հազար օպ")
```

```
// Returns 8
```

Code that explicitly handles surrogate pairs

Consider using the `Rune` type if your code calls APIs that explicitly operate on surrogate code points, such as the following methods:

- `Char.IsSurrogate`
- `Char.IsSurrogatePair`
- `Char.IsHighSurrogate`
- `Char.IsLowSurrogate`
- `Char.ConvertFromUtf32`
- `Char.ConvertToUtf32`

For example, the following method has special logic to deal with surrogate `char` pairs:

C#

```
static void ProcessStringUseChar(string s)
{
    Console.WriteLine("Using char");

    for (int i = 0; i < s.Length; i++)
    {
        if (!char.IsSurrogate(s[i]))
        {
            Console.WriteLine($"Code point: {(int)(s[i])}");
        }
        else if (i + 1 < s.Length && char.IsSurrogatePair(s[i], s[i + 1]))
        {
            int codePoint = char.ConvertToUtf32(s[i], s[i + 1]);
            Console.WriteLine($"Code point: {codePoint}");
            i++; // so that when the loop iterates it's actually +2
        }
        else
        {
            throw new Exception("String was not well-formed UTF-16.");
        }
    }
}
```

Such code is simpler if it uses `Rune`, as in the following example:

C#

```
static void ProcessStringUseRune(string s)
{
    Console.WriteLine("Using Rune");
```

```
for (int i = 0; i < s.Length;)
{
    if (!Rune.TryGetRuneAt(s, i, out Rune rune))
    {
        throw new Exception("String was not well-formed UTF-16.");
    }

    Console.WriteLine($"Code point: {rune.Value}");
    i += rune.Utf16SequenceLength; // increment the iterator by the
    number of chars in this Rune
}
}
```

When not to use `Rune`

You don't need to use the `Rune` type if your code:

- Looks for exact `char` matches
- Splits a string on a known char value

Using the `Rune` type may return incorrect results if your code:

- Counts the number of display characters in a `string`

Look for exact `char` matches

The following code iterates through a `string` looking for specific characters, returning the index of the first match. There's no need to change this code to use `Rune`, as the code is looking for characters that are represented by a single `char`.

C#

```
int GetIndexOfFirstAToZ(string s)
{
    for (int i = 0; i < s.Length; i++)
    {
        char thisChar = s[i];
        if ('A' <= thisChar && thisChar <= 'Z')
        {
            return i; // found a match
        }
    }

    return -1; // didn't find 'A' - 'Z' in the input string
}
```

Split a string on a known `char`

It's common to call `string.Split` and use delimiters such as `' '` (space) or `','` (comma), as in the following example:

C#

```
string inputString = "𠮷𠮷𠮷";
string[] splitOnSpace = inputString.Split(' ');
string[] splitOnComma = inputString.Split(',');
```

There is no need to use `Rune` here, because the code is looking for characters that are represented by a single `char`.

Count the number of display characters in a `string`

The number of `Rune` instances in a string might not match the number of user-perceivable characters shown when displaying the string.

Since `Rune` instances represent Unicode scalar values, components that follow the [Unicode text segmentation guidelines](#) can use `Rune` as a building block for counting display characters.

The `StringInfo` type can be used to count display characters, but it doesn't count correctly in all scenarios for .NET implementations other than .NET 5+.

For more information, see [Grapheme clusters](#).

How to instantiate a `Rune`

There are several ways to get a `Rune` instance. You can use a constructor to create a `Rune` directly from:

- A code point.

C#

```
Rune a = new Rune(0x0061); // LATIN SMALL LETTER A
Rune b = new Rune(0x10421); // DESERET CAPITAL LETTER ER
```

- A single `char`.

C#

```
Rune c = new Rune('a');
```

- A surrogate `char` pair.

C#

```
Rune d = new Rune('\ud83d', '\udd2e'); // U+1F52E CRYSTAL BALL
```

All of the constructors throw an `ArgumentException` if the input doesn't represent a valid Unicode scalar value.

There are `Rune.TryCreate` methods available for callers who don't want exceptions to be thrown on failure.

`Rune` instances can also be read from existing input sequences. For instance, given a `ReadOnlySpan<char>` that represents UTF-16 data, the `Rune.DecodeFromUtf16` method returns the first `Rune` instance at the beginning of the input span. The `Rune.DecodeFromUtf8` method operates similarly, accepting a `ReadOnlySpan<byte>` parameter that represents UTF-8 data. There are equivalent methods to read from the end of the span instead of the beginning of the span.

Query properties of a `Rune`

To get the integer code point value of a `Rune` instance, use the `Rune.Value` property.

C#

```
Rune rune = new Rune('\ud83d', '\udd2e'); // U+1F52E CRYSTAL BALL
int codePoint = rune.Value; // = 128302 decimal (= 0x1F52E)
```

Many of the static APIs available on the `char` type are also available on the `Rune` type. For instance, `Rune.IsWhiteSpace` and `Rune.GetUnicodeCategory` are equivalents to `Char.IsWhiteSpace` and `Char.GetUnicodeCategory` methods. The `Rune` methods correctly handle surrogate pairs.

The following example code takes a `ReadOnlySpan<char>` as input and trims from both the start and the end of the span every `Rune` that isn't a letter or a digit.

C#

```
static ReadOnlySpan<char> TrimNonLettersAndNonDigits(ReadOnlySpan<char>
span)
```

```

{
    // First, trim from the front.
    // If any Rune can't be decoded
    // (return value is anything other than "Done"),
    // or if the Rune is a letter or digit,
    // stop trimming from the front and
    // instead work from the end.
    while (Rune.DecodeFromUtf16(span, out Rune rune, out int charsConsumed)
== OperationStatus.Done)
    {
        if (Rune.IsLetterOrDigit(rune))
        { break; }
        span = span[charsConsumed..];
    }

    // Next, trim from the end.
    // If any Rune can't be decoded,
    // or if the Rune is a letter or digit,
    // break from the loop, and we're finished.
    while (Rune.DecodeLastFromUtf16(span, out Rune rune, out int
charsConsumed) == OperationStatus.Done)
    {
        if (Rune.IsLetterOrDigit(rune))
        { break; }
        span = span[..^charsConsumed];
    }

    return span;
}

```

There are some API differences between `char` and `Rune`. For example:

- There is no `Rune` equivalent to `Char.IsSurrogate(Char)`, since `Rune` instances by definition can never be surrogate code points.
- The `Rune.GetUnicodeCategory` doesn't always return the same result as `Char.GetUnicodeCategory`. It does return the same value as `CharUnicodeInfo.GetUnicodeCategory`. For more information, see the **Remarks** on `Char.GetUnicodeCategory`.

Convert a `Rune` to UTF-8 or UTF-16

Since a `Rune` is a Unicode scalar value, it can be converted to UTF-8, UTF-16, or UTF-32 encoding. The `Rune` type has built-in support for conversion to UTF-8 and UTF-16.

The `Rune.EncodeToUtf16` converts a `Rune` instance to `char` instances. To query the number of `char` instances that would result from converting a `Rune` instance to UTF-16, use the `Rune.Utf16SequenceLength` property. Similar methods exist for UTF-8 conversion.

The following example converts a `Rune` instance to a `char` array. The code assumes you have a `Rune` instance in the `rune` variable:

```
C#
```

```
char[] chars = new char[rune.Utf16SequenceLength];
int numCharsWritten = rune.EncodeToUtf16(chars);
```

Since a `string` is a sequence of UTF-16 chars, the following example also converts a `Rune` instance to UTF-16:

```
C#
```

```
string theString = rune.ToString();
```

The following example converts a `Rune` instance to a `UTF-8` byte array:

```
C#
```

```
byte[] bytes = new byte[rune.Utf8SequenceLength];
int numBytesWritten = rune.EncodeToUtf8(bytes);
```

The `Rune.EncodeToUtf16` and `Rune.EncodeToUtf8` methods return the actual number of elements written. They throw an exception if the destination buffer is too short to contain the result. There are non-throwing `TryEncodeToUtf8` and `TryEncodeToUtf16` methods as well for callers who want to avoid exceptions.

Rune in .NET vs. other languages

The term "rune" is not defined in the Unicode Standard. The term dates back to [the creation of UTF-8](#). Rob Pike and Ken Thompson were looking for a term to describe what would eventually become known as a code point. [They settled on the term "rune"](#), and Rob Pike's later influence over the Go programming language helped popularize the term.

However, the .NET `Rune` type is not the equivalent of the Go `rune` type. In Go, the `rune` type is an [alias for int32](#). A Go rune is intended to represent a Unicode code point, but it can be any 32-bit value, including surrogate code points and values that are not legal Unicode code points.

For similar types in other programming languages, see [Rust's primitive char type](#) or [Swift's Unicode.Scalar type](#), both of which represent Unicode scalar values. They

provide functionality similar to .NET's `Rune` type, and they disallow instantiation of values that are not legal Unicode scalar values.

System.Text.StringBuilder class

Article • 01/08/2024

This article provides supplementary remarks to the reference documentation for this API.

The [StringBuilder](#) class represents a string-like object whose value is a mutable sequence of characters.

StringBuilder versus String type

Although [StringBuilder](#) and [String](#) both represent sequences of characters, they are implemented differently. [String](#) is an immutable type. That is, each operation that appears to modify a [String](#) object actually creates a new string.

For example, the call to the [String.Concat](#) method in the following C# example appears to change the value of a string variable named `value`. In fact, the [Concat](#) method returns a `value` object that has a different value and address from the `value` object that was passed to the method. Note that the example must be compiled using the `/unsafe` compiler option.

C#

```
using System;

public class Example7
{
    public unsafe static void Main()
    {
        string value = "This is the first sentence" + ".";
        fixed (char* start = value)
        {
            value = String.Concat(value, "This is the second sentence. ");
            fixed (char* current = value)
            {
                Console.WriteLine(start == current);
            }
        }
    }
} // The example displays the following output:
//      False
```

For routines that perform extensive string manipulation (such as apps that modify a string numerous times in a loop), modifying a string repeatedly can exact a significant

performance penalty. The alternative is to use [StringBuilder](#), which is a mutable string class. Mutability means that once an instance of the class has been created, it can be modified by appending, removing, replacing, or inserting characters. A [StringBuilder](#) object maintains a buffer to accommodate expansions to the string. New data is appended to the buffer if room is available; otherwise, a new, larger buffer is allocated, data from the original buffer is copied to the new buffer, and the new data is then appended to the new buffer.

Important

Although the [StringBuilder](#) class generally offers better performance than the [String](#) class, you should not automatically replace [String](#) with [StringBuilder](#) whenever you want to manipulate strings. Performance depends on the size of the string, the amount of memory to be allocated for the new string, the system on which your code is executing, and the type of operation. You should be prepared to test your code to determine whether [StringBuilder](#) actually offers a significant performance improvement.

Consider using the [String](#) class under these conditions:

- When the number of changes that your code will make to a string is small. In these cases, [StringBuilder](#) might offer negligible or no performance improvement over [String](#).
- When you are performing a fixed number of concatenation operations, particularly with string literals. In this case, the compiler might combine the concatenation operations into a single operation.
- When you have to perform extensive search operations while you are building your string. The [StringBuilder](#) class lacks search methods such as `IndexOf` or `StartsWith`. You'll have to convert the [StringBuilder](#) object to a [String](#) for these operations, and this can negate the performance benefit from using [StringBuilder](#). For more information, see the [Search the text in a StringBuilder object](#) section.

Consider using the [StringBuilder](#) class under these conditions:

- When you expect your code to make an unknown number of changes to a string at design time (for example, when you are using a loop to concatenate a random number of strings that contain user input).
- When you expect your code to make a significant number of changes to a string.

How StringBuilder works

The `StringBuilder.Length` property indicates the number of characters the `StringBuilder` object currently contains. If you add characters to the `StringBuilder` object, its length increases until it equals the size of the `StringBuilder.Capacity` property, which defines the number of characters that the object can contain. If the number of added characters causes the length of the `StringBuilder` object to exceed its current capacity, new memory is allocated, the value of the `Capacity` property is doubled, new characters are added to the `StringBuilder` object, and its `Length` property is adjusted. Additional memory for the `StringBuilder` object is allocated dynamically until it reaches the value defined by the `StringBuilder.MaxCapacity` property. When the maximum capacity is reached, no further memory can be allocated for the `StringBuilder` object, and trying to add characters or expand it beyond its maximum capacity throws either an `ArgumentOutOfRangeException` or an `OutOfMemoryException` exception.

The following example illustrates how a `StringBuilder` object allocates new memory and increases its capacity dynamically as the string assigned to the object expands. The code creates a `StringBuilder` object by calling its default (parameterless) constructor. The default capacity of this object is 16 characters, and its maximum capacity is more than 2 billion characters. Appending the string "This is a sentence." results in a new memory allocation because the string length (19 characters) exceeds the default capacity of the `StringBuilder` object. The capacity of the object doubles to 32 characters, the new string is added, and the length of the object now equals 19 characters. The code then appends the string "This is an additional sentence." to the value of the `StringBuilder` object 11 times. Whenever the append operation causes the length of the `StringBuilder` object to exceed its capacity, its existing capacity is doubled and the `Append` operation succeeds.

C#

```
using System;
using System.Reflection;
using System.Text;

public class Example4
{
    public static void Main()
    {
        StringBuilder sb = new StringBuilder();
        ShowSBInfo(sb);
        sb.Append("This is a sentence.");
        ShowSBInfo(sb);
        for (int ctr = 0; ctr <= 10; ctr++)
        {
            sb.Append("This is an additional sentence.");
            ShowSBInfo(sb);
        }
    }
}
```

```

    }

    private static void ShowSBInfo(StringBuilder sb)
    {
        foreach (var prop in sb.GetType().GetProperties())
        {
            if (prop.GetIndexParameters().Length == 0)
                Console.WriteLine("{0}: {1:N0}      ", prop.Name,
prop.GetValue(sb));
        }
        Console.WriteLine();
    }
}

// The example displays the following output:
// Capacity: 16      MaxCapacity: 2,147,483,647      Length: 0
// Capacity: 32      MaxCapacity: 2,147,483,647      Length: 19
// Capacity: 64      MaxCapacity: 2,147,483,647      Length: 50
// Capacity: 128     MaxCapacity: 2,147,483,647      Length: 81
// Capacity: 128     MaxCapacity: 2,147,483,647      Length: 112
// Capacity: 256     MaxCapacity: 2,147,483,647      Length: 143
// Capacity: 256     MaxCapacity: 2,147,483,647      Length: 174
// Capacity: 256     MaxCapacity: 2,147,483,647      Length: 205
// Capacity: 256     MaxCapacity: 2,147,483,647      Length: 236
// Capacity: 512     MaxCapacity: 2,147,483,647      Length: 267
// Capacity: 512     MaxCapacity: 2,147,483,647      Length: 298
// Capacity: 512     MaxCapacity: 2,147,483,647      Length: 329
// Capacity: 512     MaxCapacity: 2,147,483,647      Length: 360

```

Memory allocation

The default capacity of a [StringBuilder](#) object is 16 characters, and its default maximum capacity is [Int32.MaxValue](#). These default values are used if you call the [StringBuilder\(\)](#) and [StringBuilder\(String\)](#) constructors.

You can explicitly define the initial capacity of a [StringBuilder](#) object in the following ways:

- By calling any of the [StringBuilder](#) constructors that includes a `capacity` parameter when you create the object.
- By explicitly assigning a new value to the [StringBuilder.Capacity](#) property to expand an existing [StringBuilder](#) object. Note that the property throws an exception if the new capacity is less than the existing capacity or greater than the [StringBuilder](#) object's maximum capacity.
- By calling the [StringBuilder.EnsureCapacity](#) method with the new capacity. The new capacity must not be greater than the [StringBuilder](#) object's maximum capacity. However, unlike an assignment to the [Capacity](#) property, [EnsureCapacity](#) does not

throw an exception if the desired new capacity is less than the existing capacity; in this case, the method call has no effect.

If the length of the string assigned to the [StringBuilder](#) object in the constructor call exceeds either the default capacity or the specified capacity, the [Capacity](#) property is set to the length of the string specified with the `value` parameter.

You can explicitly define the maximum capacity of a [StringBuilder](#) object by calling the [StringBuilder\(Int32, Int32\)](#) constructor. You can't change the maximum capacity by assigning a new value to the [MaxCapacity](#) property, because it is read-only.

As the previous section shows, whenever the existing capacity is inadequate, additional memory is allocated and the capacity of a [StringBuilder](#) object doubles up to the value defined by the [MaxCapacity](#) property.

In general, the default capacity and maximum capacity are adequate for most apps. You might consider setting these values under the following conditions:

- If the eventual size of the [StringBuilder](#) object is likely to grow exceedingly large, typically in excess of several megabytes. In this case, there may be some performance benefit from setting the initial [Capacity](#) property to a significantly high value to eliminate the need for too many memory reallocations.
- If your code is running on a system with limited memory. In this case, you may want to consider setting the [MaxCapacity](#) property to less than [Int32.MaxValue](#) if your code is handling large strings that may cause it to execute in a memory-constrained environment.

Instantiate a [StringBuilder](#) object

You instantiate a [StringBuilder](#) object by calling one of its six overloaded class constructors, which are listed in the following table. Three of the constructors instantiate a [StringBuilder](#) object whose value is an empty string, but set its [Capacity](#) and [MaxCapacity](#) values differently. The remaining three constructors define a [StringBuilder](#) object that has a specific string value and capacity. Two of the three constructors use the default maximum capacity of [Int32.MaxValue](#), whereas the third allows you to set the maximum capacity.

[+] Expand table

| Constructor | String value | Capacity | Maximum capacity |
|-------------------------------------|--|--|--------------------------------------|
| StringBuilder() | String.Empty | 16 | Int32.MaxValue |
| StringBuilder(Int32) | String.Empty | Defined by the capacity parameter | Int32.MaxValue |
| StringBuilder(Int32, Int32) | String.Empty | Defined by the capacity parameter | Defined by the maxCapacity parameter |
| StringBuilder(String) | Defined by the value parameter | 16 or value.Length, whichever is greater | Int32.MaxValue |
| StringBuilder(String, Int32) | Defined by the value parameter | Defined by the capacity parameter or value.Length, whichever is greater. | Int32.MaxValue |
| StringBuilder(String, Int32, Int32) | Defined by value.Substring(startIndex, length) | Defined by the capacity parameter or value.Length, whichever is greater. | Int32.MaxValue |

The following example uses three of these constructor overloads to instantiate [StringBuilder](#) objects.

C#

```
using System;
using System.Text;

public class Example8
{
    public static void Main()
    {
        string value = "An ordinary string";
        int index = value.IndexOf("An ") + 3;
        int capacity = 0xFFFF;

        // Instantiate a StringBuilder from a string.
        StringBuilder sb1 = new StringBuilder(value);
        ShowSBInfo(sb1);

        // Instantiate a StringBuilder from string and define a capacity.
        StringBuilder sb2 = new StringBuilder(value, capacity);
        ShowSBInfo(sb2);

        // Instantiate a StringBuilder from substring and define a capacity.
        StringBuilder sb3 = new StringBuilder(value, index,
```

```

                value.Length - index,
                capacity);

        ShowSBInfo(sb3);
    }

    public static void ShowSBInfo(StringBuilder sb)
    {
        Console.WriteLine("\nValue: {0}", sb.ToString());
        foreach (var prop in sb.GetType().GetProperties())
        {
            if (prop.GetIndexParameters().Length == 0)
                Console.Write("{0}: {1:N0}      ", prop.Name,
prop.GetValue(sb));
            }
            Console.WriteLine();
        }
    }
    // The example displays the following output:
    //   Value: An ordinary string
    //   Capacity: 18      MaxCapacity: 2,147,483,647      Length: 18
    //
    //   Value: An ordinary string
    //   Capacity: 65,535     MaxCapacity: 2,147,483,647      Length: 18
    //
    //   Value: ordinary string
    //   Capacity: 65,535     MaxCapacity: 2,147,483,647      Length: 15

```

Call StringBuilder methods

Most of the methods that modify the string in a [StringBuilder](#) instance return a reference to that same instance. This enables you to call [StringBuilder](#) methods in two ways:

- You can make individual method calls and ignore the return value, as the following example does.

C#

```

using System;
using System.Text;

public class Example
{
    public static void Main()
    {
        StringBuilder sb = new StringBuilder();
        sb.Append("This is the beginning of a sentence, ");
        sb.Replace("the beginning of ", "");
        sb.Insert(sb.ToString().IndexOf("a ") + 2, "complete ");
        sb.Replace(",", ".");
        Console.WriteLine(sb.ToString());
    }
}

```

```
}
```

```
// The example displays the following output:
```

```
//      This is a complete sentence.
```

- You can make a series of method calls in a single statement. This can be convenient if you want to write a single statement that chains successive operations. The following example consolidates three method calls from the previous example into a single line of code.

C#

```
using System;
using System.Text;

public class Example2
{
    public static void Main()
    {
        StringBuilder sb = new StringBuilder("This is the beginning of
a sentence, ");
        sb.Replace("the beginning of ",
"").Insert(sb.ToString().IndexOf("a ") + 2,
"complete
").Replace(", ", ".");
        Console.WriteLine(sb.ToString());
    }
}

// The example displays the following output:
//      This is a complete sentence.
```

Perform `StringBuilder` operations

You can use the methods of the `StringBuilder` class to iterate, add, delete, or modify characters in a `StringBuilder` object.

Iterate `StringBuilder` characters

You can access the characters in a `StringBuilder` object by using the `StringBuilder.Chars[]` property. In C#, `Chars[]` is an indexer; in Visual Basic, it is the default property of the `StringBuilder` class. This enables you to set or retrieve individual characters by using their index only, without explicitly referencing the `Chars[]` property. Characters in a `StringBuilder` object begin at index 0 (zero) and continue to index `Length - 1`.

The following example illustrates the `Chars[]` property. It appends ten random numbers to a `StringBuilder` object, and then iterates each character. If the character's Unicode

category is `UnicodeCategory.DecimalDigitNumber`, it decreases the number by 1 (or changes the number to 9 if its value is 0). The example displays the contents of the `StringBuilder` object both before and after the values of individual characters were changed.

C#

```
using System;
using System.Globalization;
using System.Text;

public class Example3
{
    public static void Main()
    {
        Random rnd = new Random();
        StringBuilder sb = new StringBuilder();

        // Generate 10 random numbers and store them in a StringBuilder.
        for (int ctr = 0; ctr <= 9; ctr++)
            sb.Append(rnd.Next().ToString("N5"));

        Console.WriteLine("The original string:");
        Console.WriteLine(sb.ToString());

        // Decrease each number by one.
        for (int ctr = 0; ctr < sb.Length; ctr++)
        {
            if (Char.GetUnicodeCategory(sb[ctr]) ==
UnicodeCategory.DecimalDigitNumber)
            {
                int number = (int)Char.GetNumericValue(sb[ctr]);
                number--;
                if (number < 0) number = 9;

                sb[ctr] = number.ToString()[0];
            }
        }
        Console.WriteLine("\nThe new string:");
        Console.WriteLine(sb.ToString());
    }
}

// The example displays the following output:
//      The original string:
//
1,457,531,530.0000940,522,609.00001,668,113,564.00001,998,992,883.00001,
792,660,834.00
//
000101,203,251.00002,051,183,075.00002,066,000,067.00001,643,701,043.0000
01,702,382,508
//      .00000
//
//      The new string:
```

```
//  
0,346,420,429.99999839,411,598.999990,557,002,453.999990,887,881,772.999990,  
681,559,723.99  
//  
999090,192,140.999991,940,072,964.999991,955,999,956.999990,532,690,932.9999  
90,691,271,497  
// .99999
```

Using character-based indexing with the [Chars\[\]](#) property can be extremely slow under the following conditions:

- The [StringBuilder](#) instance is large (for example, it consists of several tens of thousands of characters).
- The [StringBuilder](#) is "chunky." That is, repeated calls to methods such as [StringBuilder.Append](#) have automatically expanded the object's [StringBuilder.Capacity](#) property and allocated new chunks of memory to it.

Performance is severely impacted because each character access walks the entire linked list of chunks to find the correct buffer to index into.

ⓘ Note

Even for a large "chunky" [StringBuilder](#) object, using the [Chars\[\]](#) property for index-based access to one or a small number of characters has a negligible performance impact; typically, it is an $O(n)$ operation. The significant performance impact occurs when iterating the characters in the [StringBuilder](#) object, which is an $O(n^2)$ operation.

If you encounter performance issues when using character-based indexing with [StringBuilder](#) objects, you can use any of the following workarounds:

- Convert the [StringBuilder](#) instance to a [String](#) by calling the [ToString](#) method, then access the characters in the string.
- Copy the contents of the existing [StringBuilder](#) object to a new pre-sized [StringBuilder](#) object. Performance improves because the new [StringBuilder](#) object is not chunky. For example:

C#

```
// sbOriginal is the existing StringBuilder object  
var sbNew = new StringBuilder(sbOriginal.ToString(),  
sbOriginal.Length);
```

- Set the initial capacity of the [StringBuilder](#) object to a value that is approximately equal to its maximum expected size by calling the [StringBuilder\(Int32\)](#) constructor. Note that this allocates the entire block of memory even if the [StringBuilder](#) rarely reaches its maximum capacity.

Add text to a [StringBuilder](#) object

The [StringBuilder](#) class includes the following methods for expanding the contents of a [StringBuilder](#) object:

- The [Append](#) method appends a string, a substring, a character array, a portion of a character array, a single character repeated multiple times, or the string representation of a primitive data type to a [StringBuilder](#) object.
- The [AppendLine](#) method appends a line terminator or a string along with a line terminator to a [StringBuilder](#) object.
- The [AppendFormat](#) method appends a [composite format string](#) to a [StringBuilder](#) object. The string representations of objects included in the result string can reflect the formatting conventions of the current system culture or a specified culture.
- The [Insert](#) method inserts a string, a substring, multiple repetitions of a string, a character array, a portion of a character array, or the string representation of a primitive data type at a specified position in the [StringBuilder](#) object. The position is defined by a zero-based index.

The following example uses the [Append](#), [AppendLine](#), [AppendFormat](#), and [Insert](#) methods to expand the text of a [StringBuilder](#) object.

C#

```
using System;
using System.Text;

public class Example6
{
    public static void Main()
    {
        // Create a StringBuilder object with no text.
        StringBuilder sb = new StringBuilder();
        // Append some text.
        sb.Append('*', 10).Append(" Adding Text to a StringBuilder Object ");
        sb.Append('*', 10);
        sb.AppendLine("\n");
        sb.AppendLine("Some code points and their corresponding
characters:");
        // Append some formatted text.
```

```

        for (int ctr = 50; ctr <= 60; ctr++)
    {
        sb.AppendFormat("{0,12:X4} {1,12}", ctr, Convert.ToChar(ctr));
        sb.AppendLine();
    }
    // Find the end of the introduction to the column.
    int pos = sb.ToString().IndexOf("characters:") + 11 +
        Environment.NewLine.Length;
    // Insert a column header.
    sb.Insert(pos, String.Format("{2}{0,12:X4} {1,12}{2}", "Code Unit",
        "Character", "\n"));

    // Convert the StringBuilder to a string and display it.
    Console.WriteLine(sb.ToString());
}
}

// The example displays the following output:
// **** Adding Text to a StringBuilder Object ****
//
// Some code points and their corresponding characters:
//
//      Code Unit      Character
//          0032          2
//          0033          3
//          0034          4
//          0035          5
//          0036          6
//          0037          7
//          0038          8
//          0039          9
//          003A          :
//          003B          ;
//          003C          <

```

Delete text from a StringBuilder object

The [StringBuilder](#) class includes methods that can reduce the size of the current [StringBuilder](#) instance. The [Clear](#) method removes all characters and sets the [Length](#) property to zero. The [Remove](#) method deletes a specified number of characters starting at a particular index position. In addition, you can remove characters from the end of a [StringBuilder](#) object by setting its [Length](#) property to a value that is less than the length of the current instance.

The following example removes some of the text from a [StringBuilder](#) object, displays its resulting capacity, maximum capacity, and length property values, and then calls the [Clear](#) method to remove all the characters from the [StringBuilder](#) object.

```

using System;
using System.Text;

public class Example5
{
    public static void Main()
    {
        StringBuilder sb = new StringBuilder("A StringBuilder object");
        ShowSBInfo(sb);
        // Remove "object" from the text.
        string textToRemove = "object";
        int pos = sb.ToString().IndexOf(textToRemove);
        if (pos >= 0)
        {
            sb.Remove(pos, textToRemove.Length);
            ShowSBInfo(sb);
        }
        // Clear the StringBuilder contents.
        sb.Clear();
        ShowSBInfo(sb);
    }

    public static void ShowSBInfo(StringBuilder sb)
    {
        Console.WriteLine("\nValue: {0}", sb.ToString());
        foreach (var prop in sb.GetType().GetProperties())
        {
            if (prop.GetIndexParameters().Length == 0)
                Console.Write("{0}: {1:N0}      ", prop.Name,
prop.GetValue(sb));
            }
            Console.WriteLine();
        }
    }
    // The example displays the following output:
    //   Value: A StringBuilder object
    //   Capacity: 22      MaxCapacity: 2,147,483,647      Length: 22
    //
    //   Value: A StringBuilder
    //   Capacity: 22      MaxCapacity: 2,147,483,647      Length: 16
    //
    //   Value:
    //   Capacity: 22      MaxCapacity: 2,147,483,647      Length: 0
}

```

Modify the text in a StringBuilder object

The [StringBuilder.Replace](#) method replaces all occurrences of a character or a string in the entire [StringBuilder](#) object or in a particular character range. The following example uses the [Replace](#) method to replace all exclamation points (!) with question marks (?) in the [StringBuilder](#) object.

C#

```
using System;
using System.Text;

public class Example13
{
    public static void Main()
    {
        StringBuilder MyStringBuilder = new StringBuilder("Hello World!");
        MyStringBuilder.Replace('!', '?');
        Console.WriteLine(MyStringBuilder);
    }
}
// The example displays the following output:
//      Hello World?
```

Search the text in a `StringBuilder` object

The `StringBuilder` class does not include methods similar to the `String.Contains`, `String.IndexOf`, and `String.StartsWith` methods provided by the `String` class, which allow you to search the object for a particular character or a substring. Determining the presence or starting character position of a substring requires that you search a `String` value by using either a string search method or a regular expression method. There are four ways to implement such searches, as the following table shows.

[] Expand table

| Technique | Pros | Cons |
|---|---|---|
| Search string values before adding them to the <code>StringBuilder</code> object. | Useful for determining whether a substring exists. | Cannot be used when the index position of a substring is important. |
| Call <code>ToString</code> and search the returned <code>String</code> object. | Easy to use if you assign all the text to a <code>StringBuilder</code> object, and then begin to modify it. | Cumbersome to repeatedly call <code>ToString</code> if you must make modifications before all text is added to the <code>StringBuilder</code> object. You must remember to work from the end of the <code>StringBuilder</code> object's text if you're making changes. |
| Use the <code>Chars[]</code> property to sequentially search a range of characters. | Useful if you're concerned with individual characters or a small substring. | Cumbersome if the number of characters to search is large or if the search logic is complex. |

| Technique | Pros | Cons |
|---|---|--|
| | | Results in very poor performance for objects that have grown very large through repeated method calls. |
| Convert the <code>StringBuilder</code> object to a <code>String</code> object, and perform modifications on the <code>String</code> object. | Useful if the number of modifications is small. | Negates the performance benefit of the <code>StringBuilder</code> class if the number of modifications is large. |

Let's examine these techniques in greater detail.

- If the goal of the search is to determine whether a particular substring exists (that is, if you aren't interested in the position of the substring), you can search strings before storing them in the `StringBuilder` object. The following example provides one possible implementation. It defines a `StringBuilderFinder` class whose constructor is passed a reference to a `StringBuilder` object and the substring to find in the string. In this case, the example tries to determine whether recorded temperatures are in Fahrenheit or Celsius, and adds the appropriate introductory text to the beginning of the `StringBuilder` object. A random number generator is used to select an array that contains data in either degrees Celsius or degrees Fahrenheit.

C#

```

using System;
using System.Text;

public class Example9
{
    public static void Main()
    {
        Random rnd = new Random();
        string[] tempF = { "47.6F", "51.3F", "49.5F", "62.3F" };
        string[] tempC = { "21.2C", "16.1C", "23.5C", "22.9C" };
        string[][] temps = { tempF, tempC };

        StringBuilder sb = new StringBuilder();
        var f = new StringBuilderFinder(sb, "F");
        var baseDate = new DateTime(2013, 5, 1);
        String[] temperatures = temps[rnd.Next(2)];
        bool isFahrenheit = false;
        foreach (var temperature in temperatures)
        {
            if (isFahrenheit)
                sb.AppendFormat("{0:d}: {1}\n", baseDate, temperature);
        }
    }
}

```

```

        else
            isFahrenheit = f.SearchAndAppend(String.Format("{0:d}:
{1}\n",
                                                baseDate,
temperature));
            baseDate = baseDate.AddDays(1);
        }
        if (isFahrenheit)
        {
            sb.Insert(0, "Average Daily Temperature in Degrees
Fahrenheit");
            sb.Insert(47, "\n\n");
        }
        else
        {
            sb.Insert(0, "Average Daily Temperature in Degrees
Celsius");
            sb.Insert(44, "\n\n");
        }
        Console.WriteLine(sb.ToString());
    }
}

public class StringBuilderFinder
{
    private StringBuilder sb;
    private String text;

    public StringBuilderFinder(StringBuilder sb, String textToFind)
    {
        this.sb = sb;
        this.text = textToFind;
    }

    public bool SearchAndAppend(String stringToSearch)
    {
        sb.Append(stringToSearch);
        return stringToSearch.Contains(text);
    }
}
// The example displays output similar to the following:
//      Average Daily Temperature in Degrees Celsius
//
//      5/1/2013: 21.2C
//      5/2/2013: 16.1C
//      5/3/2013: 23.5C
//      5/4/2013: 22.9C

```

- Call the `StringBuilder.ToString` method to convert the `StringBuilder` object to a `String` object. You can search the string by using methods such as `String.LastIndexOf` or `String.StartsWith`, or you can use regular expressions and the `Regex` class to search for patterns. Because both `StringBuilder` and `String` objects

use UTF-16 encoding to store characters, the index positions of characters, substrings, and regular expression matches are the same in both objects. This enables you to use [StringBuilder](#) methods to make changes at the same position at which that text is found in the [String](#) object.

ⓘ Note

If you adopt this approach, you should work from the end of the [StringBuilder](#) object to its beginning so that you don't have to repeatedly convert the [StringBuilder](#) object to a string.

The following example illustrates this approach. It stores four occurrences of each letter of the English alphabet in a [StringBuilder](#) object. It then converts the text to a [String](#) object and uses a regular expression to identify the starting position of each four-character sequence. Finally, it adds an underscore before each four-character sequence except for the first sequence, and converts the first character of the sequence to uppercase.

```
C#  
  
using System;  
using System.Text;  
using System.Text.RegularExpressions;  
  
public class Example10  
{  
    public static void Main()  
    {  
        // Create a StringBuilder object with 4 successive occurrences  
        // of each character in the English alphabet.  
        StringBuilder sb = new StringBuilder();  
        for (ushort ctr = (ushort)'a'; ctr <= (ushort)'z'; ctr++)  
            sb.Append(Convert.ToChar(ctr), 4);  
  
        // Create a parallel string object.  
        String sbString = sb.ToString();  
        // Determine where each new character sequence begins.  
        String pattern = @"(\w)\1+";  
        MatchCollection matches = Regex.Matches(sbString, pattern);  
  
        // Uppercase the first occurrence of the sequence, and separate  
        // it from the previous sequence by an underscore character.  
        for (int ctr = matches.Count - 1; ctr >= 0; ctr--)  
        {  
            Match m = matches[ctr];  
            sb[m.Index] = Char.ToUpper(sb[m.Index]);  
            if (m.Index > 0) sb.Insert(m.Index, "_");  
        }  
    }  
}
```

```

        }
        // Display the resulting string.
        sbString = sb.ToString();
        int line = 0;
        do
        {
            int nChars = line * 80 + 79 <= sbString.Length ?
                80 : sbString.Length - line * 80;
            Console.WriteLine(sbString.Substring(line * 80, nChars));
            line++;
        } while (line * 80 < sbString.Length);
    }
}

// The example displays the following output:
//
Aaaa_Bbbb_Cccc_Dddd_Eeee_Ffff_Gggg_Hhhh_Iiii_Jjjj_Kkkk_Llll_Mmmm_Nnnn_O
ooo_Pppp_
//    Qqqq_Rrrr_Ssss_Tttt_Uuuu_Vvvv_Wwww_Xxxx_Yyyy_Zzzz

```

- Use the [StringBuilder.Chars\[\]](#) property to sequentially search a range of characters in a [StringBuilder](#) object. This approach may not be practical if the number of characters to be searched is large or the search logic is particularly complex. For the performance implications of character-by-character index-based access for very large, chunked [StringBuilder](#) objects, see the documentation for the [StringBuilder.Chars\[\]](#) property.

The following example is identical in functionality to the previous example but differs in implementation. It uses the [Chars\[\]](#) property to detect when a character value has changed, inserts an underscore at that position, and converts the first character in the new sequence to uppercase.

C#

```

using System;
using System.Text;

public class Example11
{
    public static void Main()
    {
        // Create a StringBuilder object with 4 successive occurrences
        // of each character in the English alphabet.
        StringBuilder sb = new StringBuilder();
        for (ushort ctr = (ushort)'a'; ctr <= (ushort)'z'; ctr++)
            sb.Append(Convert.ToChar(ctr), 4);

        // Iterate the text to determine when a new character sequence
        // occurs.
        int position = 0;
        Char current = '\u0000';

```

```

do
{
    if (sb[position] != current)
    {
        current = sb[position];
        sb[position] = Char.ToUpper(sb[position]);
        if (position > 0)
            sb.Insert(position, "_");
        position += 2;
    }
    else
    {
        position++;
    }
} while (position <= sb.Length - 1);
// Display the resulting string.
String sbString = sb.ToString();
int line = 0;
do
{
    int nChars = line * 80 + 79 <= sbString.Length ?
                80 : sbString.Length - line * 80;
    Console.WriteLine(sbString.Substring(line * 80, nChars));
    line++;
} while (line * 80 < sbString.Length);
}
}

// The example displays the following output:
//
Aaaa_Bbbb_Cccc_Dddd_Eeee_Ffff_Gggg_Hhhh_Iiii_Jjjj_Kkkk_Llll_Mmmm_Nnnn_O
ooo_Pppp_
//    Qqqq_Rrrr_Ssss_Tttt_Uuuu_Vvvv_Wwww_Xxxx_Yyyy_Zzzz

```

- Store all the unmodified text in the [StringBuilder](#) object, call the [StringBuilder.ToString](#) method to convert the [StringBuilder](#) object to a [String](#) object, and perform the modifications on the [String](#) object. You can use this approach if you have only a few modifications; otherwise, the cost of working with immutable strings may negate the performance benefits of using a [StringBuilder](#) object.

The following example is identical in functionality to the previous two examples but differs in implementation. It creates a [StringBuilder](#) object, converts it to a [String](#) object, and then uses a regular expression to perform all remaining modifications on the string. The [Regex.Replace\(String, String, MatchEvaluator\)](#) method uses a lambda expression to perform the replacement on each match.

C#

```

using System;
using System.Text;

```

```

using System.Text.RegularExpressions;

public class Example12
{
    public static void Main()
    {
        // Create a StringBuilder object with 4 successive occurrences
        // of each character in the English alphabet.
        StringBuilder sb = new StringBuilder();
        for (ushort ctr = (ushort)'a'; ctr <= (ushort)'z'; ctr++)
            sb.Append(Convert.ToChar(ctr), 4);

        // Convert it to a string.
        String sbString = sb.ToString();

        // Use a regex to uppercase the first occurrence of the
        sequence,
        // and separate it from the previous sequence by an underscore.
        string pattern = @"(\w)(\1+)";
        sbString = Regex.Replace(sbString, pattern,
                                m => (m.Index > 0 ? "_" : "") +
                                m.Groups[1].Value.ToUpper() +
                                m.Groups[2].Value);

        // Display the resulting string.
        int line = 0;
        do
        {
            int nChars = line * 80 + 79 <= sbString.Length ?
                        80 : sbString.Length - line * 80;
            Console.WriteLine(sbString.Substring(line * 80, nChars));
            line++;
        } while (line * 80 < sbString.Length);
    }
}

// The example displays the following output:
//
Aaaa_Bbbb_Cccc_Dddd_Eeee_Ffff_Gggg_Hhhh_Iiii_Jjjj_Kkkk_Llll_Mmmm_Nnnn_O
ooo_Pppp_
//   Qqqq_Rrrr_Ssss_Tttt_Uuuu_Vvvv_Wwww_Xxxx_Yyyy_Zzzz

```

Convert the `StringBuilder` object to a `string`

You must convert the `StringBuilder` object to a `String` object before you can pass the string represented by the `StringBuilder` object to a method that has a `String` parameter or display it in the user interface. You perform this conversion by calling the `StringBuilder.ToString` method. For an illustration, see the previous example, which calls the `ToString` method to convert a `StringBuilder` object to a string so that it can be passed to a regular expression method.

.NET regular expressions

Article • 03/08/2023

Regular expressions provide a powerful, flexible, and efficient method for processing text. The extensive pattern-matching notation of regular expressions enables you to quickly parse large amounts of text to:

- Find specific character patterns.
- Validate text to ensure that it matches a predefined pattern (such as an email address).
- Extract, edit, replace, or delete text substrings.
- Add extracted strings to a collection in order to generate a report.

For many applications that deal with strings or that parse large blocks of text, regular expressions are an indispensable tool.

How regular expressions work

The centerpiece of text processing with regular expressions is the regular expression engine, which is represented by the [System.Text.RegularExpressions.Regex](#) object in .NET. At a minimum, processing text using regular expressions requires that the regular expression engine be provided with the following two items of information:

- The regular expression pattern to identify in the text.

In .NET, regular expression patterns are defined by a special syntax or language, which is compatible with Perl 5 regular expressions and adds some additional features such as right-to-left matching. For more information, see [Regular Expression Language - Quick Reference](#).

- The text to parse for the regular expression pattern.

The methods of the [Regex](#) class let you perform the following operations:

- Determine whether the regular expression pattern occurs in the input text by calling the [Regex.IsMatch](#) method. For an example that uses the [IsMatch](#) method for validating text, see [How to: Verify that Strings Are in Valid Email Format](#).
- Retrieve one or all occurrences of text that matches the regular expression pattern by calling the [Regex.Match](#) or [Regex.Matches](#) method. The former method returns a [System.Text.RegularExpressions.Match](#) object that provides information about the matching text. The latter returns a [MatchCollection](#) object that contains one

`System.Text.RegularExpressions.Match` object for each match found in the parsed text.

- Replace text that matches the regular expression pattern by calling the `Regex.Replace` method. For examples that use the `Replace` method to change date formats and remove invalid characters from a string, see [How to: Strip Invalid Characters from a String](#) and [Example: Changing Date Formats](#).

For an overview of the regular expression object model, see [The Regular Expression Object Model](#).

For more information about the regular expression language, see [Regular Expression Language - Quick Reference](#) or download and print one of the following brochures:

- [Quick Reference in Word \(.docx\) format](#)
- [Quick Reference in PDF \(.pdf\) format](#)

Regular expression examples

The `String` class includes string search and replacement methods that you can use when you want to locate literal strings in a larger string. Regular expressions are most useful either when you want to locate one of several substrings in a larger string, or when you want to identify patterns in a string, as the following examples illustrate.

⚠ Warning

When using `System.Text.RegularExpressions` to process untrusted input, pass a timeout. A malicious user can provide input to `RegularExpression`, causing a [Denial-of-Service attack](#). ASP.NET Core framework APIs that use `RegularExpression` pass a timeout.

💡 Tip

The `System.Web.RegularExpressions` namespace contains a number of regular expression objects that implement predefined regular expression patterns for parsing strings from HTML, XML, and ASP.NET documents. For example, the `TagRegex` class identifies start tags in a string, and the `CommentRegex` class identifies ASP.NET comments in a string.

Example 1: Replace substrings

Assume that a mailing list contains names that sometimes include a title (Mr., Mrs., Miss, or Ms.) along with a first and last name. Suppose you don't want to include the titles when you generate envelope labels from the list. In that case, you can use a regular expression to remove the titles, as the following example illustrates:

```
C#  
  
using System;  
using System.Text.RegularExpressions;  
  
public class Example  
{  
    public static void Main()  
    {  
        string pattern = "(Mr\\..? |Mrs\\..? |Miss |Ms\\..? )";  
        string[] names = { "Mr. Henry Hunt", "Ms. Sara Samuels",  
                           "Abraham Adams", "Ms. Nicole Norris" };  
        foreach (string name in names)  
            Console.WriteLine(Regex.Replace(name, pattern, String.Empty));  
    }  
}  
// The example displays the following output:  
//     Henry Hunt  
//     Sara Samuels  
//     Abraham Adams  
//     Nicole Norris
```

The regular expression pattern `(Mr\..? |Mrs\..? |Miss |Ms\..?)` matches any occurrence of "Mr ", "Mr. ", "Mrs ", "Mrs. ", "Miss ", "Ms ", or "Ms. ". The call to the `Regex.Replace` method replaces the matched string with `String.Empty`; in other words, it removes it from the original string.

Example 2: Identify duplicated words

Accidentally duplicating words is a common error that writers make. Use a regular expression to identify duplicated words, as the following example shows:

```
C#  
  
using System;  
using System.Text.RegularExpressions;  
  
public class Class1  
{  
    public static void Main()  
    {  
        string pattern = @"\b(\w+)\s\1\b";  
        string input = "This this is a nice day. What about this? This tastes
```

```

good. I saw a a dog.";
    foreach (Match match in Regex.Matches(input, pattern,
RegexOptions.IgnoreCase))
        Console.WriteLine("{0} (duplicates '{1}') at position {2}",
                           match.Value, match.Groups[1].Value, match.Index);
    }
}
// The example displays the following output:
//      This this (duplicates 'This') at position 0
//      a a (duplicates 'a') at position 66

```

The regular expression pattern `\b(\w+?)\s\1\b` can be interpreted as follows:

| Pattern | Interpretation |
|---------------------|--|
| <code>\b</code> | Start at a word boundary. |
| <code>(\w+?)</code> | Match one or more word characters, but as few characters as possible. Together, they form a group that can be referred to as <code>\1</code> . |
| <code>\s</code> | Match a white-space character. |
| <code>\1</code> | Match the substring that's equal to the group named <code>\1</code> . |
| <code>\b</code> | Match a word boundary. |

The `Regex.Matches` method is called with regular expression options set to `RegexOptions.IgnoreCase`. Therefore, the match operation is case-insensitive, and the example identifies the substring "This this" as a duplication.

The input string includes the substring "this? This". However, because of the intervening punctuation mark, it isn't identified as a duplication.

Example 3: Dynamically build a culture-sensitive regular expression

The following example illustrates the power of regular expressions combined with the flexibility offered by .NET's globalization features. It uses the `NumberFormatInfo` object to determine the format of currency values in the system's current culture. It then uses that information to dynamically construct a regular expression that extracts currency values from the text. For each match, it extracts the subgroup that contains the numeric string only, converts it to a `Decimal` value, and calculates a running total.

C#

```

using System;
using System.Collections.Generic;

```

```

using System.Globalization;
using System.Text.RegularExpressions;

public class Example
{
    public static void Main()
    {
        // Define text to be parsed.
        string input = "Office expenses on 2/13/2008:\n" +
            "Paper (500 sheets)                $3.95\n" +
            "Pencils (box of 10)               $1.00\n" +
            "Pens (box of 10)                 $4.49\n" +
            "Erasers                          $2.19\n" +
            "Ink jet printer                  $69.95\n\n" +
            "Total Expenses                   $ 81.58\n";

        // Get current culture's NumberFormatInfo object.
        NumberFormatInfo nfi = CultureInfo.CurrentCulture.NumberFormat;
        // Assign needed property values to variables.
        string currencySymbol = nfi.CurrencySymbol;
        bool symbolPrecedesIfPositive = nfi.CurrencyPositivePattern % 2 == 0;
        string groupSeparator = nfi.CurrencyGroupSeparator;
        string decimalSeparator = nfi.CurrencyDecimalSeparator;

        // Form regular expression pattern.
        string pattern = Regex.Escape( symbolPrecedesIfPositive ?
currencySymbol : "") + @"^\s*[-+]?([0-9]{0,3})(\s+groupSeparator\s+|[0-
9]{3})*(\s+
Regex.Escape(decimalSeparator) + "[0-9]+)?)" +
(! symbolPrecedesIfPositive ? currencySymbol : ""));
        Console.WriteLine( "The regular expression pattern is:");
        Console.WriteLine("    " + pattern);

        // Get text that matches regular expression pattern.
        MatchCollection matches = Regex.Matches(input, pattern,
RegexOptions.IgnorePatternWhitespace);
        Console.WriteLine("Found {0} matches.", matches.Count);

        // Get numeric string, convert it to a value, and add it to List
object.
        List<decimal> expenses = new List<Decimal>();

        foreach (Match match in matches)
            expenses.Add(Decimal.Parse(match.Groups[1].Value));

        // Determine whether total is present and if present, whether it is
correct.
        decimal total = 0;
        foreach (decimal value in expenses)
            total += value;

        if (total / 2 == expenses[expenses.Count - 1])
            Console.WriteLine("The expenses total {0:C2}.",

```

```

expenses[expenses.Count - 1]);
else
    Console.WriteLine("The expenses total {0:C2}.", total);
}
}
// The example displays the following output:
//      The regular expression pattern is:
//      \$\s*[-+]?([0-9]{0,3}(,[0-9]{3})*(\.[0-9]+)?)?
//      Found 6 matches.
//      The expenses total $81.58.

```

On a computer whose current culture is English - United States (en-US), the example dynamically builds the regular expression `\$\s*[-+]?([0-9]{0,3}(,[0-9]{3})*(\.[0-9]+)?)?`. This regular expression pattern can be interpreted as follows:

| Pattern | Interpretation |
|---|---|
| <code>\\$</code> | Look for a single occurrence of the dollar symbol (\$) in the input string. The regular expression pattern string includes a backslash to indicate that the dollar symbol is to be interpreted literally rather than as a regular expression anchor. The \$ symbol alone would indicate that the regular expression engine should try to begin its match at the end of a string. To ensure that the current culture's currency symbol isn't misinterpreted as a regular expression symbol, the example calls the Regex.Escape method to escape the character. |
| <code>\s*</code> | Look for zero or more occurrences of a white-space character. |
| <code>[+-]?</code> | Look for zero or one occurrence of either a positive or negative sign. |
| <code>([0-9]{0,3}(,[0-9]{3})*(\.[0-9]+)?)?</code> | The outer parentheses define this expression as a capturing group or a subexpression. If a match is found, information about this part of the matching string can be retrieved from the second Group object in the GroupCollection object returned by the Match.Groups property. The first element in the collection represents the entire match. |
| <code>[0-9]{0,3}</code> | Look for zero to three occurrences of the decimal digits 0 through 9. |
| <code>(,[0-9]{3})*</code> | Look for zero or more occurrences of a group separator followed by three decimal digits. |
| <code>\.</code> | Look for a single occurrence of the decimal separator. |
| <code>[0-9]+</code> | Look for one or more decimal digits. |
| <code>(\.[0-9]+)?</code> | Look for zero or one occurrence of the decimal separator followed by at least one decimal digit. |

If each subpattern is found in the input string, the match succeeds, and a [Match](#) object that contains information about the match is added to the [MatchCollection](#) object.

.NET regular expression source generators

Article • 06/01/2023

A regular expression, or regex, is a string that enables a developer to express a pattern being searched for, making it a very common way to search text and extract results as a subset from the searched string. In .NET, the `System.Text.RegularExpressions` namespace is used to define `Regex` instances and static methods, and match on user-defined patterns. In this article, you'll learn how to use source generation to generate `Regex` instances to optimize performance.

ⓘ Note

Where possible, use source generated regular expressions instead of compiling regular expressions using the `RegexOptions.Compiled` option. Source generation can help your app start faster, run more quickly and be more trimmable. To learn when source generation is possible, see [When to use it](#).

Compiled regular expressions

When you write `new Regex("somepattern")`, a few things happen. The specified pattern is parsed, both to ensure the validity of the pattern and to transform it into an internal tree that represents the parsed regex. The tree is then optimized in various ways, transforming the pattern into a functionally equivalent variation that can be more efficiently executed. The tree is written into a form that can be interpreted as a series of opcodes and operands that provide instructions to the regex interpreter engine on how to match. When a match is performed, the interpreter simply walks through those instructions, processing them against the input text. When instantiating a new `Regex` instance or calling one of the static methods on `Regex`, the interpreter is the default engine employed.

When you specify `RegexOptions.Compiled`, all of the same construction-time work would be performed. The resulting instructions would be transformed further by the reflection-emit-based compiler into IL instructions that would be written to a few `DynamicMethods`. When a match was performed, those `DynamicMethod`s would be invoked. This IL would essentially do exactly what the interpreter would do, except specialized for the exact pattern being processed. For example, if the pattern contained `[ac]`, the interpreter would see an opcode that said "match the input character at the

current position against the set specified in this set description" whereas the compiled IL would contain code that effectively said, "match the input character at the current position against 'a' or 'c'". This special casing and the ability to perform optimizations based on knowledge of the pattern are some of the main reasons for specifying `RegexOptions.Compiled` yields much faster-matching throughput than does the interpreter.

There are several downsides to `RegexOptions.Compiled`. The most impactful is that it incurs much more construction cost than using the interpreter. Not only are all of the same costs paid as for the interpreter, but it then needs to compile that resulting `RegexNode` tree and generated opcodes/operands into IL, which adds non-trivial expense. The generated IL further needs to be JIT-compiled on first use leading to even more expense at startup. `RegexOptions.Compiled` represents a fundamental tradeoff between overheads on the first use and overheads on every subsequent use. The use of `System.Reflection.Emit` also inhibits the use of `RegexOptions.Compiled` in certain environments; some operating systems don't permit dynamically generated code to be executed, and on such systems, `Compiled` will become a no-op.

Source generation

.NET 7 introduces a new `RegexGenerator` source generator. When the C# compiler was rewritten as the "[Roslyn](#)" C# compiler, it exposed object models for the entire compilation pipeline, as well as analyzers. More recently, Roslyn enabled source generators. Just like an analyzer, a source generator is a component that plugs into the compiler and is handed all of the same information as an analyzer, but in addition to being able to emit diagnostics, it can also augment the compilation unit with additional source code. The .NET 7 SDK includes a new source generator that recognizes the new `GeneratedRegexAttribute` on a partial method that returns `Regex`. The source generator provides an implementation of that method that implements all the logic for the `Regex`. For example, you might have written code like this:

C#

```
private static readonly Regex s_abcOrDefGeneratedRegex =
    new(pattern: "abc|def",
        options: RegexOptions.Compiled | RegexOptions.IgnoreCase);

private static void EvaluateText(string text)
{
    if (s_abcOrDefGeneratedRegex.IsMatch(text))
    {
        // Take action with matching text
    }
}
```

```
    }  
}
```

You can now rewrite the previous code as follows:

C#

```
[GeneratedRegex("abc|def", RegexOptions.IgnoreCase, "en-US")]  
private static partial Regex AbcOrDefGeneratedRegex();  
  
private static void EvaluateText(string text)  
{  
    if (AbcOrDefGeneratedRegex().IsMatch(text))  
    {  
        // Take action with matching text  
    }  
}
```

The generated implementation of `AbcOrDefGeneratedRegex()` similarly caches a singleton `Regex` instance, so no additional caching is needed to consume code.

💡 Tip

The `RegexOptions.Compiled` flag is ignored by the source generator, thus making it no longer needed in the source generated version.

```
/// <summary>Cached, thread-safe singleton instance.</summary>  
internal static readonly AbcOrDefGeneratedRegex_0 Instance = new AbcOrDefGeneratedRegex_0();
```

But as can be seen, it's not just doing `new Regex(...)`. Rather, the source generator is emitting as C# code a custom `Regex`-derived implementation with logic similar to what `RegexOptions.Compiled` emits in IL. You get all the throughput performance benefits of `RegexOptions.Compiled` (more, in fact) and the start-up benefits of `Regex.CompileToAssembly`, but without the complexity of `CompileToAssembly`. The source that's emitted is part of your project, which means it's also easily viewable and debuggable.

```

81     /// <summary>Search <paramref name="inputSpan"/> starting from base.runtexpos for the next location a
82     /// <param name="inputSpan">The text being scanned by the regular expression.</param>
83     /// <returns>true if a possible match was found; false if no more matches are possible.</returns>
84     private bool TryFindNextPossibleStartingPosition(ReadOnlySpan<char> inputSpan)
85     {
86         int pos = base.runtexpos;
87         ulong charMinusLow;
88
89         // Any possible match is at least 3 characters.
90         if (pos <= inputSpan.Length - 3)
91         {
92             // The pattern matches a character in the set [CFcf] at index 2.
93             // Find the next occurrence. If it can't be found, there's no match.
94             ReadOnlySpan<char> span = inputSpan.Slice(pos);
95             for (int i = 0; i < span.Length - 2; i++)
96             {
97                 int indexOfPos = span.Slice(i + 2).IndexOfAny("CFcf");
98                 if (indexOfPos < 0)
99                 {
100                     goto NoMatchFound;
101                 }
102                 i += indexOfPos;
103             }
104         }

```

Tip

In Visual Studio, right-click on your partial method declaration and select **Go To Definition**. Or, alternatively, select the project node in **Solution Explorer**, then expand **Dependencies > Analyzers > System.Text.RegularExpressions.Generator > System.Text.RegularExpressions.Generator.RegexGenerator > RegexGenerator.g.cs** to see the generated C# code from this regex generator.

You can set breakpoints in it, you can step through it, and you can use it as a learning tool to understand exactly how the regex engine is processing your pattern with your input. The generator even generates [triple-slash \(XML\) comments](#) to help make the expression understandable at a glance and where it's used.

```

[GeneratedRegex(pattern: "abc|def", options: RegexOptions.IgnoreCase)]
2 references | 0 changes | 0 authors, 0 changes
private static partial Regex AbcOrDefGeneratedRegex();

```

1 reference | 0 changes | 0 authors, 0 changes

```

private static void EvaluateText()
{
    if (s_abcOrDefGeneratedRegex
    {
        }
}

```

Regex Program.AbcOrDefGeneratedRegex()

Pattern explanation:

- o Match with 2 alternative expressions, atomically.
 - o Match a sequence of expressions.
 - o Match a character in the set [Aa].
 - o Match a character in the set [Bb].
 - o Match a character in the set [Cc].
 - o Match a sequence of expressions.
 - o Match a character in the set [Dd].
 - o Match a character in the set [Ee].
 - o Match a character in the set [Ff].

Inside the source-generated files

With .NET 7, both the source generator and `RegexCompiler` were almost entirely rewritten, fundamentally changing the structure of the generated code. This approach has been extended to handle all constructs (with one caveat), and both `RegexCompiler` and the source generator still map mostly 1:1 with each other, following the new approach. Consider the source generator output for one of the primary functions from the `(a|bc)d` expression:

C#

```
private bool TryMatchAtCurrentPosition(ReadOnlySpan<char> inputSpan)
{
    int pos = base.runtextrpos;
    int matchStart = pos;
    int capture_starting_pos = 0;
    ReadOnlySpan<char> slice = inputSpan.Slice(pos);

    // 1st capture group.
    //{
        capture_starting_pos = pos;

        // Match with 2 alternative expressions.
        //{
            if (slice.IsEmpty)
            {
                UncaptureUntil(0);
                return false; // The input didn't match.
            }

            switch (slice[0])
            {
                case 'a':
                    pos++;
                    slice = inputSpan.Slice(pos);
                    break;

                case 'b':
                    // Match 'c'.
                    if ((uint)slice.Length < 2 || slice[1] != 'c')
                    {
                        UncaptureUntil(0);
                        return false; // The input didn't match.
                    }

                    pos += 2;
                    slice = inputSpan.Slice(pos);
                    break;

                default:
                    UncaptureUntil(0);
                    return false; // The input didn't match.
            }
        //}
    //}
}
```

```

        base.Capture(1, capture_starting_pos, pos);
    //}

    // Match 'd'.
    if (slice.IsEmpty || slice[0] != 'd')
    {
        UncaptureUntil(0);
        return false; // The input didn't match.
    }

    // The input matched.
    pos++;
    base.runtextpos = pos;
    base.Capture(0, matchStart, pos);
    return true;

    // <summary>Undo captures until it reaches the specified capture
    position.</summary>
    [MethodImpl(MethodImplOptions.AggressiveInlining)]
    void UncaptureUntil(int capturePosition)
    {
        while (base.Crawlpos() > capturePosition)
        {
            base.Uncapture();
        }
    }
}

```

The goal of the source-generated code is to be understandable, with an easy-to-follow structure, with comments explaining what's being done at each step, and in general with code emitted under the guiding principle that the generator should emit code as if a human had written it. Even when backtracking is involved, the structure of the backtracking becomes part of the structure of the code, rather than relying on a stack to indicate where to jump next. For example, here's the code for the same generated matching function when the expression is `[ab]*[bc]`:

C#

```

private bool TryMatchAtCurrentPosition(ReadOnlySpan<char> inputSpan)
{
    int pos = base.runtextpos;
    int matchStart = pos;
    int charloop_starting_pos = 0, charloop_ending_pos = 0;
    ReadOnlySpan<char> slice = inputSpan.Slice(pos);

    // Match a character in the set [ab] greedily any number of times.
    //{
        charloop_starting_pos = pos;

        int iteration = slice.IndexOfAnyExcept('a', 'b');

```

```

    if (iteration < 0)
    {
        iteration = slice.Length;
    }

    slice = slice.Slice(iteration);
    pos += iteration;

    charloop_ending_pos = pos;
    goto CharLoopEnd;

CharLoopBacktrack:

    if (Utilities.s_hasTimeout)
    {
        base.CheckTimeout();
    }

    if (charloop_starting_pos >= charloop_ending_pos ||
        (charloop_ending_pos = inputSpan.Slice(
            charloop_starting_pos, charloop_ending_pos -
charloop_starting_pos
            .LastIndexOfAny('b', 'c')) < 0)
    {
        return false; // The input didn't match.
    }
    charloop_ending_pos += charloop_starting_pos;
    pos = charloop_ending_pos;
    slice = inputSpan.Slice(pos);

    CharLoopEnd:
}

// Advance the next matching position.
if (base.runtextrpos < pos)
{
    base.runtextrpos = pos;
}

// Match a character in the set [bc].
if (slice.IsEmpty || !char.IsBetween(slice[0], 'b', 'c'))
{
    goto CharLoopBacktrack;
}

// The input matched.
pos++;
base.runtextrpos = pos;
base.Capture(0, matchStart, pos);
return true;
}

```

You can see the structure of the backtracking in the code, with a `CharLoopBacktrack` label emitted for where to backtrack to and a `goto` used to jump to that location when a subsequent portion of the regex fails.

If you look at the code implementing `RegexCompiler` and the source generator, they will look extremely similar: similarly named methods, similar call structure, and even similar comments throughout the implementation. For the most part, they result in identical code, albeit one in IL and one in C#. Of course, the C# compiler is then responsible for translating the C# into IL, so the resulting IL in both cases likely won't be identical. The source generator relies on that in various cases, taking advantage of the fact that the C# compiler will further optimize various C# constructs. There are a few specific things the source generator will thus produce more optimized matching code than does `RegexCompiler`. For example, in one of the previous examples, you can see the source generator emitting a switch statement, with one branch for `'a'` and another branch for `'b'`. Because the C# compiler is very good at optimizing switch statements, with multiple strategies at its disposal for how to do so efficiently, the source generator has a special optimization that `RegexCompiler` does not. For `alternations`, the source generator looks at all of the branches, and if it can prove that every branch begins with a different starting character, it will emit a switch statement over that first character and avoid outputting any backtracking code for that alternation.

Here's a slightly more complicated example of that. In .NET 7, alternations are more heavily analyzed to determine whether it's possible to refactor them in a way that will make them more easily optimized by the backtracking engines and that will lead to simpler source-generated code. One such optimization supports extracting common prefixes from branches, and if the alternation is atomic such that ordering doesn't matter, reordering branches to allow for more such extraction. You can see the impact of that for the following weekday pattern

`Monday|Tuesday|Wednesday|Thursday|Friday|Saturday|Sunday`, which produces a matching function like this:

C#

```
private bool TryMatchAtCurrentPosition(ReadOnlySpan<char> inputSpan)
{
    int pos = base.runtextrpos;
    int matchStart = pos;
    ReadOnlySpan<char> slice = inputSpan.Slice(pos);

    // Match with 5 alternative expressions, atomically.
    {
        if (slice.IsEmpty)
        {
            return false; // The input didn't match.
        }
    }
}
```

```

    }

    switch (slice[0])
    {
        case 'M':
            // Match the string "onday".
            if (!slice.Slice(1).StartsWith("onday"))
            {
                return false; // The input didn't match.
            }

            pos += 6;
            slice = inputSpan.Slice(pos);
            break;

        case 'T':
            // Match with 2 alternative expressions, atomically.
            {
                if ((uint)slice.Length < 2)
                {
                    return false; // The input didn't match.
                }

                switch (slice[1])
                {
                    case 'u':
                        // Match the string "esday".
                        if (!slice.Slice(2).StartsWith("esday"))
                        {
                            return false; // The input didn't match.
                        }

                        pos += 7;
                        slice = inputSpan.Slice(pos);
                        break;

                    case 'h':
                        // Match the string "ursday".
                        if (!slice.Slice(2).StartsWith("ursday"))
                        {
                            return false; // The input didn't match.
                        }

                        pos += 8;
                        slice = inputSpan.Slice(pos);
                        break;

                    default:
                        return false; // The input didn't match.
                }
            }
    }

    break;

    case 'W':

```

```
// Match the string "ednesday".
if (!slice.Slice(1).StartsWith("ednesday"))
{
    return false; // The input didn't match.
}

pos += 9;
slice = inputSpan.Slice(pos);
break;

case 'F':
// Match the string "riday".
if (!slice.Slice(1).StartsWith("riday"))
{
    return false; // The input didn't match.
}

pos += 6;
slice = inputSpan.Slice(pos);
break;

case 'S':
// Match with 2 alternative expressions, atomically.
{
    if ((uint)slice.Length < 2)
    {
        return false; // The input didn't match.
    }

    switch (slice[1])
    {
        case 'a':
            // Match the string "turday".
            if (!slice.Slice(2).StartsWith("turday"))
            {
                return false; // The input didn't match.
            }

            pos += 8;
            slice = inputSpan.Slice(pos);
            break;

        case 'u':
            // Match the string "nday".
            if (!slice.Slice(2).StartsWith("nday"))
            {
                return false; // The input didn't match.
            }

            pos += 6;
            slice = inputSpan.Slice(pos);
            break;
    }
}

default:
return false; // The input didn't match.
```

```

        }

        break;

    default:
        return false; // The input didn't match.
    }
}

// The input matched.
base.runtextrpos = pos;
base.Capture(0, matchStart, pos);
return true;
}

```

Take notice of how `Thursday` was reordered to be just after `Tuesday`, and how for both the `Tuesday / Thursday` pair and the `Saturday / Sunday` pair, you end up with multiple levels of switches. In the extreme, if you were to create a long alternation of many different words, the source generator would end up emitting the logical equivalent of a trie¹, reading each character and `switch`'ing to the branch for handling the remainder of the word. This is a very efficient way to match words, and it's what the source generator is doing here.

At the same time, the source generator has other issues to contend with that simply don't exist when outputting to IL directly. If you look a couple of code examples back, you can see some braces somewhat strangely commented out. That's not a mistake. The source generator is recognizing that, if those braces weren't commented out, the structure of the backtracking is relying on jumping from outside of the scope to a label defined inside of that scope; such a label would not be visible to such a `goto` and the code would fail to compile. Thus, the source generator needs to avoid there being a scope in the way. In some cases, it'll simply comment out the scope as was done here. In other cases where that's not possible, it may sometimes avoid constructs that require scopes (such as a multi-statement `if` block) if doing so would be problematic.

The source generator handles everything `RegexCompiler` handles, with one exception. As with handling `RegexOptions.IgnoreCase`, the implementations now use a casing table to generate sets at construction time, and how `IgnoreCase` backreference matching needs to consult that casing table. That table is internal to

`System.Text.RegularExpressions.dll`, and for now, at least, the code external to that assembly (including code emitted by the source generator) does not have access to it. That makes handling `IgnoreCase` backreferences a challenge in the source generator and they aren't supported. This is the one construct not supported by the source generator that is supported by `RegexCompiler`. If you try to use a pattern that has one of

these (which is rare), the source generator won't emit a custom implementation and will instead fall back to caching a regular `Regex` instance:

```
/// <summary>Cached, thread-safe singleton instance.</summary>
internal static readonly Regex Instance =
    new Regex(pattern: "(\\w)\\1", options: RegexOptions.IgnoreCase)
```

Also, neither `RegexCompiler` nor the source generator supports the new `RegexOptions.NonBacktracking`. If you specify `RegexOptions.Compiled` | `RegexOptions.NonBacktracking`, the `Compiled` flag will just be ignored, and if you specify `NonBacktracking` to the source generator, it will similarly fall back to caching a regular `Regex` instance.

When to use it

The general guidance is if you can use the source generator, use it. If you're using `Regex` today in C# with arguments known at compile time, and especially if you're already using `RegexOptions.Compiled` (because the regex has been identified as a hot spot that would benefit from faster throughput), you should prefer to use the source generator. The source generator will give your regex the following benefits:

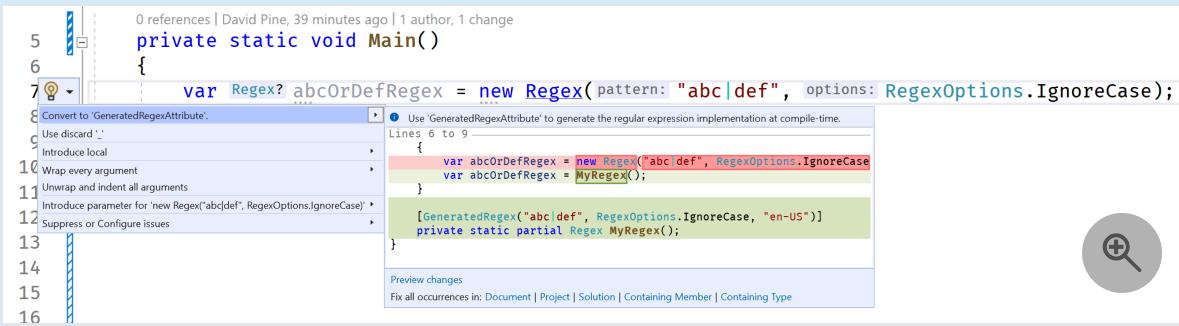

- All the throughput benefits of `RegexOptions.Compiled`.
- The startup benefits of not having to do all the regex parsing, analysis, and compilation at run time.
- The option of using ahead-of-time compilation with the code generated for the regex.
- Better debuggability and understanding of the regex.
- The possibility to reduce the size of your trimmed app by trimming out large swaths of code associated with `RegexCompiler` (and potentially even reflection emit itself).

When used with an option like `RegexOptions.NonBacktracking` for which the source generator can't generate a custom implementation, it will still emit caching and XML comments that describe the implementation, making it valuable. The main downside of the source generator is that it emits additional code into your assembly, so there's the potential for increased size. The more regexes in your app and the larger they are, the more code will be emitted for them. In some situations, just as `RegexOptions.Compiled` may be unnecessary, so too may be the source generator. For example, if you have a

regex that's needed only rarely and for which throughput doesn't matter, it could be more beneficial to just rely on the interpreter for that sporadic usage.

ⓘ Important

.NET 7 includes an [analyzer](#) that identifies the use of `Regex` that could be converted to the source generator, and a fixer that does the conversion for you:

Regular Expression Language - Quick Reference

Article • 06/18/2022

A regular expression is a pattern that the regular expression engine attempts to match in input text. A pattern consists of one or more character literals, operators, or constructs. For a brief introduction, see [.NET Regular Expressions](#).

Each section in this quick reference lists a particular category of characters, operators, and constructs that you can use to define regular expressions.

We've also provided this information in two formats that you can download and print for easy reference:

- [Download in Word \(.docx\) format](#)
- [Download in PDF \(.pdf\) format](#)

Character Escapes

The backslash character (\) in a regular expression indicates that the character that follows it either is a special character (as shown in the following table), or should be interpreted literally. For more information, see [Character Escapes](#).

| Escaped character | Description | Pattern | Matches |
|-------------------|---|-----------|--|
| \a | Matches a bell character, \u0007. | \a | "\u0007" in "Error!" + '\u0007' |
| \b | In a character class, matches a backspace, \u0008. | [\b]{3,} | "\b\b\b\b" in "\b\b\b\b" |
| \t | Matches a tab, \u0009. | (\w+)\t | "item1\t", "item2\t" in "item1\item2\t" |
| \r | Matches a carriage return, \u000D. (\r is not equivalent to the newline character, \n.) | \r\n(\w+) | "\r\nThese" in "\r\nThese are\ntwo lines." |
| \v | Matches a vertical tab, \u000B. | [\v]{2,} | "\v\v\v" in "\v\v\v" |

| Escaped character | Description | Pattern | Matches |
|-------------------|---|------------------|---|
| \f | Matches a form feed, \u000C. | [\f]{2,} | "\f\f\f" in "\f\f\f" |
| \n | Matches a new line, \u000A. | \r\n(\w+) | "\r\nThese" in "\r\nThese are\n two lines." |
| \e | Matches an escape, \u001B. | \e | "\x001B" in "\x001B" |
| \ nnn | Uses octal representation to specify a character (<i>nnn</i> consists of two or three digits). | \w\040\w | "a b", "c d" in "a bc d" |
| \x nn | Uses hexadecimal representation to specify a character (<i>nn</i> consists of exactly two digits). | \w\x20\w | "a b", "c d" in "a bc d" |
| \c X | Matches the ASCII control character that is specified by <i>X</i> or <i>x</i> , where <i>X</i> or <i>x</i> is the letter of the control character. | \cc | "\x0003" in "\x0003" (Ctrl-C) |
| \c x | | | |
| \u nnnn | Matches a Unicode character by using hexadecimal representation (exactly four digits, as represented by <i>nnnn</i>). | \w\u0020\w | "a b", "c d" in "a bc d" |
| \ | When followed by a character that is not recognized as an escaped character in this and other tables in this topic, matches that character. For example, * is the same as \xA, and \. is the same as \xE. This allows the regular expression engine to disambiguate language elements (such as * or ?) and character literals (represented by * or \?). | \d+[\+\-\x*]\d+ | "2+2" and "3*9" in "(2+2) * 3*9" |

Character Classes

A character class matches any one of a set of characters. Character classes include the language elements listed in the following table. For more information, see [Character Classes](#).

| Character class | Description | Pattern | Matches |
|----------------------------|---|---------|---------------|
| [<i>character_group</i>] | Matches any single character in <i>character_group</i> . By default, the match is case-sensitive. | [ae] | "a" in "gray" |

| Character class | Description | Pattern | Matches |
|----------------------|---|----------------|--|
| | | | "a", "e" in "lane" |
| [^ character_group] | Negation: Matches any single character that is not in <i>character_group</i> . By default, characters in <i>character_group</i> are case-sensitive. | [^aei] | "r", "g", "n" in "reign" |
| [first - last] | Character range: Matches any single character in the range from <i>first</i> to <i>last</i> . | [A-Z] | "A", "B" in "AB123" |
| . | Wildcard: Matches any single character except \n . | a.e | "ave" in "nave" |
| | To match a literal period character (.) or (\u002E), you must precede it with the escape character (\.). | | "ate" in "water" |
| \p{ name } | Matches any single character in the Unicode general category or named block specified by <i>name</i> . | \p{Lu} | "C", "L" in "City Lights" |
| | | \p{IsCyrillic} | "д", "ж" in "Джем" |
| \P{ name } | Matches any single character that is not in the Unicode general category or named block specified by <i>name</i> . | \P{Lu} | "i", "t", "у" in "City" |
| | | \P{IsCyrillic} | "е", "м" in "Джем" |
| \w | Matches any word character . | \w | "I", "D", "A", "1", "3" in "ID A1.3" |
| \W | Matches any non-word character . | \W | " ", "." in "ID A1.3" |
| \s | Matches any white-space character . | \w\s | "D " in "ID A1.3" |
| \S | Matches any non-white-space character . | \s\S | " _" in "int _ctr" |
| \d | Matches any decimal digit . | \d | "4" in "4 = IV" |
| \D | Matches any character other than a decimal digit . | \D | " ", "=" , " " , "I", "v" in "4 |

| Character class | Description | Pattern | Matches |
|-----------------|-------------|---------|---------|
| | | = IV" | |

Anchors

Anchors, or atomic zero-width assertions, cause a match to succeed or fail depending on the current position in the string, but they do not cause the engine to advance through the string or consume characters. The metacharacters listed in the following table are anchors. For more information, see [Anchors](#).

| Assertion | Description | Pattern | Matches |
|-----------|---|--------------|---|
| ^ | By default, the match must start at the beginning of the string; in multiline mode, it must start at the beginning of the line. | ^\d{3} | "901" in "901-333-" |
| \$ | By default, the match must occur at the end of the string or before \n at the end of the string; in multiline mode, it must occur before the end of the line or before \n at the end of the line. | -\d{3}\$ | "-333" in "-901-333" |
| \A | The match must occur at the start of the string. | \A\d{3} | "901" in "901-333-" |
| \z | The match must occur at the end of the string or before \n at the end of the string. | -\d{3}\z | "-333" in "-901-333" |
| \z | The match must occur at the end of the string. | -\d{3}\z | "-333" in "-901-333" |
| \G | The match must occur at the point where the previous match ended, or if there was no previous match, at the position in the string where matching started. | \G\(\d\) | "(1)", "(3)", "(5)" in "(1)(3)(5)[7](9)" |
| \b | The match must occur on a boundary between a \w (alphanumeric) and a \W (nonalphanumeric) character. | \b\w+\s\w+\b | "them theme", "them them" in "them theme them them" |
| \B | The match must not occur on a \b boundary. | \Bend\w*\b | "ends", "ender" in "end sends endure lender" |

Grouping Constructs

Grouping constructs delineate subexpressions of a regular expression and typically capture substrings of an input string. Grouping constructs include the language elements listed in the following table. For more information, see [Grouping Constructs](#).

| Grouping construct | Description | Pattern | Matches |
|---|---|--|---|
| (<i>subexpression</i>) | Captures the matched subexpression and assigns it a one-based ordinal number. | (\w)\1 | "ee" in "deep" |
| (? <i>name</i> < <i>subexpression</i> >) or (?' <i>name</i> ' <i>subexpression</i>) | Captures the matched subexpression into a named group. | (?<double>\w)\k<double> | "ee" in "deep" |
| (? <i>name1</i> - <i>name2</i> > <i>subexpression</i>) or (?' <i>name1</i> - <i>name2</i> ' <i>subexpression</i>) | Defines a balancing group definition. For more information, see the "Balancing Group Definition" section in Grouping Constructs . | ((('Open'\()[^\\(\)]*+((('Close-Open'\())[^\(\)]*+)*((('Open')(!))\$ | "((1-3)*(3-1))" in "3+2*((1-3)*(3-1))" |
| (?: <i>subexpression</i>) | Defines a noncapturing group. | Write(?:Line)? | "WriteLine" in "Console.WriteLine()" "Write" in "Console.WriteLine(value)" |
| (?imnsx- imnsx: <i>subexpression</i>) | Applies or disables the specified options within <i>subexpression</i> . For more information, see Regular Expression Options . | A\d{2}(?i:\w+)\b | "A12x1", "A12XL" in "A12x1 A12XL a12x1" |
| (?= <i>subexpression</i>) | Zero-width positive lookahead assertion. | \b\w+\b(?.+and.+) | "cats", "dogs" in |

| Grouping construct | Description | Pattern | Matches |
|----------------------------|---|---|--|
| | | | "cats, dogs and some mice." |
| (?! subexpression) | Zero-width negative lookahead assertion. | \b\w+\b(?! .+and.+) | "and", "some", "mice" in "cats, dogs and some mice." |
| (?<= subexpression) | Zero-width positive lookbehind assertion. | \b\w+\b(?<=.+and.+) _____ \b\w+\b(?<=.+and.*) | "some", "mice" in "cats, dogs and some mice." _____ "and", "some", "mice" in "cats, dogs and some mice." |
| (?<! subexpression) | Zero-width negative lookbehind assertion. | \b\w+\b(?<! .+and.+) _____ \b\w+\b(?<! .+and.*) | "cats", "dogs", "and" in "cats, dogs and some mice." _____ "cats", "dogs" in "cats, dogs and some mice." |
| (?> subexpression) | Atomic group. | (?>a ab)c | "ac" in "ac" nothing in "abc" |

Lookarounds at a glance

When the regular expression engine hits a **lookaround expression**, it takes a substring reaching from the current position to the start (lookbehind) or end (lookahead) of the original string, and then runs [Regex.IsMatch](#) on that substring using the lookahead pattern. Success of this subexpression's result is then determined by whether it's a positive or negative assertion.

| Lookaround | Name | Function |
|------------|--------------------|---|
| (?=check) | Positive Lookahead | Asserts that what immediately follows the current position in the string is "check" |

| Lookaround | Name | Function |
|-------------|---------------------|--|
| (?<=>check) | Positive Lookbehind | Asserts that what immediately precedes the current position in the string is "check" |
| (?!=check) | Negative Lookahead | Asserts that what immediately follows the current position in the string is not "check" |
| (?<!check) | Negative Lookbehind | Asserts that what immediately precedes the current position in the string is not "check" |

Once they have matched, **atomic groups** won't be re-evaluated again, even when the remainder of the pattern fails due to the match. This can significantly improve performance when quantifiers occur within the atomic group or the remainder of the pattern.

Quantifiers

A quantifier specifies how many instances of the previous element (which can be a character, a group, or a character class) must be present in the input string for a match to occur. Quantifiers include the language elements listed in the following table. For more information, see [Quantifiers](#).

| Quantifier | Description | Pattern | Matches |
|------------|--|---------------------|--|
| * | Matches the previous element zero or more times. | a.*c | "abcabc" in "abcabc" |
| + | Matches the previous element one or more times. | "be+" | "bee" in "been", "be" in "bent" |
| ? | Matches the previous element zero or one time. | "rai?" | "rai" in "rain" |
| { n } | Matches the previous element exactly n times. | ",\d{3}" | ",043" in "1,043.6", ",876", ",543", and ",210" in "9,876,543,210" |
| { n , } | Matches the previous element at least n times. | "166", "29", "1930" | |
| { n , m } | Matches the previous element at least n times, but no more than m times. | \d{3,5} | "166", "17668", "19302" in "193024" |
| *? | Matches the previous element zero or more times, but as few | a.*?c | "abc" in "abcabc" |

| Quantifier | Description | Pattern | Matches |
|------------|---|---------------------|--|
| | times as possible. | | |
| +? | Matches the previous element one or more times, but as few times as possible. | "be+?" | "be" in "been", "be" in "bent" |
| ?? | Matches the previous element zero or one time, but as few times as possible. | "rai??" | "ra" in "rain" |
| { n }? | Matches the preceding element exactly <i>n</i> times. | ",\d{3}?" | ",043" in "1,043.6", ",876", ",543", and ",210" in "9,876,543,210" |
| { n , }? | Matches the previous element at least <i>n</i> times, but as few times as possible. | "166", "29", "1930" | |
| { n , m } | Matches the previous element between <i>n</i> and <i>m</i> times, but as few times as possible. | \d{3,5}?" | "166", "17668" |

Backreference Constructs

A backreference allows a previously matched subexpression to be identified subsequently in the same regular expression. The following table lists the backreference constructs supported by regular expressions in .NET. For more information, see [Backreference Constructs](#).

| Backreference construct | Description | Pattern | Matches |
|-------------------------|---|--------------------------------------|----------------|
| \ <i>number</i> | Backreference. Matches the value of a numbered subexpression. | (\w)\1 | "ee" in "seek" |
| \k< <i>name</i> > | Named backreference. Matches the value of a named expression. | (? <i>char</i>)\w)\k< <i>char</i> > | "ee" in "seek" |

Alternation Constructs

Alternation constructs modify a regular expression to enable either/or matching. These constructs include the language elements listed in the following table. For more information, see [Alternation Constructs](#).

| Alternation construct | Description | Pattern | Matches |
|---|--|---|---|
| <code> </code> | Matches any one element separated by the vertical bar (<code> </code>) character. | <code>th(e is at)</code> | "the", "this" in "this is the day." |
| <code>(?(<expression>) yes no)</code> or <code>(?(<expression>) yes)</code> | Matches <i>yes</i> if the regular expression pattern designated by <i>expression</i> matches; otherwise, matches the optional <i>no</i> part. <i>expression</i> is interpreted as a zero-width assertion. | <code>(? (A)A\d{2}\b \b\d{3}\b)</code> | "A10", "910" in "A10 C103 910" |
| | To avoid ambiguity with a named or numbered capturing group, you can optionally use an explicit assertion, like this: <code>(?(<= expression>) yes no)</code> | | |
| <code>(?(<name>) yes no)</code> or <code>(?(<name>) yes)</code> | Matches <i>yes</i> if <i>name</i> , a named or numbered capturing group, has a match; otherwise, matches the optional <i>no</i> . | <code>(?<quoted>)?(? (quoted).+?" \s+\s)</code> | "Dogs.jpg ", "\\"Yiska playing.jpg"" in "Dogs.jpg \"Yiska playing.jpg"" |

Substitutions

Substitutions are regular expression language elements that are supported in replacement patterns. For more information, see [Substitutions](#). The metacharacters listed in the following table are atomic zero-width assertions.

| Character | Description | Pattern | Replacement pattern | Input string | Result string |
|--------------------------|--|---|--|------------------------|---------------|
| <code>\$ number</code> | Substitutes the substring matched by group <i>number</i> . | <code>\b(\w+)(\s) (\w+)\b</code> | <code>\$3\$2\$1</code> | "one two" | "two one" |
| <code> \${ name }</code> | Substitutes the substring matched by the | <code>\b(?<word1>\w+) (\s)(? <word2>\w+)\b</code> | <code> \${word2} \${word1}</code> | "one two" "two one" | "two one" |

| Character | Description | Pattern | Replacement pattern | Input string | Result string |
|-----------|--|------------------|---------------------|--------------|---------------|
| | named group <i>name</i> . | | | | |
| \$\$ | Substitutes a literal "\$". | \b(\d+)\s?USD | \$\$\\$1 | "103 USD" | "\$103" |
| \$& | Substitutes a copy of the whole match. | \\$?\d*\.\.? \d+ | **\$&** | "\$1.30" | "**\$1.30**" |
| \$` | Substitutes all the text of the input string before the match. | B+ | \$` | "AABBCC" | "AAAACC" |
| \$' | Substitutes all the text of the input string after the match. | B+ | \$' | "AABBCC" | "AACCCC" |
| \$+ | Substitutes the last group that was captured. | B+(C+) | \$+ | "AABBCCDD" | "AACCDD" |
| \$_ | Substitutes the entire input string. | B+ | \$_ | "AABBCC" | "AAAABBCCCC" |

Regular Expression Options

You can specify options that control how the regular expression engine interprets a regular expression pattern. Many of these options can be specified either inline (in the regular expression pattern) or as one or more [RegexOptions](#) constants. This quick reference lists only inline options. For more information about inline and [RegexOptions](#) options, see the article [Regular Expression Options](#).

You can specify an inline option in two ways:

- By using the [miscellaneous construct](#) `(?imnsx-imnsx)`, where a minus sign (-) before an option or set of options turns those options off. For example, `(?i-mn)` turns case-insensitive matching (`i`) on, turns multiline mode (`m`) off, and turns unnamed group captures (`n`) off. The option applies to the regular expression pattern from the point at which the option is defined, and is effective either to the end of the pattern or to the point where another construct reverses the option.

- By using the [grouping construct](#) (`(?imnsx-imnsx: subexpression)`), which defines options for the specified group only.

The .NET regular expression engine supports the following inline options:

| Option | Description | Pattern | Matches |
|----------------|---|---------------------------------|--|
| <code>i</code> | Use case-insensitive matching. | <code>\b(?i)a(?-i)a\w+\b</code> | "aardvark", "aaaAuto" in "aardvark AAAuto aaaAuto Adam breakfast" |
| <code>m</code> | Use multiline mode. <code>^</code> and <code>\$</code> match the beginning and end of a line, instead of the beginning and end of a string. | | For an example, see the "Multiline Mode" section in Regular Expression Options . |
| <code>n</code> | Do not capture unnamed groups. | | For an example, see the "Explicit Captures Only" section in Regular Expression Options . |
| <code>s</code> | Use single-line mode. | | For an example, see the "Single-line Mode" section in Regular Expression Options . |
| <code>x</code> | Ignore unescaped white space in the regular expression pattern. | <code>\b(?x) \d+ \s \w+</code> | "1 aardvark", "2 cats" in "1 aardvark 2 cats IV centurions" |

Miscellaneous Constructs

Miscellaneous constructs either modify a regular expression pattern or provide information about it. The following table lists the miscellaneous constructs supported by .NET. For more information, see [Miscellaneous Constructs](#).

| Construct | Definition | Example |
|-----------------------------|--|--|
| <code>(?imnsx-imnsx)</code> | Sets or disables options such as case insensitivity in the middle of a pattern. For more information, see Regular Expression Options . | <code>\bA(?i)b\w+\b</code> matches "ABA", "Able" in "ABA Able Act" |
| <code>(?# comment)</code> | Inline comment. The comment ends at the first closing parenthesis. | <code>\bA(?#Matches words starting with A)\w+\b</code> |

| Construct | Definition | Example |
|--------------------|--|--|
| # [to end of line] | X-mode comment. The comment starts at an unescaped # and continues to the end of the line. | (?x)\bA\w+\b#Matches words starting with A |

Character Escapes in Regular Expressions

Article • 09/15/2021

The backslash (\) in a regular expression indicates one of the following:

- The character that follows it is a special character, as shown in the table in the following section. For example, `\b` is an anchor that indicates that a regular expression match should begin on a word boundary, `\t` represents a tab, and `\x020` represents a space.
- A character that otherwise would be interpreted as an unescaped language construct should be interpreted literally. For example, a brace (`{`) begins the definition of a quantifier, but a backslash followed by a brace (`\{`) indicates that the regular expression engine should match the brace. Similarly, a single backslash marks the beginning of an escaped language construct, but two backslashes (`\\"`) indicate that the regular expression engine should match the backslash.

ⓘ Note

Character escapes are recognized in regular expression patterns but not in replacement patterns.

Character Escapes in .NET

The following table lists the character escapes supported by regular expressions in .NET.

| Character or sequence | Description |
|--|--|
| All characters except for the following: <code>.</code> <code>\$</code> <code>^</code> <code>{</code> <code>[</code> <code>(</code> <code> </code> <code>)</code> <code>*</code> <code>+</code> <code>?</code> <code>\</code> | Characters other than those listed in the Character or sequence column have no special meaning in regular expressions; they match themselves. The characters included in the Character or sequence column are special regular expression language elements. To match them in a regular expression, they must be escaped or included in a positive character group . For example, the regular expression <code>\\$\d+</code> or <code>[\$]\d+</code> matches "\$1200". |
| <code>\a</code> | Matches a bell (alarm) character, <code>\u0007</code> . |

| Character or sequence | Description |
|-----------------------|---|
| \b | In a [character_group] character class, matches a backspace, \u0008. (See Character Classes .) Outside a character class, \b is an anchor that matches a word boundary. (See Anchors .) |
| \t | Matches a tab, \u0009. |
| \r | Matches a carriage return, \u000D. Note that \r is not equivalent to the newline character, \n. |
| \v | Matches a vertical tab, \u000B. |
| \f | Matches a form feed, \u000C. |
| \n | Matches a new line, \u000A. |
| \e | Matches an escape, \u001B. |
| \ nnn | Matches an ASCII character, where <i>nnn</i> consists of two or three digits that represent the octal character code. For example, \040 represents a space character. This construct is interpreted as a backreference if it has only one digit (for example, \2) or if it corresponds to the number of a capturing group. (See Backreference Constructs .) |
| \x nn | Matches an ASCII character, where <i>nn</i> is a two-digit hexadecimal character code. |
| \c X | Matches an ASCII control character, where <i>X</i> is the letter of the control character. For example, \cc is CTRL-C. |
| \u nnnn | Matches a UTF-16 code unit whose value is <i>nnnn</i> hexadecimal. Note: The Perl 5 character escape that is used to specify Unicode is not supported by .NET. The Perl 5 character escape has the form \x{ #####... }, where #####... is a series of hexadecimal digits. Instead, use \u <i>nnnn</i> . |
| \ | When followed by a character that is not recognized as an escaped character, matches that character. For example, * matches an asterisk (*) and is the same as \x2A. |

An Example

The following example illustrates the use of character escapes in a regular expression. It parses a string that contains the names of the world's largest cities and their populations in 2009. Each city name is separated from its population by a tab (\t) or a vertical bar (| or \u007c). Individual cities and their populations are separated from each other by a carriage return and line feed.

C#

```
using System;
using System.Text.RegularExpressions;

public class Example
{
    public static void Main()
    {
        string delimited = @"\G(.+)[\t\u007c](.+)\r?\n";
        string input = "Mumbai, India|13,922,125\t\n" +
                      "Shanghai, China\t13,831,900\n" +
                      "Karachi, Pakistan|12,991,000\n" +
                      "Delhi, India\t12,259,230\n" +
                      "Istanbul, Türkiye|11,372,613\n";
        Console.WriteLine("Population of the World's Largest Cities, 2009");
        Console.WriteLine();
        Console.WriteLine("{0,-20} {1,10}", "City", "Population");
        Console.WriteLine();
        foreach (Match match in Regex.Matches(input, delimited))
            Console.WriteLine("{0,-20} {1,10}", match.Groups[1].Value,
                             match.Groups[2].Value);
    }
}

// The example displays the following output:
//      Population of the World's Largest Cities, 2009
//
//      City          Population
//
//      Mumbai, India      13,922,125
//      Shanghai, China     13,831,900
//      Karachi, Pakistan   12,991,000
//      Delhi, India        12,259,230
//      Istanbul, Türkiye   11,372,613
```

The regular expression `\G(.+)[\t\u007c](.+)\r?\n` is interpreted as shown in the following table.

| Pattern | Description |
|-------------------------|--|
| <code>\G</code> | Begin the match where the last match ended. |
| <code>(.+)</code> | Match any character one or more times. This is the first capturing group. |
| <code>[\t\u007c]</code> | Match a tab (<code>\t</code>) or a vertical bar (<code> </code>). |
| <code>(.+)</code> | Match any character one or more times. This is the second capturing group. |
| <code>\r?\n</code> | Match zero or one occurrence of a carriage return followed by a new line. |

Character classes in regular expressions

Article • 06/27/2023

A character class defines a set of characters, any one of which can occur in an input string for a match to succeed. The regular expression language in .NET supports the following character classes:

- Positive character groups. A character in the input string must match one of a specified set of characters. For more information, see [Positive Character Group](#).
- Negative character groups. A character in the input string must not match one of a specified set of characters. For more information, see [Negative Character Group](#).
- Any character. The `.` (dot or period) character in a regular expression is a wildcard character that matches any character except `\n`. For more information, see [Any Character](#).
- A general Unicode category or named block. A character in the input string must be a member of a particular Unicode category or must fall within a contiguous range of Unicode characters for a match to succeed. For more information, see [Unicode Category or Unicode Block](#).
- A negative general Unicode category or named block. A character in the input string must not be a member of a particular Unicode category or must not fall within a contiguous range of Unicode characters for a match to succeed. For more information, see [Negative Unicode Category or Unicode Block](#).
- A word character. A character in the input string can belong to any of the Unicode categories that are appropriate for characters in words. For more information, see [Word Character](#).
- A non-word character. A character in the input string can belong to any Unicode category that is not a word character. For more information, see [Non-Word Character](#).
- A white-space character. A character in the input string can be any Unicode separator character, as well as any one of a number of control characters. For more information, see [White-Space Character](#).
- A non-white-space character. A character in the input string can be any character that is not a white-space character. For more information, see [Non-White-Space Character](#).

- A decimal digit. A character in the input string can be any of a number of characters classified as Unicode decimal digits. For more information, see [Decimal Digit Character](#).
- A non-decimal digit. A character in the input string can be anything other than a Unicode decimal digit. For more information, see [Decimal Digit Character](#).

.NET supports character class subtraction expressions, which enables you to define a set of characters as the result of excluding one character class from another character class. For more information, see [Character Class Subtraction](#).

 **Note**

Character classes that match characters by category, such as `\w` to match word characters or `\p{}` to match a Unicode category, rely on the `CharUnicodeInfo` class to provide information about character categories. In .NET Framework 4.6.2 and later versions, character categories are based on [The Unicode Standard, Version 8.0.0](#).

Positive character group: []

A positive character group specifies a list of characters, any one of which may appear in an input string for a match to occur. This list of characters may be specified individually, as a range, or both.

The syntax for specifying a list of individual characters is as follows:

```
[*character_group*]
```

where *character_group* is a list of the individual characters that can appear in the input string for a match to succeed. *character_group* can consist of any combination of one or more literal characters, [escape characters](#), or character classes.

The syntax for specifying a range of characters is as follows:

```
[firstCharacter-lastCharacter]
```

where *firstCharacter* is the character that begins the range and *lastCharacter* is the character that ends the range. A character range is a contiguous series of characters defined by specifying the first character in the series, a hyphen (-), and then the last character in the series. Two characters are contiguous if they have adjacent Unicode

code points. *firstCharacter* must be the character with the lower code point, and *lastCharacter* must be the character with the higher code point.

ⓘ Note

Because a positive character group can include both a set of characters and a character range, a hyphen character (-) is always interpreted as the range separator unless it is the first or last character of the group.

To include a hyphen as a nonperipheral member of a character group, escape it. For instance, to create a character group for the character a and the characters from - to /, the correct syntax is [a\--/].

Some common regular expression patterns that contain positive character classes are listed in the following table.

| Pattern | Description |
|-----------|---|
| [aeiou] | Match all vowels. |
| [\p{P}\d] | Match all punctuation and decimal digit characters. |
| [\s\p{P}] | Match all white space and punctuation. |

The following example defines a positive character group that contains the characters "a" and "e" so that the input string must contain the words "grey" or "gray" followed by another word for a match to occur.

C#

```
using System;
using System.Text.RegularExpressions;

public class Example
{
    public static void Main()
    {
        string pattern = @"gr[ae]y\s\S+?[\s\p{P}]";
        string input = "The gray wolf jumped over the grey wall.";
        MatchCollection matches = Regex.Matches(input, pattern);
        foreach (Match match in matches)
            Console.WriteLine($"'{match.Value}'");
    }
}
// The example displays the following output:
```

```
//      'gray wolf '
//      'grey wall.'
```

The regular expression `gr[ae]y\s\S+?[\s|\p{P}]` is defined as follows:

| Pattern | Description |
|------------------------|---|
| <code>gr</code> | Match the literal characters "gr". |
| <code>[ae]</code> | Match either an "a" or an "e". |
| <code>y\s</code> | Match the literal character "y" followed by a white-space character. |
| <code>\S+?</code> | Match one or more non-white-space characters, but as few as possible. |
| <code>[\s\p{P}]</code> | Match either a white-space character or a punctuation mark. |

The following example matches words that begin with any capital letter. It uses the subexpression `[A-Z]` to represent the range of capital letters from A to Z.

C#

```
using System;
using System.Text.RegularExpressions;

public class Example
{
    public static void Main()
    {
        string pattern = @"\b[A-Z]\w*\b";
        string input = "A city Albany Zulu maritime Marseilles";
        foreach (Match match in Regex.Matches(input, pattern))
            Console.WriteLine(match.Value);
    }
}
// The example displays the following output:
//      A
//      Albany
//      Zulu
//      Marseilles
```

The regular expression `\b[A-Z]\w*\b` is defined as shown in the following table.

| Pattern | Description |
|--------------------|--|
| <code>\b</code> | Start at a word boundary. |
| <code>[A-Z]</code> | Match any uppercase character from A to Z. |
| <code>\w*</code> | Match zero or more word characters. |

| Pattern | Description |
|---------|------------------------|
| \b | Match a word boundary. |

Negative character group: [^]

A negative character group specifies a list of characters that must not appear in an input string for a match to occur. The list of characters may be specified individually, as a range, or both.

The syntax for specifying a list of individual characters is as follows:

```
[*^character_group*]
```

where *character_group* is a list of the individual characters that cannot appear in the input string for a match to succeed. *character_group* can consist of any combination of one or more literal characters, [escape characters](#), or character classes.

The syntax for specifying a range of characters is as follows:

```
[^*firstCharacter*-*lastCharacter*]
```

where *firstCharacter* is the character that begins the range and *lastCharacter* is the character that ends the range. A character range is a contiguous series of characters defined by specifying the first character in the series, a hyphen (-), and then the last character in the series. Two characters are contiguous if they have adjacent Unicode code points. *firstCharacter* must be the character with the lower code point, and *lastCharacter* must be the character with the higher code point.

Note

Because a negative character group can include both a set of characters and a character range, a hyphen character (-) is always interpreted as the range separator unless it is the first or last character of the group.

Two or more character ranges can be concatenated. For example, to specify the range of decimal digits from "0" through "9", the range of lowercase letters from "a" through "f", and the range of uppercase letters from "A" through "F", use `[0-9a-fA-F]`.

The leading caret character (^) in a negative character group is mandatory and indicates the character group is a negative character group instead of a positive character group.

Important

A negative character group in a larger regular expression pattern is not a zero-width assertion. That is, after evaluating the negative character group, the regular expression engine advances one character in the input string.

Some common regular expression patterns that contain negative character groups are listed in the following table.

| Pattern | Description |
|------------|---|
| [^aeiou] | Match all characters except vowels. |
| [^\p{P}\d] | Match all characters except punctuation and decimal digit characters. |

The following example matches any word that begins with the characters "th" and is not followed by an "o".

C#

```
using System;
using System.Text.RegularExpressions;

public class Example
{
    public static void Main()
    {
        string pattern = @"\bth[^o]\w+\b";
        string input = "thought thing though them through thus thorough this";
        foreach (Match match in Regex.Matches(input, pattern))
            Console.WriteLine(match.Value);
    }
}
// The example displays the following output:
//      thing
//      them
//      through
//      thus
//      this
```

The regular expression `\bth[^o]\w+\b` is defined as shown in the following table.

| Pattern | Description |
|---------|---|
| \b | Start at a word boundary. |
| th | Match the literal characters "th". |
| [^o] | Match any character that is not an "o". |

| Pattern | Description |
|---------|------------------------------------|
| \w+ | Match one or more word characters. |
| \b | End at a word boundary. |

Any character: .

The period character (.) matches any character except `\n` (the newline character), with the following two qualifications:

- If a regular expression pattern is modified by the [RegexOptions.Singleline](#) option, or if the portion of the pattern that contains the `.` character class is modified by the `s` option, `.` matches any character. For more information, see [Regular Expression Options](#).

The following example illustrates the different behavior of the `.` character class by default and with the [RegexOptions.Singleline](#) option. The regular expression `^.+` starts at the beginning of the string and matches every character. By default, the match ends at the end of the first line; the regular expression pattern matches the carriage return character, `\r`, but it does not match `\n`. Because the [RegexOptions.Singleline](#) option interprets the entire input string as a single line, it matches every character in the input string, including `\n`.

```
C#
using System;
using System.Text.RegularExpressions;

public class Example
{
    public static void Main()
    {
        string pattern = "^.+";
        string input = "This is one line and" + Environment.NewLine +
"this is the second.";
        foreach (Match match in Regex.Matches(input, pattern))
            Console.WriteLine(Regex.Escape(match.Value));

        Console.WriteLine();
        foreach (Match match in Regex.Matches(input, pattern,
RegexOptions.Singleline))
            Console.WriteLine(Regex.Escape(match.Value));
    }
}
// The example displays the following output:
//      This\ is\ one\ line\ and\r
```

```
//  
//      This\ is\ one\ line\ and\r\nthis\ is\ the\ second\.
```

ⓘ Note

Because it matches any character except `\n`, the `.` character class also matches `\r` (the carriage return character).

- In a positive or negative character group, a period is treated as a literal period character, and not as a character class. For more information, see [Positive Character Group](#) and [Negative Character Group](#) earlier in this topic. The following example provides an illustration by defining a regular expression that includes the period character `(.)` both as a character class and as a member of a positive character group. The regular expression `\b.*[.?!;:](\s|\z)` begins at a word boundary, matches any character until it encounters one of five punctuation marks, including a period, and then matches either a white-space character or the end of the string.

```
C#  
  
using System;  
using System.Text.RegularExpressions;  
  
public class Example  
{  
    public static void Main()  
    {  
        string pattern = @"\b.*[.?!;:](\s|\z)";  
        string input = "this. what: is? go, thing.";  
        foreach (Match match in Regex.Matches(input, pattern))  
            Console.WriteLine(match.Value);  
    }  
}  
// The example displays the following output:  
//      this. what: is? go, thing.
```

ⓘ Note

Because it matches any character, the `.` language element is often used with a lazy quantifier if a regular expression pattern attempts to match any character multiple times. For more information, see [Quantifiers](#).

Unicode category or Unicode block: \p{}

The Unicode standard assigns each character a general category. For example, a particular character can be an uppercase letter (represented by the `Lu` category), a decimal digit (the `Nd` category), a math symbol (the `Sm` category), or a paragraph separator (the `Z1` category). Specific character sets in the Unicode standard also occupy a specific range or block of consecutive code points. For example, the basic Latin character set is found from `\u0000` through `\u007F`, while the Arabic character set is found from `\u0600` through `\u06FF`.

The regular expression construct

```
\p{ name }
```

matches any character that belongs to a Unicode general category or named block, where *name* is the category abbreviation or named block name. For a list of category abbreviations, see the [Supported Unicode General Categories](#) section later in this topic. For a list of named blocks, see the [Supported Named Blocks](#) section later in this topic.

Tip

Matching may be improved if the string is first normalized by calling the `String.Normalize` method.

The following example uses the `\p{ name }` construct to match both a Unicode general category (in this case, the `Pd`, or Punctuation, Dash category) and a named block (the `IsGreek` and `IsBasicLatin` named blocks).

C#

```
using System;
using System.Text.RegularExpressions;

public class Example
{
    public static void Main()
    {
        string pattern = @"\b(\p{IsGreek}+(\s)?)+\p{Pd}\s(\p{IsBasicLatin}+
(\s)?)+";
        string input = "Κατα Μαθηταιον - The Gospel of Matthew";

        Console.WriteLine(Regex.IsMatch(input, pattern));           // Displays
        True.
```

```
}
```

The regular expression `\b(\p{IsGreek}+(\s)?)+\p{Pd}\s(\p{IsBasicLatin}+(\s)?)+` is defined as shown in the following table.

| Pattern | Description |
|--|---|
| <code>\b</code> | Start at a word boundary. |
| <code>\p{IsGreek}+</code> | Match one or more Greek characters. |
| <code>(\s)?</code> | Match zero or one white-space character. |
| <code>(\p{IsGreek}+(\s)?)+</code> | Match the pattern of one or more Greek characters followed by zero or one white-space characters one or more times. |
| <code>\p{Pd}</code> | Match a Punctuation, Dash character. |
| <code>\s</code> | Match a white-space character. |
| <code>\p{IsBasicLatin}+</code> | Match one or more basic Latin characters. |
| <code>(\s)?</code> | Match zero or one white-space character. |
| <code>(\p{IsBasicLatin}+(\s)?)+</code> | Match the pattern of one or more basic Latin characters followed by zero or one white-space characters one or more times. |

Negative Unicode category or Unicode block: `\P{}`

The Unicode standard assigns each character a general category. For example, a particular character can be an uppercase letter (represented by the `Lu` category), a decimal digit (the `Nd` category), a math symbol (the `Sm` category), or a paragraph separator (the `Zl` category). Specific character sets in the Unicode standard also occupy a specific range or block of consecutive code points. For example, the basic Latin character set is found from `\u0000` through `\u007F`, while the Arabic character set is found from `\u0600` through `\u06FF`.

The regular expression construct

```
\P{ name }
```

matches any character that does not belong to a Unicode general category or named block, where *name* is the category abbreviation or named block name. For a list of

category abbreviations, see the [Supported Unicode General Categories](#) section later in this topic. For a list of named blocks, see the [Supported Named Blocks](#) section later in this topic.

Tip

Matching may be improved if the string is first normalized by calling the [String.Normalize](#) method.

The following example uses the `\P{ name }` construct to remove any currency symbols (in this case, the `Sc`, or Symbol, Currency category) from numeric strings.

C#

```
using System;
using System.Text.RegularExpressions;

public class Example
{
    public static void Main()
    {
        string pattern = @"\P{Sc}+";

        string[] values = { "$164,091.78", "£1,073,142.68", "73¢", "€120" };
        foreach (string value in values)
            Console.WriteLine(Regex.Match(value, pattern).Value);
    }
}
// The example displays the following output:
//      164,091.78
//      1,073,142.68
//      73
//      120
```

The regular expression pattern `(\P{Sc})+` matches one or more characters that are not currency symbols; it effectively strips any currency symbol from the result string.

Word character: \w

`\w` matches any word character. A word character is a member of any of the Unicode categories listed in the following table.

| Category | Description |
|----------|-------------------|
| L | Letter, Lowercase |

| Category | Description |
|----------|--|
| Lu | Letter, Uppercase |
| Lt | Letter, Titlecase |
| Lo | Letter, Other |
| Lm | Letter, Modifier |
| Mn | Mark, Nonspacing |
| Nd | Number, Decimal Digit |
| Pc | Punctuation, Connector. This category includes ten characters, the most commonly used of which is the LOWLINE character (_), u+005F. |

If ECMAScript-compliant behavior is specified, `\w` is equivalent to `[a-zA-Z_0-9]`. For information on ECMAScript regular expressions, see the "ECMAScript Matching Behavior" section in [Regular Expression Options](#).

ⓘ Note

Because it matches any word character, the `\w` language element is often used with a lazy quantifier if a regular expression pattern attempts to match any word character multiple times, followed by a specific word character. For more information, see [Quantifiers](#).

The following example uses the `\w` language element to match duplicate characters in a word. The example defines a regular expression pattern, `(\w)\1`, which can be interpreted as follows.

| Element | Description |
|-------------------|--|
| <code>(\w)</code> | Match a word character. This is the first capturing group. |
| <code>\1</code> | Match the value of the first capture. |

C#

```
using System;
using System.Text.RegularExpressions;

public class Example
{
    public static void Main()
    {
```

```

        string pattern = @"(\w)\1";
        string[] words = { "trellis", "seer", "latter", "summer",
                           "hoarse", "lesser", "aardvark", "stunned" };
        foreach (string word in words)
        {
            Match match = Regex.Match(word, pattern);
            if (match.Success)
                Console.WriteLine($"'{0}' found in '{1}' at position {2}.",
                                  match.Value, word, match.Index);
            else
                Console.WriteLine("No double characters in '{0}'.", word);
        }
    }
}

// The example displays the following output:
//      'll' found in 'trellis' at position 3.
//      'ee' found in 'seer' at position 1.
//      'tt' found in 'latter' at position 2.
//      'mm' found in 'summer' at position 2.
//      No double characters in 'hoarse'.
//      'ss' found in 'lesser' at position 2.
//      'aa' found in 'aardvark' at position 0.
//      'nn' found in 'stunned' at position 3.

```

Non-word character: \W

\W matches any non-word character. The \W language element is equivalent to the following character class:

```
[^\p{Ll}\p{Lu}\p{Lt}\p{Lo}\p{Nd}\p{Pc}\p{Lm}]
```

In other words, it matches any character except for those in the Unicode categories listed in the following table.

| Category | Description |
|----------|-----------------------|
| Ll | Letter, Lowercase |
| Lu | Letter, Uppercase |
| Lt | Letter, Titlecase |
| Lo | Letter, Other |
| Lm | Letter, Modifier |
| Mn | Mark, Nonspacing |
| Nd | Number, Decimal Digit |

| Category | Description |
|----------|--|
| Pc | Punctuation, Connector. This category includes ten characters, the most commonly used of which is the LOWLINE character (_), u+005F. |

If ECMAScript-compliant behavior is specified, `\w` is equivalent to `[^a-zA-Z_0-9]`. For information on ECMAScript regular expressions, see the "ECMAScript Matching Behavior" section in [Regular Expression Options](#).

ⓘ Note

Because it matches any non-word character, the `\w` language element is often used with a lazy quantifier if a regular expression pattern attempts to match any non-word character multiple times followed by a specific non-word character. For more information, see [Quantifiers](#).

The following example illustrates the `\w` character class. It defines a regular expression pattern, `\b(\w+)(\w){1,2}`, that matches a word followed by one or two non-word characters, such as white space or punctuation. The regular expression is interpreted as shown in the following table.

| Element | Description |
|------------------------|---|
| <code>\b</code> | Begin the match at a word boundary. |
| <code>(\w+)</code> | Match one or more word characters. This is the first capturing group. |
| <code>(\w){1,2}</code> | Match a non-word character either one or two times. This is the second capturing group. |

C#

```
using System;
using System.Text.RegularExpressions;

public class Example
{
    public static void Main()
    {
        string pattern = @"\b(\w+)(\w){1,2}";
        string input = "The old, grey mare slowly walked across the narrow,
green pasture.";
        foreach (Match match in Regex.Matches(input, pattern))
        {
            Console.WriteLine(match.Value);
            Console.Write(" Non-word character(s):");
        }
    }
}
```

```

        CaptureCollection captures = match.Groups[2].Captures;
        for (int ctr = 0; ctr < captures.Count; ctr++)
            Console.WriteLine(@"'{0}' (\u{1}){2}", captures[ctr].Value,
Convert.ToInt16(captures[ctr].Value[0]).ToString("X4"),
                ctr < captures.Count - 1 ? ", " : "");
            Console.WriteLine();
        }
    }
// The example displays the following output:
//      The
//          Non-word character(s):' ' (\u0020)
//      old,
//          Non-word character(s):',' (\u002C), ' ' (\u0020)
//      grey
//          Non-word character(s):' ' (\u0020)
//      mare
//          Non-word character(s):' ' (\u0020)
//      slowly
//          Non-word character(s):' ' (\u0020)
//      walked
//          Non-word character(s):' ' (\u0020)
//      across
//          Non-word character(s):' ' (\u0020)
//      the
//          Non-word character(s):' ' (\u0020)
//      narrow,
//          Non-word character(s):',' (\u002C), ' ' (\u0020)
//      green
//          Non-word character(s):' ' (\u0020)
//      pasture.
//          Non-word character(s):'.' (\u002E)

```

Because the [Group](#) object for the second capturing group contains only a single captured non-word character, the example retrieves all captured non-word characters from the [CaptureCollection](#) object that is returned by the [Group.Captures](#) property.

Whitespace character: \s

\s matches any whitespace character. It is equivalent to the escape sequences and Unicode categories listed in the following table.

| Category | Description |
|----------|--|
| \f | The form feed character, \u000C. |
| \n | The newline character, \u000A. |
| \r | The carriage return character, \u000D. |

| Category | Description |
|----------|--|
| \t | The tab character, \u0009. |
| \v | The vertical tab character, \u000B. |
| \x85 | The NEXT LINE (NEL) character, \u0085. |
| \p{Z} | Matches all separator characters . This includes the <code>zs</code> , <code>z1</code> , and <code>Zp</code> categories. |

If ECMAScript-compliant behavior is specified, `\s` is equivalent to `[\f\n\r\t\v]`. For information on ECMAScript regular expressions, see the "ECMAScript Matching Behavior" section in [Regular Expression Options](#).

The following example illustrates the `\s` character class. It defines a regular expression pattern, `\b\w+(e)?s(\s|$)`, that matches a word ending in either "s" or "es" followed by either a white-space character or the end of the input string. The regular expression is interpreted as shown in the following table.

| Element | Description |
|---------|--|
| \b | Begin the match at a word boundary. |
| \w+ | Match one or more word characters. |
| (e)? | Match an "e" either zero or one time. |
| s | Match an "s". |
| (\s \$) | Match either a white-space character or the end of the input string. |

C#

```

using System;
using System.Text.RegularExpressions;

public class Example
{
    public static void Main()
    {
        string pattern = @"\b\w+(e)?s(\s|$)";
        string input = "matches stores stops leave leaves";
        foreach (Match match in Regex.Matches(input, pattern))
            Console.WriteLine(match.Value);
    }
}
// The example displays the following output:
//      matches
//      stores

```

```
//      stops  
//      leaves
```

Non-whitespace character: \S

\s matches any non-white-space character. It is equivalent to the [^\f\n\r\t\v\x85\p{Z}] regular expression pattern, or the opposite of the regular expression pattern that is equivalent to \s, which matches white-space characters. For more information, see [White-Space Character: \s](#).

If ECMAScript-compliant behavior is specified, \s is equivalent to [^\f\n\r\t\v]. For information on ECMAScript regular expressions, see the "ECMAScript Matching Behavior" section in [Regular Expression Options](#).

The following example illustrates the \s language element. The regular expression pattern \b(\S+)\s? matches strings that are delimited by white-space characters. The second element in the match's [GroupCollection](#) object contains the matched string. The regular expression can be interpreted as shown in the following table.

| Element | Description |
|---------|--|
| \b | Begin the match at a word boundary. |
| (\S+) | Match one or more non-white-space characters. This is the first capturing group. |
| \s? | Match zero or one white-space character. |

C#

```
using System;  
using System.Text.RegularExpressions;  
  
public class Example  
{  
    public static void Main()  
    {  
        string pattern = @"\b(\S+)\s?";  
        string input = "This is the first sentence of the first paragraph. " +  
                      "This is the second sentence.\n" +  
                      "This is the only sentence of the second  
paragraph.";  
        foreach (Match match in Regex.Matches(input, pattern))  
            Console.WriteLine(match.Groups[1]);  
    }  
}  
// The example displays the following output:  
//      This
```

```
// is
// the
// first
// sentence
// of
// the
// first
// paragraph.
// This
// is
// the
// second
// sentence.
// This
// is
// the
// only
// sentence
// of
// the
// second
// paragraph.
```

Decimal digit character: \d

\d matches any decimal digit. It is equivalent to the \p{Nd} regular expression pattern, which includes the standard decimal digits 0-9 as well as the decimal digits of a number of other character sets.

If ECMAScript-compliant behavior is specified, \d is equivalent to [0-9]. For information on ECMAScript regular expressions, see the "ECMAScript Matching Behavior" section in [Regular Expression Options](#).

The following example illustrates the \d language element. It tests whether an input string represents a valid telephone number in the United States and Canada. The regular expression pattern ^(\(?(\d{3})\)?[\s-])?\d{3}-\d{4}\$ is defined as shown in the following table.

| Element | Description |
|---------|---|
| ^ | Begin the match at the beginning of the input string. |
| \(?) | Match zero or one literal "(" character. |
| \d{3} | Match three decimal digits. |
| \)?) | Match zero or one literal ")" character. |

| Element | Description |
|-------------------------|--|
| [\s-] | Match a hyphen or a white-space character. |
| (\(\?\d{3}\)\)?[\s-]?)? | Match an optional opening parenthesis followed by three decimal digits, an optional closing parenthesis, and either a white-space character or a hyphen zero or one time. This is the first capturing group. |
| \d{3}-\d{4} | Match three decimal digits followed by a hyphen and four more decimal digits. |
| \$ | Match the end of the input string. |

C#

```

using System;
using System.Text.RegularExpressions;

public class Example
{
    public static void Main()
    {
        string pattern = @"^(\(\?\d{3}\)\)?[\s-]?)?\d{3}-\d{4}$";
        string[] inputs = { "111 111-1111", "222-2222", "222 333-444",
                            "(212) 111-1111", "111-AB1-1111",
                            "212-111-1111", "01 999-9999" };

        foreach (string input in inputs)
        {
            if (Regex.IsMatch(input, pattern))
                Console.WriteLine(input + ": matched");
            else
                Console.WriteLine(input + ": match failed");
        }
    }
}

// The example displays the following output:
//      111 111-1111: matched
//      222-2222: matched
//      222 333-444: match failed
//      (212) 111-1111: matched
//      111-AB1-1111: match failed
//      212-111-1111: matched
//      01 999-9999: match failed

```

Non-digit character: \D

\D matches any non-digit character. It is equivalent to the \P{Nd} regular expression pattern.

If ECMAScript-compliant behavior is specified, `\D` is equivalent to `[^0-9]`. For information on ECMAScript regular expressions, see the "ECMAScript Matching Behavior" section in [Regular Expression Options](#).

The following example illustrates the `\D` language element. It tests whether a string such as a part number consists of the appropriate combination of decimal and non-decimal characters. The regular expression pattern `^\D\d{1,5}\D*$` is defined as shown in the following table.

| Element | Description |
|----------------------|---|
| <code>^</code> | Begin the match at the beginning of the input string. |
| <code>\D</code> | Match a non-digit character. |
| <code>\d{1,5}</code> | Match from one to five decimal digits. |
| <code>\D*</code> | Match zero, one, or more non-decimal characters. |
| <code>\$</code> | Match the end of the input string. |

C#

```
using System;
using System.Text.RegularExpressions;

public class Example
{
    public static void Main()
    {
        string pattern = @"^\D\d{1,5}\D*$";
        string[] inputs = { "A1039C", "AA0001", "C18A", "Y938518" };

        foreach (string input in inputs)
        {
            if (Regex.IsMatch(input, pattern))
                Console.WriteLine(input + ": matched");
            else
                Console.WriteLine(input + ": match failed");
        }
    }
}

// The example displays the following output:
//      A1039C: matched
//      AA0001: match failed
//      C18A: matched
//      Y938518: match failed
```

Supported Unicode general categories

Unicode defines the general categories listed in the following table. For more information, see the "UCD File Format" and "General Category Values" subtopics at the [Unicode Character Database](#), Sec. 5.7.1, Table 12.

| Category | Description |
|----------|---|
| Lu | Letter, Uppercase |
| Ll | Letter, Lowercase |
| Lt | Letter, Titlecase |
| Lm | Letter, Modifier |
| Lo | Letter, Other |
| L | All letter characters. This includes the Lu, Ll, Lt, Lm, and Lo characters. |
| Mn | Mark, Nonspacing |
| Mc | Mark, Spacing Combining |
| Me | Mark, Enclosing |
| M | All combining marks. This includes the Mn, Mc, and Me categories. |
| Nd | Number, Decimal Digit |
| Nl | Number, Letter |
| No | Number, Other |
| N | All numbers. This includes the Nd, Nl, and No categories. |
| Pc | Punctuation, Connector |
| Pd | Punctuation, Dash |
| Ps | Punctuation, Open |
| Pe | Punctuation, Close |
| Pi | Punctuation, Initial quote (may behave like Ps or Pe depending on usage) |
| Pf | Punctuation, Final quote (may behave like Ps or Pe depending on usage) |
| Po | Punctuation, Other |

| Category | Description |
|----------|---|
| P | All punctuation characters. This includes the <code>Pc</code> , <code>Pd</code> , <code>Ps</code> , <code>Pe</code> , <code>Pi</code> , <code>Pf</code> , and <code>Po</code> categories. |
| Sm | Symbol, Math |
| Sc | Symbol, Currency |
| Sk | Symbol, Modifier |
| So | Symbol, Other |
| S | All symbols. This includes the <code>Sm</code> , <code>Sc</code> , <code>Sk</code> , and <code>So</code> categories. |
| Zs | Separator, Space |
| Zl | Separator, Line |
| Zp | Separator, Paragraph |
| Z | All separator characters. This includes the <code>Zs</code> , <code>Zl</code> , and <code>Zp</code> categories. |
| Cc | Other, Control |
| Cf | Other, Format |
| Cs | Other, Surrogate |
| Co | Other, Private Use |
| Cn | Other, Not Assigned or Noncharacter |
| C | All other characters. This includes the <code>Cc</code> , <code>Cf</code> , <code>Cs</code> , <code>Co</code> , and <code>Cn</code> categories. |

You can determine the Unicode category of any particular character by passing that character to the [GetUnicodeCategory](#) method. The following example uses the [GetUnicodeCategory](#) method to determine the category of each element in an array that contains selected Latin characters.

C#

```
using System;
using System.Text.RegularExpressions;

public class Example
{
    public static void Main()
    {
        char[] chars = { 'a', 'X', '8', ',', ' ', '\u0009', '!' };
```

```

        foreach (char ch in chars)
            Console.WriteLine("{0}': {1}",
                Regex.Escape(ch.ToString()),
                Char.GetUnicodeCategory(ch));
    }
}

// The example displays the following output:
//      'a': LowercaseLetter
//      'X': UppercaseLetter
//      '8': DecimalDigitNumber
//      ',': OtherPunctuation
//      '\ ': SpaceSeparator
//      '\t': Control
//      '!': OtherPunctuation

```

Supported named blocks

.NET provides the named blocks listed in the following table. The set of supported named blocks is based on Unicode 4.0 and Perl 5.6. For a regular expression that uses named blocks, see the [Unicode category or Unicode block: \p{}](#) section.

| Code point range | Block name |
|------------------|-----------------------------|
| 0000 - 007F | IsBasicLatin |
| 0080 - 00FF | IsLatin-1Supplement |
| 0100 - 017F | IsLatinExtended-A |
| 0180 - 024F | IsLatinExtended-B |
| 0250 - 02AF | IsIPAExtensions |
| 02B0 - 02FF | IsSpacingModifierLetters |
| 0300 - 036F | IsCombiningDiacriticalMarks |
| 0370 - 03FF | IsGreek |
| -or- | |
| | IsGreekandCoptic |
| 0400 - 04FF | IsCyrillic |
| 0500 - 052F | IsCyrillicSupplement |
| 0530 - 058F | IsArmenian |
| 0590 - 05FF | IsHebrew |

| Code point range | Block name |
|-------------------------|--------------------------------------|
| 0600 - 06FF | IsArabic |
| 0700 - 074F | IsSyriac |
| 0780 - 07BF | IsThaana |
| 0900 - 097F | IsDevanagari |
| 0980 - 09FF | IsBengali |

Character class subtraction: [base_group - [excluded_group]]

A character class defines a set of characters. Character class subtraction yields a set of characters that is the result of excluding the characters in one character class from another character class.

A character class subtraction expression has the following form:

[*base_group* -[*excluded_group*]]

The square brackets ([]) and hyphen (-) are mandatory. The *base_group* is a [positive character group](#) or a [negative character group](#). The *excluded_group* component is another positive or negative character group, or another character class subtraction expression (that is, you can nest character class subtraction expressions).

For example, suppose you have a base group that consists of the character range from "a" through "z". To define the set of characters that consists of the base group except for the character "m", use `[a-z-[m]]`. To define the set of characters that consists of the base group except for the set of characters "d", "j", and "p", use `[a-z-[djp]]`. To define the set of characters that consists of the base group except for the character range from "m" through "p", use `[a-z-[m-p]]`.

Consider the nested character class subtraction expression, `[a-z-[d-w-[m-o]]]`. The expression is evaluated from the innermost character range outward. First, the character range from "m" through "o" is subtracted from the character range "d" through "w", which yields the set of characters from "d" through "l" and "p" through "w". That set is then subtracted from the character range from "a" through "z", which yields the set of characters `[abcuvwxyz]`.

You can use any character class with character class subtraction. To define the set of characters that consists of all Unicode characters from \u0000 through \uFFFF except white-space characters (`\s`), the characters in the punctuation general category (`\p{P}`), the characters in the `IsGreek` named block (`\p{IsGreek}`), and the Unicode NEXT LINE control character (`\x85`), use `[\u0000-\uFFFF-[\s\p{P}\p{IsGreek}\x85]]`.

Choose character classes for a character class subtraction expression that will yield useful results. Avoid an expression that yields an empty set of characters, which cannot match anything, or an expression that is equivalent to the original base group. For example, the empty set is the result of the expression `[\p{IsBasicLatin}-[\x00-\x7F]]`, which subtracts all characters in the `IsBasicLatin` character range from the `IsBasicLatin` general category. Similarly, the original base group is the result of the expression `[a-z-[0-9]]`. This is because the base group, which is the character range of letters from "a" through "z", does not contain any characters in the excluded group, which is the character range of decimal digits from "0" through "9".

The following example defines a regular expression, `^[0-9-[2468]]+$`, that matches zero and odd digits in an input string. The regular expression is interpreted as shown in the following table.

| Element | Description |
|----------------|---|
| <code>^</code> | Begin the match at the start of the input string. |

| Element | Description |
|---------------|--|
| [0-9-[2468]]+ | Match one or more occurrences of any character from 0 to 9 except for 2, 4, 6, and 8. In other words, match one or more occurrences of zero or an odd digit. |
| \$ | End the match at the end of the input string. |

C#

```
using System;
using System.Text.RegularExpressions;

public class Example
{
    public static void Main()
    {
        string[] inputs = { "123", "13579753", "3557798", "335599901" };
        string pattern = @"^-[0-9-[2468]]+$";

        foreach (string input in inputs)
        {
            Match match = Regex.Match(input, pattern);
            if (match.Success)
                Console.WriteLine(match.Value);
        }
    }
}
// The example displays the following output:
//      13579753
//      335599901
```

Anchors in Regular Expressions

Article • 06/27/2023

Anchors, or atomic zero-width assertions, specify a position in the string where a match must occur. When you use an anchor in your search expression, the regular expression engine does not advance through the string or consume characters; it looks for a match in the specified position only. For example, `^` specifies that the match must start at the beginning of a line or string. Therefore, the regular expression `^http:` matches "http:" only when it occurs at the beginning of a line. The following table lists the anchors supported by the regular expressions in .NET.

| Anchor | Description |
|-----------------|---|
| <code>^</code> | By default, the match must occur at the beginning of the string; in multiline mode, it must occur at the beginning of the line. For more information, see Start of String or Line . |
| <code>\$</code> | By default, the match must occur at the end of the string or before <code>\n</code> at the end of the string; in multiline mode, it must occur at the end of the line or before <code>\n</code> at the end of the line. For more information, see End of String or Line . |
| <code>\A</code> | The match must occur at the beginning of the string only (no multiline support). For more information, see Start of String Only . |
| <code>\Z</code> | The match must occur at the end of the string, or before <code>\n</code> at the end of the string. For more information, see End of String or Before Ending Newline . |
| <code>\z</code> | The match must occur at the end of the string only. For more information, see End of String Only . |
| <code>\G</code> | The match must start at the position where the previous match ended, or if there was no previous match, at the position in the string where matching started. For more information, see Contiguous Matches . |
| <code>\b</code> | The match must occur on a word boundary. For more information, see Word Boundary . |
| <code>\B</code> | The match must not occur on a word boundary. For more information, see Non-Word Boundary . |

Start of String or Line: `^`

By default, the `^` anchor specifies that the following pattern must begin at the first character position of the string. If you use `^` with the `RegexOptions.Multiline` option (see [Regular Expression Options](#)), the match must occur at the beginning of each line.

The following example uses the `^` anchor in a regular expression that extracts information about the years during which some professional baseball teams existed. The example calls two overloads of the `Regex.Matches` method:

- The call to the `Matches(String, String)` overload finds only the first substring in the input string that matches the regular expression pattern.
- The call to the `Matches(String, String, RegexOptions)` overload with the `options` parameter set to `RegexOptions.Multiline` finds all five substrings.

C#

```
using System;
using System.Text.RegularExpressions;

public class Example
{
    public static void Main()
    {
        string input = "Brooklyn Dodgers, National League, 1911, 1912, 1932-
1957\n" +
                      "Chicago Cubs, National League, 1903-present\n" +
                      "Detroit Tigers, American League, 1901-present\n" +
                      "New York Giants, National League, 1885-1957\n" +
                      "Washington Senators, American League, 1901-1960\n";
        string pattern = @"^((\w+(\s?)){2,}),\s(\w+\s\w+),(\s\d{4}(-
(\d{4}|present))?,?)+" ;
        Match match;

        match = Regex.Match(input, pattern);
        while (match.Success)
        {
            Console.Write("The {0} played in the {1} in",
                         match.Groups[1].Value, match.Groups[4].Value);
            foreach (Capture capture in match.Groups[5].Captures)
                Console.Write(capture.Value);

            Console.WriteLine(".");
            match = match.NextMatch();
        }
        Console.WriteLine();

        match = Regex.Match(input, pattern, RegexOptions.Multiline);
        while (match.Success)
        {
            Console.Write("The {0} played in the {1} in",
                         match.Groups[1].Value, match.Groups[4].Value);
            foreach (Capture capture in match.Groups[5].Captures)
                Console.Write(capture.Value);

            Console.WriteLine(".");
            match = match.NextMatch();
        }
    }
}
```

```

        }
        Console.WriteLine();
    }
}

// The example displays the following output:
//   The Brooklyn Dodgers played in the National League in 1911, 1912,
1932-1957.
//
//   The Brooklyn Dodgers played in the National League in 1911, 1912,
1932-1957.
//   The Chicago Cubs played in the National League in 1903-present.
//   The Detroit Tigers played in the American League in 1901-present.
//   The New York Giants played in the National League in 1885-1957.
//   The Washington Senators played in the American League in 1901-1960.

```

The regular expression pattern `^((\w+(\s?)){2,}),\s(\w+\s\w+),(\s\d{4}(-\d{4}|present))?,?)+` is defined as shown in the following table.

| Pattern | Description |
|---|---|
| <code>^</code> | Begin the match at the beginning of the input string (or the beginning of the line if the method is called with the RegexOptions.Multiline option). |
| <code>((\w+(\s?)){2,},)</code> | Match one or more word characters followed either by zero or by one space at least two times. This is the first capturing group. This expression also defines a second and third capturing group: The second consists of the captured word, and the third consists of the captured white space. |
| <code>,\s</code> | Match a comma followed by a white-space character. |
| <code>(\w+\s\w+)</code> | Match one or more word characters followed by a space, followed by one or more word characters. This is the fourth capturing group. |
| <code>,</code> | Match a comma. |
| <code>\s\d{4}</code> | Match a space followed by four decimal digits. |
| <code>(-\d{4} present)?</code> | Match zero or one occurrence of a hyphen followed by four decimal digits or the string "present". This is the sixth capturing group. It also includes a seventh capturing group. |
| <code>,?</code> | Match zero or one occurrence of a comma. |
| <code>(\s\d{4}(-\d{4} present))?,?)+</code> | Match one or more occurrences of the following: a space, four decimal digits, zero or one occurrence of a hyphen followed by four decimal digits or the string "present", and zero or one comma. This is the fifth capturing group. |

End of String or Line: \$

The `$` anchor specifies that the preceding pattern must occur at the end of the input string, or before `\n` at the end of the input string.

If you use `$` with the [RegexOptions.Multiline](#) option, the match can also occur at the end of a line. Note that `$` is satisfied at `\n` but not at `\r\n` (the combination of carriage return and newline characters, or CR/LF). To handle the CR/LF character combination, include `\r?\$` in the regular expression pattern. Note that `\r?\$` will include any `\r` in the match.

The following example adds the `$` anchor to the regular expression pattern used in the example in the [Start of String or Line](#) section. When used with the original input string, which includes five lines of text, the [Regex.Matches\(String, String\)](#) method is unable to find a match, because the end of the first line does not match the `$` pattern. When the original input string is split into a string array, the [Regex.Matches\(String, String\)](#) method succeeds in matching each of the five lines. When the [Regex.Matches\(String, String, RegexOptions\)](#) method is called with the `options` parameter set to [RegexOptions.Multiline](#), no matches are found because the regular expression pattern does not account for the carriage return character `\r`. However, when the regular expression pattern is modified by replacing `$` with `\r?\$`, calling the [Regex.Matches\(String, String, RegexOptions\)](#) method with the `options` parameter set to [RegexOptions.Multiline](#) again finds five matches.

C#

```
using System;
using System.Text.RegularExpressions;

public class Example
{
    public static void Main()
    {
        string cr = Environment.NewLine;
        string input = "Brooklyn Dodgers, National League, 1911, 1912, 1932-
1957" + cr +
                      "Chicago Cubs, National League, 1903-present" + cr +
                      "Detroit Tigers, American League, 1901-present" + cr +
+
                      "New York Giants, National League, 1885-1957" + cr +
                      "Washington Senators, American League, 1901-1960" +
cr;
        Match match;

        string basePattern = @"^((\w+(\s?)){2,}),\s(\w+\s\w+),(\s\d{4}(-
(\d{4}|present))?,?)+";
```

```

        string pattern = basePattern + "$";
        Console.WriteLine("Attempting to match the entire input string:");
        match = Regex.Match(input, pattern);
        while (match.Success)
        {
            Console.Write("The {0} played in the {1} in",
                         match.Groups[1].Value, match.Groups[4].Value);
            foreach (Capture capture in match.Groups[5].Captures)
                Console.Write(capture.Value);

            Console.WriteLine(".");
            match = match.NextMatch();
        }
        Console.WriteLine();

        string[] teams = input.Split(new String[] { cr },
StringSplitOptions.RemoveEmptyEntries);
        Console.WriteLine("Attempting to match each element in a string
array:");
        foreach (string team in teams)
        {
            match = Regex.Match(team, pattern);
            if (match.Success)
            {
                Console.Write("The {0} played in the {1} in",
                             match.Groups[1].Value, match.Groups[4].Value);
                foreach (Capture capture in match.Groups[5].Captures)
                    Console.Write(capture.Value);
                Console.WriteLine(".");
            }
        }
        Console.WriteLine();

        Console.WriteLine("Attempting to match each line of an input string
with '$':");
        match = Regex.Match(input, pattern, RegexOptions.Multiline);
        while (match.Success)
        {
            Console.Write("The {0} played in the {1} in",
                         match.Groups[1].Value, match.Groups[4].Value);
            foreach (Capture capture in match.Groups[5].Captures)
                Console.Write(capture.Value);

            Console.WriteLine(".");
            match = match.NextMatch();
        }
        Console.WriteLine();

        pattern = basePattern + "\r?";
        Console.WriteLine(@"Attempting to match each line of an input string
with '\r?:');
        match = Regex.Match(input, pattern, RegexOptions.Multiline);
        while (match.Success)
        {
            Console.Write("The {0} played in the {1} in",

```

```

                match.Groups[1].Value, match.Groups[4].Value);
        foreach (Capture capture in match.Groups[5].Captures)
            Console.WriteLine(capture.Value);

        Console.WriteLine(".");
        match = match.NextMatch();
    }
    Console.WriteLine();
}
}

// The example displays the following output:
//   Attempting to match the entire input string:
//
//   Attempting to match each element in a string array:
//   The Brooklyn Dodgers played in the National League in 1911, 1912,
1932-1957.
//   The Chicago Cubs played in the National League in 1903-present.
//   The Detroit Tigers played in the American League in 1901-present.
//   The New York Giants played in the National League in 1885-1957.
//   The Washington Senators played in the American League in 1901-1960.
//
//   Attempting to match each line of an input string with '$':
//
//   Attempting to match each line of an input string with '\r?$':
//   The Brooklyn Dodgers played in the National League in 1911, 1912,
1932-1957.
//   The Chicago Cubs played in the National League in 1903-present.
//   The Detroit Tigers played in the American League in 1901-present.
//   The New York Giants played in the National League in 1885-1957.
//   The Washington Senators played in the American League in 1901-1960.

```

Start of String Only: \A

The `\A` anchor specifies that a match must occur at the beginning of the input string. It is identical to the `^` anchor, except that `\A` ignores the [RegexOptions.Multiline](#) option. Therefore, it can only match the start of the first line in a multiline input string.

The following example is similar to the examples for the `^` and `$` anchors. It uses the `\A` anchor in a regular expression that extracts information about the years during which some professional baseball teams existed. The input string includes five lines. The call to the [Regex.Matches\(String, String, RegexOptions\)](#) method finds only the first substring in the input string that matches the regular expression pattern. As the example shows, the [Multiline](#) option has no effect.

C#

```

using System;
using System.Text.RegularExpressions;

```

```

public class Example
{
    public static void Main()
    {
        string input = "Brooklyn Dodgers, National League, 1911, 1912, 1932-
1957\n" +
                      "Chicago Cubs, National League, 1903-present\n" +
                      "Detroit Tigers, American League, 1901-present\n" +
                      "New York Giants, National League, 1885-1957\n" +
                      "Washington Senators, American League, 1901-1960\n";

        string pattern = @"\A(((\w+(\s?)){2,}),\s(\w+\s\w+),(\s\d{4}(-
(\d{4}|present))?,?)+";

        Match match = Regex.Match(input, pattern, RegexOptions.Multiline);
        while (match.Success)
        {
            Console.Write("The {0} played in the {1} in",
                         match.Groups[1].Value, match.Groups[4].Value);
            foreach (Capture capture in match.Groups[5].Captures)
                Console.Write(capture.Value);

            Console.WriteLine(".");
            match = match.NextMatch();
        }
        Console.WriteLine();
    }
}

// The example displays the following output:
//   The Brooklyn Dodgers played in the National League in 1911, 1912,
//   1932-1957.

```

End of String or Before Ending Newline: \Z

The `\Z` anchor specifies that a match must occur at the end of the input string, or before `\n` at the end of the input string. It is identical to the `$` anchor, except that `\Z` ignores the `RegexOptions.Multiline` option. Therefore, in a multiline string, it can only be satisfied by the end of the last line, or the last line before `\n`.

Note that `\Z` is satisfied at `\n` but is not satisfied at `\r\n` (the CR/LF character combination). To treat CR/LF as if it were `\n`, include `\r?\Z` in the regular expression pattern. Note that this will make the `\r` part of the match.

The following example uses the `\Z` anchor in a regular expression that is similar to the example in the [Start of String or Line](#) section, which extracts information about the years during which some professional baseball teams existed. The subexpression `\r?\Z` in the regular expression `^((\w+(\s?)){2,}),\s(\w+\s\w+),(\s\d{4}(-(\d{4}|present))?,?)+\r?`

\z is satisfied at the end of a string, and also at the end of a string that ends with \n or \r\n. As a result, each element in the array matches the regular expression pattern.

```
C#  
  
using System;  
using System.Text.RegularExpressions;  
  
public class Example  
{  
    public static void Main()  
    {  
        string[] inputs = { "Brooklyn Dodgers, National League, 1911, 1912,  
1932-1957",  
                           "Chicago Cubs, National League, 1903-present" +  
Environment.NewLine,  
                           "Detroit Tigers, American League, 1901-present" +  
Regex.Unescape(@"\n"),  
                           "New York Giants, National League, 1885-1957",  
                           "Washington Senators, American League, 1901-1960"  
+ Environment.NewLine};  
        string pattern = @"^((\w+(\s?)){2,}),\s(\w+\s\w+),(\s\d{4}(-  
(\d{4}|present))?,?)+\r?\Z";  
  
        foreach (string input in inputs)  
        {  
            Console.WriteLine(Regex.Escape(input));  
            Match match = Regex.Match(input, pattern);  
            if (match.Success)  
                Console.WriteLine("    Match succeeded.");  
            else  
                Console.WriteLine("    Match failed.");  
        }  
    }  
    // The example displays the following output:  
    // Brooklyn\ Dodgers,\ National\ League,\ 1911,\ 1912,\ 1932-1957  
    //         Match succeeded.  
    // Chicago\ Cubs,\ National\ League,\ 1903-present\r\n  
    //         Match succeeded.  
    // Detroit\ Tigers,\ American\ League,\ 1901-present\r\n  
    //         Match succeeded.  
    // New\ York\ Giants,\ National\ League,\ 1885-1957  
    //         Match succeeded.  
    // Washington\ Senators,\ American\ League,\ 1901-1960\r\n  
    //         Match succeeded.
```

End of String Only: \z

The `\z` anchor specifies that a match must occur at the end of the input string. Like the `$` language element, `\z` ignores the `RegexOptions.Multiline` option. Unlike the `\z` language element, `\z` is not satisfied by a `\n` character at the end of a string. Therefore, it can only match the end of the input string.

The following example uses the `\z` anchor in a regular expression that is otherwise identical to the example in the previous section, which extracts information about the years during which some professional baseball teams existed. The example tries to match each of five elements in a string array with the regular expression pattern `^((\w+(\s?)){2,}),\s(\w+\s\w+),(\s\d{4}(-(\d{4}|present))?,?)+'\r?\z`. Two of the strings end with carriage return and line feed characters, one ends with a line feed character, and two end with neither a carriage return nor a line feed character. As the output shows, only the strings without a carriage return or line feed character match the pattern.

```
C#
```

```
using System;
using System.Text.RegularExpressions;

public class Example
{
    public static void Main()
    {
        string[] inputs = { "Brooklyn Dodgers, National League, 1911, 1912,
1932-1957",
                            "Chicago Cubs, National League, 1903-present" +
Environment.NewLine,
                            "Detroit Tigers, American League, 1901-present\n",
                            "New York Giants, National League, 1885-1957",
                            "Washington Senators, American League, 1901-1960"
+ Environment.NewLine };
        string pattern = @"^((\w+(\s?)){2,}),\s(\w+\s\w+),(\s\d{4}(-
(\d{4}|present))?,?)+'\r?\z";

        foreach (string input in inputs)
        {
            Console.WriteLine(Regex.Escape(input));
            Match match = Regex.Match(input, pattern);
            if (match.Success)
                Console.WriteLine("  Match succeeded.");
            else
                Console.WriteLine("  Match failed.");
        }
    }
// The example displays the following output:
//   Brooklyn\ Dodgers,\ National\ League,\ 1911,\ 1912,\ 1932-1957
//       Match succeeded.
//   Chicago\ Cubs,\ National\ League,\ 1903-present\r\n
//       Match failed.
```

```
// Detroit\ Tigers,\ American\ League,\ 1901-present\n
//      Match failed.
// New\ York\ Giants,\ National\ League,\ 1885-1957
//      Match succeeded.
// Washington\ Senators,\ American\ League,\ 1901-1960\r\n
//      Match failed.
```

Contiguous Matches: \G

The `\G` anchor specifies that a match must occur at the point where the previous match ended, or if there was no previous match, at the position in the string where matching started. When you use this anchor with the [Regex.Matches](#) or [Match.NextMatch](#) method, it ensures that all matches are contiguous.

Tip

Typically, you place a `\G` anchor at the left end of your pattern. In the uncommon case you're performing a right-to-left search, place the `\G` anchor at the right end of your pattern.

The following example uses a regular expression to extract the names of rodent species from a comma-delimited string.

```
C#  
  
using System;
using System.Text.RegularExpressions;  
  
public class Example
{
    public static void Main()
    {
        string input = "capybara,squirrel,chipmunk,porcupine,gopher," +
                      "beaver,groundhog,hamster,guinea pig,gerbil," +
                      "chinchilla,prairie dog,mouse,rat";
        string pattern = @"\G(\w+\s?\w*),?";
        Match match = Regex.Match(input, pattern);
        while (match.Success)
        {
            Console.WriteLine(match.Groups[1].Value);
            match = match.NextMatch();
        }
    }
}  
// The example displays the following output:  
//      capybara  
//      squirrel
```

```
//      chipmunk
//      porcupine
//      gopher
//      beaver
//      groundhog
//      hamster
//      guinea pig
//      gerbil
//      chinchilla
//      prairie dog
//      mouse
//      rat
```

The regular expression `\G(\w+\s?\w*),?` is interpreted as shown in the following table.

| Pattern | Description |
|--------------------------|---|
| <code>\G</code> | Begin where the last match ended. |
| <code>\w+</code> | Match one or more word characters. |
| <code>\s?</code> | Match zero or one space. |
| <code>\w*</code> | Match zero or more word characters. |
| <code>(\w+\s?\w*)</code> | Match one or more word characters followed by zero or one space, followed by zero or more word characters. This is the first capturing group. |
| <code>,?</code> | Match zero or one occurrence of a literal comma character. |

Word Boundary: \b

The `\b` anchor specifies that the match must occur on a boundary between a word character (the `\w` language element) and a non-word character (the `\W` language element). Word characters consist of alphanumeric characters and underscores; a non-word character is any character that is not alphanumeric or an underscore. (For more information, see [Character Classes](#).) The match may also occur on a word boundary at the beginning or end of the string.

The `\b` anchor is frequently used to ensure that a subexpression matches an entire word instead of just the beginning or end of a word. The regular expression `\bare\w*\b` in the following example illustrates this usage. It matches any word that begins with the substring "are". The output from the example also illustrates that `\b` matches both the beginning and the end of the input string.

```

using System;
using System.Text.RegularExpressions;

public class Example
{
    public static void Main()
    {
        string input = "area bare arena mare";
        string pattern = @"\bare\w*\b";
        Console.WriteLine("Words that begin with 'are':");
        foreach (Match match in Regex.Matches(input, pattern))
            Console.WriteLine("{0} found at position {1}",
                match.Value, match.Index);
    }
}
// The example displays the following output:
//     Words that begin with 'are':
//     'area' found at position 0
//     'arena' found at position 10

```

The regular expression pattern is interpreted as shown in the following table.

| Pattern | Description |
|---------|-------------------------------------|
| \b | Begin the match at a word boundary. |
| are | Match the substring "are". |
| \w* | Match zero or more word characters. |
| \b | End the match at a word boundary. |

Non-Word Boundary: \B

The `\B` anchor specifies that the match must not occur on a word boundary. It is the opposite of the `\b` anchor.

The following example uses the `\B` anchor to locate occurrences of the substring "qu" in a word. The regular expression pattern `\Bqu\w+` matches a substring that begins with a "qu" that does not start a word and that continues to the end of the word.

C#

```

using System;
using System.Text.RegularExpressions;

public class Example
{

```

```

public static void Main()
{
    string input = "equity queen equip acquaint quiet";
    string pattern = @"\Bqu\w+";
    foreach (Match match in Regex.Matches(input, pattern))
        Console.WriteLine("{0} found at position {1}",
                          match.Value, match.Index);
}
// The example displays the following output:
//      'quity' found at position 1
//      'quip' found at position 14
//      'quaint' found at position 21

```

The regular expression pattern is interpreted as shown in the following table.

| Pattern | Description |
|---------|--|
| \B | Do not begin the match at a word boundary. |
| qu | Match the substring "qu". |
| \w+ | Match one or more word characters. |

Grouping constructs in regular expressions

Article • 05/08/2023

Grouping constructs delineate the subexpressions of a regular expression and capture the substrings of an input string. You can use grouping constructs to do the following:

- Match a subexpression that's repeated in the input string.
- Apply a quantifier to a subexpression that has multiple regular expression language elements. For more information about quantifiers, see [Quantifiers](#).
- Include a subexpression in the string that's returned by the [Regex.Replace](#) and [Match.Result](#) methods.
- Retrieve individual subexpressions from the [Match.Groups](#) property and process them separately from the matched text as a whole.

The following table lists the grouping constructs supported by the .NET regular expression engine and indicates whether they are capturing or noncapturing.

| Grouping construct | Capturing or noncapturing |
|---|---------------------------|
| Matched subexpressions | Capturing |
| Named matched subexpressions | Capturing |
| Balancing group definitions | Capturing |
| Noncapturing groups | Noncapturing |
| Group options | Noncapturing |
| Zero-width positive lookahead assertions | Noncapturing |
| Zero-width negative lookahead assertions | Noncapturing |
| Zero-width positive lookbehind assertions | Noncapturing |
| Zero-width negative lookbehind assertions | Noncapturing |
| Atomic groups | Noncapturing |

For information on groups and the regular expression object model, see [Grouping constructs and regular expression objects](#).

Matched subexpressions

The following grouping construct captures a matched subexpression:

(*subexpression*)

Here, *subexpression* is any valid regular expression pattern. Captures that use parentheses are numbered automatically from left to right based on the order of the opening parentheses in the regular expression, starting from 1. However, [named capture groups](#) are always ordered last, after non-named capture groups. The capture that's numbered 0 is the text matched by the entire regular expression pattern.

① Note

By default, the (*subexpression*) language element captures the matched subexpression. But if the `RegexOptions` parameter of a regular expression pattern matching method includes the `RegexOptions.ExplicitCapture` flag, or if the `n` option is applied to this subexpression (see [Group options](#) later in this article), the matched subexpression is not captured.

You can access captured groups in four ways:

- By using the backreference construct within the regular expression. The matched subexpression is referenced in the same regular expression by using the syntax `\number`, where *number* is the ordinal number of the captured subexpression.
- By using the named backreference construct within the regular expression. The matched subexpression is referenced in the same regular expression by using the syntax `\k<name>`, where *name* is the name of a capturing group, or `\k<number>`, where *number* is the ordinal number of a capturing group. A capturing group has a default name that is identical to its ordinal number. For more information, see [Named matched subexpressions](#) later in this topic.
- By using the `$number` replacement sequence in a `Regex.Replace` or `Match.Result` method call, where *number* is the ordinal number of the captured subexpression.
- Programmatically, by using the `GroupCollection` object returned by the `Match.Groups` property. The member at position zero in the collection represents the entire regular expression match. Each subsequent member represents a matched subexpression. For more information, see the [Grouping Constructs and Regular Expression Objects](#) section.

The following example illustrates a regular expression that identifies duplicated words in text. The regular expression pattern's two capturing groups represent the two instances

of the duplicated word. The second instance is captured to report its starting position in the input string.

```
C#  
  
using System;  
using System.Text.RegularExpressions;  
  
public class Example  
{  
    public static void Main()  
    {  
        string pattern = @"(\w+)\s(\1)\W";  
        string input = "He said that that was the the correct answer.";  
        foreach (Match match in Regex.Matches(input, pattern,  
RegexOptions.IgnoreCase))  
            Console.WriteLine("Duplicate '{0}' found at positions {1} and  
{2}.",  
                match.Groups[1].Value, match.Groups[1].Index,  
                match.Groups[2].Index);  
    }  
}  
// The example displays the following output:  
//     Duplicate 'that' found at positions 8 and 13.  
//     Duplicate 'the' found at positions 22 and 26.
```

The regular expression pattern is the following:

```
(\w+)\s(\1)\W
```

The following table shows how the regular expression pattern is interpreted.

| Pattern | Description |
|---------|---|
| (\w+) | Match one or more word characters. This is the first capturing group. |
| \s | Match a white-space character. |
| (\1) | Match the string in the first captured group. This is the second capturing group. The example assigns it to a captured group so that the starting position of the duplicate word can be retrieved from the <code>Match.Index</code> property. |
| \W | Match a non-word character, including white space and punctuation. This prevents the regular expression pattern from matching a word that starts with the word from the first captured group. |

Named matched subexpressions

The following grouping construct captures a matched subexpression and lets you access it by name or by number:

```
(?<name>subexpression)
```

or:

```
(?'name' subexpression)
```

Here, *name* is a valid group name, and *subexpression* is any valid regular expression pattern. *name* must not contain any punctuation characters and cannot begin with a number.

ⓘ Note

If the `RegexOptions` parameter of a regular expression pattern matching method includes the `RegexOptions.ExplicitCapture` flag, or if the `n` option is applied to this subexpression (see [Group options](#) later in this topic), the only way to capture a subexpression is to explicitly name capturing groups.

You can access named captured groups in the following ways:

- By using the named backreference construct within the regular expression. The matched subexpression is referenced in the same regular expression by using the syntax `\k<name>`, where *name* is the name of the captured subexpression.
- By using the backreference construct within the regular expression. The matched subexpression is referenced in the same regular expression by using the syntax `\number`, where *number* is the ordinal number of the captured subexpression. Named matched subexpressions are numbered consecutively from left to right after matched subexpressions.
- By using the `${name}` replacement sequence in a `Regex.Replace` or `Match.Result` method call, where *name* is the name of the captured subexpression.
- By using the `$number` replacement sequence in a `Regex.Replace` or `Match.Result` method call, where *number* is the ordinal number of the captured subexpression.
- Programmatically, by using the `GroupCollection` object returned by the `Match.Groups` property. The member at position zero in the collection represents the entire regular expression match. Each subsequent member represents a matched subexpression. Named captured groups are stored in the collection after numbered captured groups.

- Programmatically, by providing the subexpression name to the `GroupCollection` object's indexer (in C#) or to its `Item[]` property (in Visual Basic).

A simple regular expression pattern illustrates how numbered (unnamed) and named groups can be referenced either programmatically or by using regular expression language syntax. The regular expression `((?<One>abc)\d+)?(?<Two>xyz)(.*)` produces the following capturing groups by number and by name. The first capturing group (number 0) always refers to the entire pattern. (Named groups are always ordered last.)

| Number | Name | Pattern |
|--------|------------------|---|
| 0 | 0 (default name) | <code>((?<One>abc)\d+)?(?<Two>xyz)(.*)</code> |
| 1 | 1 (default name) | <code>((?<One>abc)\d+)</code> |
| 2 | 2 (default name) | <code>(.*)</code> |
| 3 | One | <code>(?<One>abc)</code> |
| 4 | Two | <code>(?<Two>xyz)</code> |

The following example illustrates a regular expression that identifies duplicated words and the word that immediately follows each duplicated word. The regular expression pattern defines two named subexpressions: `duplicateWord`, which represents the duplicated word, and `nextWord`, which represents the word that follows the duplicated word.

C#

```
using System;
using System.Text.RegularExpressions;

public class Example
{
    public static void Main()
    {
        string pattern = @"(?<duplicateWord>\w+)\s\k<duplicateWord>\W(?<nextWord>\w+)";
        string input = "He said that that was the the correct answer.";
        foreach (Match match in Regex.Matches(input, pattern,
RegexOptions.IgnoreCase))
            Console.WriteLine("A duplicate '{0}' at position {1} is followed by
'{2}'.",
                match.Groups["duplicateWord"].Value,
                match.Groups["duplicateWord"].Index,
                match.Groups["nextWord"].Value);
    }
}

// The example displays the following output:
```

```
//      A duplicate 'that' at position 8 is followed by 'was'.
//      A duplicate 'the' at position 22 is followed by 'correct'.
```

The regular expression pattern is as follows:

```
(?<duplicateWord>\w+)\s\k<duplicateWord>\W(?<nextWord>\w+)
```

The following table shows how the regular expression is interpreted.

| Pattern | Description |
|---------------------------|---|
| (? <duplicateWord>\w+) | Match one or more word characters. Name this capturing group <code>duplicateWord</code> . |
| \s | Match a white-space character. |
| \k<duplicateWord> | Match the string from the captured group that is named <code>duplicateWord</code> . |
| \W | Match a non-word character, including white space and punctuation. This prevents the regular expression pattern from matching a word that starts with the word from the first captured group. |
| (?<nextWord>\w+) | Match one or more word characters. Name this capturing group <code>nextWord</code> . |

A group name can be repeated in a regular expression. For example, it's possible for more than one group to be named `digit`, as the following example illustrates. In the case of duplicate names, the value of the [Group](#) object is determined by the last successful capture in the input string. In addition, the [CaptureCollection](#) is populated with information about each capture just as it would be if the group name was not duplicated.

In the following example, the regular expression `\D+(?<digit>\d+)\D+(?<digit>\d+)?` includes two occurrences of a group named `digit`. The first `digit` named group captures one or more digit characters. The second `digit` named group captures either zero or one occurrence of one or more digit characters. As the output from the example shows, if the second capturing group successfully matches text, the value of that text defines the value of the [Group](#) object. If the second capturing group does not match the input string, the value of the last successful match defines the value of the [Group](#) object.

```
C#
```

```
using System;
using System.Text.RegularExpressions;

public class Example
{
```

```

public static void Main()
{
    String pattern = @"\D+(?<digit>\d+)\D+(?<digit>\d+)?";
    String[] inputs = { "abc123def456", "abc123def" };
    foreach (var input in inputs) {
        Match m = Regex.Match(input, pattern);
        if (m.Success) {
            Console.WriteLine("Match: {0}", m.Value);
            for (int grpCtr = 1; grpCtr < m.Groups.Count; grpCtr++) {
                Group grp = m.Groups[grpCtr];
                Console.WriteLine("Group {0}: {1}", grpCtr, grp.Value);
                for (int capCtr = 0; capCtr < grp.Captures.Count; capCtr++)
                    Console.WriteLine("    Capture {0}: {1}",
                                      capCtr,
                                      grp.Captures[capCtr].Value);
            }
        }
        else {
            Console.WriteLine("The match failed.");
        }
        Console.WriteLine();
    }
}
// The example displays the following output:
//      Match: abc123def456
//          Group 1: 456
//              Capture 0: 123
//              Capture 1: 456
//
//      Match: abc123def
//          Group 1: 123
//              Capture 0: 123

```

The following table shows how the regular expression is interpreted.

| Pattern | Description |
|-------------------------|---|
| \D+ | Match one or more non-decimal digit characters. |
| (?<digit>\d+) | Match one or more decimal digit characters. Assign the match to the <code>digit</code> named group. |
| \D+ | Match one or more non-decimal digit characters. |
| (? <digit>\d+)?</digit> | Match zero or one occurrence of one or more decimal digit characters. Assign the match to the <code>digit</code> named group. |

Balancing group definitions

A balancing group definition deletes the definition of a previously defined group and stores, in the current group, the interval between the previously defined group and the current group. This grouping construct has the following format:

```
(?<name1-name2>subexpression)
```

or:

```
(?'name1-name2' subexpression)
```

Here, *name1* is the current group (optional), *name2* is a previously defined group, and *subexpression* is any valid regular expression pattern. The balancing group definition deletes the definition of *name2* and stores the interval between *name2* and *name1* in *name1*. If no *name2* group is defined, the match backtracks. Because deleting the last definition of *name2* reveals the previous definition of *name2*, this construct lets you use the stack of captures for group *name2* as a counter for keeping track of nested constructs such as parentheses or opening and closing brackets.

The balancing group definition uses *name2* as a stack. The beginning character of each nested construct is placed in the group and in its [Group.Captures](#) collection. When the closing character is matched, its corresponding opening character is removed from the group, and the [Captures](#) collection is decreased by one. After the opening and closing characters of all nested constructs have been matched, *name2* is empty.

Note

After you modify the regular expression in the following example to use the appropriate opening and closing character of a nested construct, you can use it to handle most nested constructs, such as mathematical expressions or lines of program code that include multiple nested method calls.

The following example uses a balancing group definition to match left and right angle brackets (<>) in an input string. The example defines two named groups, `open` and `close`, that are used like a stack to track matching pairs of angle brackets. Each captured left angle bracket is pushed into the capture collection of the `open` group, and each captured right angle bracket is pushed into the capture collection of the `close` group. The balancing group definition ensures that there is a matching right angle bracket for each left angle bracket. If there is not, the final subpattern, `(?(Open)(?!))`, is evaluated only if the `open` group is not empty (and, therefore, if all nested constructs have not been closed). If the final subpattern is evaluated, the match fails, because the `(?!)` subpattern is a zero-width negative lookahead assertion that always fails.

C#

```
using System;
using System.Text.RegularExpressions;

class Example
{
    public static void Main()
    {
        string pattern = "^[^<>]*" +
                         "(" +
                         "(?'Open'<)[^<>]*)+" +
                         "(?'Close-Open'>)[^<>]*)+" +
                         ")"* +
                         "(?(Open)(?!))$";
        string input = "<abc><mno<xyz>>";

        Match m = Regex.Match(input, pattern);
        if (m.Success == true)
        {
            Console.WriteLine("Input: \"{0}\" \nMatch: \"{1}\"", input, m);
            int grpCtr = 0;
            foreach (Group grp in m.Groups)
            {
                Console.WriteLine("    Group {0}: {1}", grpCtr, grp.Value);
                grpCtr++;
                int capCtr = 0;
                foreach (Capture cap in grp.Captures)
                {
                    Console.WriteLine("        Capture {0}: {1}", capCtr,
cap.Value);
                    capCtr++;
                }
            }
        }
        else
        {
            Console.WriteLine("Match failed.");
        }
    }
}

// The example displays the following output:
//   Input: "<abc><mno<xyz>>"
//   Match: "<abc><mno<xyz>>"
//       Group 0: <abc><mno<xyz>>
//           Capture 0: <abc><mno<xyz>>
//           Group 1: <mno<xyz>>
//               Capture 0: <abc>
//               Capture 1: <mno<xyz>>
//               Group 2: <xyz
//                   Capture 0: <abc
//                   Capture 1: <mno
//                   Capture 2: <xyz
//                   Group 3: >
```

```

//      Capture 0: >
//      Capture 1: >
//      Capture 2: >
//      Group 4:
//      Group 5: mno<xyz>
//      Capture 0: abc
//      Capture 1: xyz
//      Capture 2: mno<xyz>

```

The regular expression pattern is:

```
^[^<>]*(((?'Open'<)[^<>]*+)((?'Close-Open'>)[^<>]*+)*?(?Open)(?!))$
```

The regular expression is interpreted as follows:

| Pattern | Description |
|---|--|
| <code>^</code> | Begin at the start of the string. |
| <code>[^<>]*</code> | Match zero or more characters that are not left or right angle brackets. |
| <code>(?'Open'<)</code> | Match a left angle bracket and assign it to a group named <code>Open</code> . |
| <code>[^<>]*</code> | Match zero or more characters that are not left or right angle brackets. |
| <code>((?'Open'<)[^<>]*+)</code> | Match one or more occurrences of a left angle bracket followed by zero or more characters that are not left or right angle brackets. This is the second capturing group. |
| <code>(?'Close-Open'>)</code> | Match a right angle bracket, assign the substring between the <code>Open</code> group and the current group to the <code>Close</code> group, and delete the definition of the <code>Open</code> group. |
| <code>[^<>]*</code> | Match zero or more occurrences of any character that is neither a left nor a right angle bracket. |
| <code>((?'Close-Open'>)[^<>]*+)</code> | Match one or more occurrences of a right angle bracket, followed by zero or more occurrences of any character that is neither a left nor a right angle bracket. When matching the right angle bracket, assign the substring between the <code>Open</code> group and the current group to the <code>Close</code> group, and delete the definition of the <code>Open</code> group. This is the third capturing group. |
| <code>((?'Open'<)[^<>]*+((?'Close-Open'>)[^<>]*+)*?)</code> | Match zero or more occurrences of the following pattern: one or more occurrences of a left angle bracket, followed by zero or more non-angle bracket characters, followed by one or more occurrences of a right angle bracket, followed by zero or more occurrences of non-angle brackets. When matching the right angle bracket, delete the definition of the <code>Open</code> group, and assign the substring between the <code>Open</code> group and the current group to the <code>Close</code> group. This is the first capturing group. |

| Pattern | Description |
|---------------|--|
| (?(Open)(?!)) | If the <code>Open</code> group exists, abandon the match if an empty string can be matched, but do not advance the position of the regular expression engine in the string. This is a zero-width negative lookahead assertion. Because an empty string is always implicitly present in an input string, this match always fails. Failure of this match indicates that the angle brackets are not balanced. |
| \$ | Match the end of the input string. |

The final subexpression, `(?(Open)(?!))`, indicates whether the nesting constructs in the input string are properly balanced (for example, whether each left angle bracket is matched by a right angle bracket). It uses conditional matching based on a valid captured group; for more information, see [Alternation Constructs](#). If the `Open` group is defined, the regular expression engine attempts to match the subexpression `(?!)` in the input string. The `Open` group should be defined only if nesting constructs are unbalanced. Therefore, the pattern to be matched in the input string should be one that always causes the match to fail. In this case, `(?!)` is a zero-width negative lookahead assertion that always fails, because an empty string is always implicitly present at the next position in the input string.

In the example, the regular expression engine evaluates the input string "`<abc><mno<xyz>`" as shown in the following table.

| Step | Pattern | Result |
|------|---------------------------------------|--|
| 1 | <code>^</code> | Starts the match at the beginning of the input string |
| 2 | <code>[^<>]*</code> | Looks for non-angle bracket characters before the left angle bracket; finds no matches. |
| 3 | <code>((? 'Open' <)</code> | Matches the left angle bracket in " <code><abc></code> " and assigns it to the <code>Open</code> group. |
| 4 | <code>[^<>]*</code> | Matches "abc". |
| 5 | <code>) +</code> | " <code><abc</code> " is the value of the second captured group. The next character in the input string is not a left angle bracket, so the regular expression engine does not loop back to the <code>(? 'Open' <)[^<>]*</code> subpattern. |
| 6 | <code>((? 'Close- Open' >)</code> | Matches the right angle bracket in " <code><abc></code> ", assigns "abc", which is the substring between the <code>Open</code> group and the right angle bracket, to the <code>Close</code> group, and deletes the current value (" <code><</code> ") of the <code>Open</code> group, leaving it empty. |

| Step | Pattern | Result |
|------|-------------------|---|
| 7 | [^<>]* | Looks for non-angle bracket characters after the right angle bracket; finds no matches. |
| 8 |)+ | The value of the third captured group is ">". The next character in the input string is not a right angle bracket, so the regular expression engine does not loop back to the <code>(?'Close-Open') [^<>]*</code> subpattern. |
| 9 |)* | The value of the first captured group is "<abc>". The next character in the input string is a left angle bracket, so the regular expression engine loops back to the <code>((?'Open'<)</code> subpattern. |
| 10 | ((?'Open'<) | Matches the left angle bracket in "<mnō" and assigns it to the <code>Open</code> group. Its Group.Captures collection now has a single value, "<". |
| 11 | [^<>]* | Matches "mnō". |
| 12 |)+ | "<mnō" is the value of the second captured group. The next character in the input string is an left angle bracket, so the regular expression engine loops back to the <code>(?'Open'<)[^<>]*</code> subpattern. |
| 13 | ((?'Open'<) | Matches the left angle bracket in "<xyz>" and assigns it to the <code>Open</code> group. The Group.Captures collection of the <code>Open</code> group now includes two captures: the left angle bracket from "<mnō", and the left angle bracket from "<xyz>". |
| 14 | [^<>]* | Matches "xyz". |
| 15 |)+ | "<xyz" is the value of the second captured group. The next character in the input string is not a left angle bracket, so the regular expression engine does not loop back to the <code>(?'Open'<)[^<>]*</code> subpattern. |
| 16 | ((?'Close-Open'>) | Matches the right angle bracket in "<xyz>". "xyz", assigns the substring between the <code>Open</code> group and the right angle bracket to the <code>Close</code> group, and deletes the current value of the <code>Open</code> group. The value of the previous capture (the left angle bracket in "<mnō") becomes the current value of the <code>Open</code> group. The Captures collection of the <code>Open</code> group now includes a single capture, the left angle bracket from "<xyz>". |
| 17 | [^<>]* | Looks for non-angle bracket characters; finds no matches. |
| 18 |)+ | The value of the third captured group is ">". |

| Step | Pattern | Result |
|------|-----------------------------------|--|
| | | The next character in the input string is a right angle bracket, so the regular expression engine loops back to the <code>((?'Close-Open'>)[^<>]*)</code> subpattern. |
| 19 | <code>((?'Close-Open'>)</code> | Matches the final right angle bracket in "xyz>", assigns "mno<xyz>" (the substring between the <code>Open</code> group and the right angle bracket) to the <code>Close</code> group, and deletes the current value of the <code>Open</code> group. The <code>Open</code> group is now empty. |
| 20 | <code>[^<>]*</code> | Looks for non-angle bracket characters; finds no matches. |
| 21 | <code>)+</code> | The value of the third captured group is ">". |
| | | The next character in the input string is not a right angle bracket, so the regular expression engine does not loop back to the <code>((?'Close-Open'>)[^<>]*)</code> subpattern. |
| 22 | <code>)*</code> | The value of the first captured group is "<mno<xyz>>". |
| | | The next character in the input string is not a left angle bracket, so the regular expression engine does not loop back to the <code>((?'Open'<)</code> subpattern. |
| 23 | <code>(?(Open)(?!))</code> | The <code>Open</code> group is not defined, so no match is attempted. |
| 24 | <code>\$</code> | Matches the end of the input string. |

Noncapturing groups

The following grouping construct does not capture the substring that's matched by a subexpression:

`(?:subexpression)`

Here, *subexpression* is any valid regular expression pattern. The noncapturing group construct is typically used when a quantifier is applied to a group, but the substrings captured by the group are of no interest.

ⓘ Note

If a regular expression includes nested grouping constructs, an outer noncapturing group construct does not apply to the inner nested group constructs.

The following example illustrates a regular expression that includes noncapturing groups. Note that the output does not include any captured groups.

```
C#  
  
using System;  
using System.Text.RegularExpressions;  
  
public class Example  
{  
    public static void Main()  
    {  
        string pattern = @"(?:\b(?:\w+)\W*)+\.";  
        string input = "This is a short sentence.";  
        Match match = Regex.Match(input, pattern);  
        Console.WriteLine("Match: {0}", match.Value);  
        for (int ctr = 1; ctr < match.Groups.Count; ctr++)  
            Console.WriteLine("    Group {0}: {1}", ctr,  
match.Groups[ctr].Value);  
    }  
}  
// The example displays the following output:  
//      Match: This is a short sentence.
```

The regular expression `(?:\b(?:\w+)\W*)+\.` matches a sentence that is terminated by a period. Because the regular expression focuses on sentences and not on individual words, grouping constructs are used exclusively as quantifiers. The regular expression pattern is interpreted as shown in the following table.

| Pattern | Description |
|--------------------------------|--|
| <code>\b</code> | Begin the match at a word boundary. |
| <code>(?:\w+)</code> | Match one or more word characters. Do not assign the matched text to a captured group. |
| <code>\W*</code> | Match zero or more non-word characters. |
| <code>(?:\b(?:\w+)\W*)+</code> | Match the pattern of one or more word characters starting at a word boundary, followed by zero or more non-word characters, one or more times. Do not assign the matched text to a captured group. |
| <code>\.</code> | Match a period. |

Group options

The following grouping construct applies or disables the specified options within a subexpression:

```
(?imnsx-imnsx: subexpression )
```

Here, *subexpression* is any valid regular expression pattern. For example, `(?i-s:)` turns on case insensitivity and disables single-line mode. For more information about the inline options you can specify, see [Regular Expression Options](#).

ⓘ Note

You can specify options that apply to an entire regular expression rather than a subexpression by using a `System.Text.RegularExpressions.Regex` class constructor or a static method. You can also specify inline options that apply after a specific point in a regular expression by using the `(?imnsx-imnsx)` language construct.

The group options construct is not a capturing group. That is, although any portion of a string that is captured by *subexpression* is included in the match, it is not included in a captured group nor used to populate the `GroupCollection` object.

For example, the regular expression `\b(?ix: d \w+)\s` in the following example uses inline options in a grouping construct to enable case-insensitive matching and ignore pattern white space in identifying all words that begin with the letter "d". The regular expression is defined as shown in the following table.

| Pattern | Description |
|---------------------------|--|
| <code>\b</code> | Begin the match at a word boundary. |
| <code>(?ix: d \w+)</code> | Using case-insensitive matching and ignoring white space in this pattern, match a "d" followed by one or more word characters. |
| <code>\s</code> | Match a white-space character. |

C#

```
string pattern = @"\b(?ix: d \w+)\s";
string input = "Dogs are decidedly good pets.";

foreach (Match match in Regex.Matches(input, pattern))
    Console.WriteLine("{0}// found at index {1}.", match.Value,
match.Index);
// The example displays the following output:
//    'Dogs // found at index 0.
//    'decidedly // found at index 9.
```

Zero-width positive lookahead assertions

The following grouping construct defines a zero-width positive lookahead assertion:

```
(?= subexpression )
```

Here, *subexpression* is any regular expression pattern. For a match to be successful, the input string must match the regular expression pattern in *subexpression*, although the matched substring is not included in the match result. A zero-width positive lookahead assertion does not backtrack.

Typically, a zero-width positive lookahead assertion is found at the end of a regular expression pattern. It defines a substring that must be found at the end of a string for a match to occur but that should not be included in the match. It is also useful for preventing excessive backtracking. You can use a zero-width positive lookahead assertion to ensure that a particular captured group begins with text that matches a subset of the pattern defined for that captured group. For example, if a capturing group matches consecutive word characters, you can use a zero-width positive lookahead assertion to require that the first character be an alphabetical uppercase character.

The following example uses a zero-width positive lookahead assertion to match the word that precedes the verb "is" in the input string.

C#

```
using System;
using System.Text.RegularExpressions;

public class Example
{
    public static void Main()
    {
        string pattern = @"\b\w+(?=\\sis\\b)";
        string[] inputs = { "The dog is a Malamute.",
                            "The island has beautiful birds.",
                            "The pitch missed home plate.",
                            "Sunday is a weekend day." };

        foreach (string input in inputs)
        {
            Match match = Regex.Match(input, pattern);
            if (match.Success)
                Console.WriteLine("{0}' precedes 'is'.", match.Value);
            else
                Console.WriteLine("{0}' does not match the pattern.", input);
        }
    }
}

// The example displays the following output:
//      'dog' precedes 'is'.
//      'The island has beautiful birds.' does not match the pattern.
```

```
//      'The pitch missed home plate.' does not match the pattern.  
//      'Sunday' precedes 'is'.
```

The regular expression `\b\w+(?=\\sis\\b)` is interpreted as shown in the following table.

| Pattern | Description |
|--------------------------------|---|
| <code>\b</code> | Begin the match at a word boundary. |
| <code>\w+</code> | Match one or more word characters. |
| <code>(? =\\sis\\b)</code> | Determine whether the word characters are followed by a white-space character and the string "is", which ends on a word boundary. If so, the match is successful. |

Zero-width negative lookahead assertions

The following grouping construct defines a zero-width negative lookahead assertion:

```
(?! subexpression)
```

Here, *subexpression* is any regular expression pattern. For the match to be successful, the input string must not match the regular expression pattern in *subexpression*, although the matched string is not included in the match result.

A zero-width negative lookahead assertion is typically used either at the beginning or at the end of a regular expression. At the beginning of a regular expression, it can define a specific pattern that should not be matched when the beginning of the regular expression defines a similar but more general pattern to be matched. In this case, it is often used to limit backtracking. At the end of a regular expression, it can define a subexpression that cannot occur at the end of a match.

The following example defines a regular expression that uses a zero-width lookahead assertion at the beginning of the regular expression to match words that do not begin with "un".

C#

```
using System;  
using System.Text.RegularExpressions;  
  
public class Example  
{  
    public static void Main()  
    {  
        string pattern = @"\b(?!un)\w+\b";  
        string input = "unite one unethical ethics use untie ultimate";
```

```

        foreach (Match match in Regex.Matches(input, pattern,
RegexOptions.IgnoreCase))
            Console.WriteLine(match.Value);
    }
}

// The example displays the following output:
//      one
//      ethics
//      use
//      ultimate

```

The regular expression `\b(?!un)\w+\b` is interpreted as shown in the following table.

| Pattern | Description |
|---------------------|---|
| <code>\b</code> | Begin the match at a word boundary. |
| <code>(?!un)</code> | Determine whether the next two characters are "un". If they are not, a match is possible. |
| <code>\w+</code> | Match one or more word characters. |
| <code>\b</code> | End the match at a word boundary. |

The following example defines a regular expression that uses a zero-width lookahead assertion at the end of the regular expression to match words that do not end with a punctuation character.

C#

```

using System;
using System.Text.RegularExpressions;

public class Example
{
    public static void Main()
    {
        string pattern = @"\b\w+\b(?!\\p{P})";
        string input = "Disconnected, disjointed thoughts in a sentence
fragment.";
        foreach (Match match in Regex.Matches(input, pattern))
            Console.WriteLine(match.Value);
    }
}

// The example displays the following output:
//      disjointed
//      thoughts
//      in
//      a
//      sentence

```

The regular expression `\b\w+\b(?!\\p{P})` is interpreted as shown in the following table.

| Pattern | Description |
|--------------------|--|
| <code>\b</code> | Begin the match at a word boundary. |
| <code>\w+</code> | Match one or more word characters. |
| <code>\b</code> | End the match at a word boundary. |
| <code>\p{P}</code> | If the next character is not a punctuation symbol (such as a period or a comma), the match succeeds. |

Zero-width positive lookbehind assertions

The following grouping construct defines a zero-width positive lookbehind assertion:

```
(?<= subexpression )
```

Here, *subexpression* is any regular expression pattern. For a match to be successful, *subexpression* must occur at the input string to the left of the current position, although *subexpression* is not included in the match result. A zero-width positive lookbehind assertion does not backtrack.

Zero-width positive lookbehind assertions are typically used at the beginning of regular expressions. The pattern that they define is a precondition for a match, although it is not a part of the match result.

For example, the following example matches the last two digits of the year for the twenty first century (that is, it requires that the digits "20" precede the matched string).

```
C#  
  
using System;  
using System.Text.RegularExpressions;  
  
public class Example  
{  
    public static void Main()  
    {  
        string input = "2010 1999 1861 2140 2009";  
        string pattern = @"(?<=\b20)\d{2}\b";  
  
        foreach (Match match in Regex.Matches(input, pattern))  
            Console.WriteLine(match.Value);  
    }  
}  
// The example displays the following output:
```

```
//      10  
//      09
```

The regular expression pattern `(?<=\b20)\d{2}\b` is interpreted as shown in the following table.

| Pattern | Description |
|---------------------------|--|
| <code>\d{2}</code> | Match two decimal digits. |
| <code>(?<=\b20)</code> | Continue the match if the two decimal digits are preceded by the decimal digits "20" on a word boundary. |
| <code>\b</code> | End the match at a word boundary. |

Zero-width positive lookbehind assertions are also used to limit backtracking when the last character or characters in a captured group must be a subset of the characters that match that group's regular expression pattern. For example, if a group captures all consecutive word characters, you can use a zero-width positive lookbehind assertion to require that the last character be alphabetical.

Zero-width negative lookbehind assertions

The following grouping construct defines a zero-width negative lookbehind assertion:

```
(?<! subexpression )
```

Here, *subexpression* is any regular expression pattern. For a match to be successful, *subexpression* must not occur at the input string to the left of the current position. However, any substring that does not match `subexpression` is not included in the match result.

Zero-width negative lookbehind assertions are typically used at the beginning of regular expressions. The pattern that they define precludes a match in the string that follows. They are also used to limit backtracking when the last character or characters in a captured group must not be one or more of the characters that match that group's regular expression pattern. For example, if a group captures all consecutive word characters, you can use a zero-width positive lookbehind assertion to require that the last character not be an underscore (_).

The following example matches the date for any day of the week that is not a weekend (that is, that is neither Saturday nor Sunday).

```

using System;
using System.Text.RegularExpressions;

public class Example
{
    public static void Main()
    {
        string[] dates = { "Monday February 1, 2010",
                           "Wednesday February 3, 2010",
                           "Saturday February 6, 2010",
                           "Sunday February 7, 2010",
                           "Monday, February 8, 2010" };
        string pattern = @"(?<!(Saturday|Sunday) )\b\w+ \d{1,2}, \d{4}\b";

        foreach (string dateValue in dates)
        {
            Match match = Regex.Match(dateValue, pattern);
            if (match.Success)
                Console.WriteLine(match.Value);
        }
    }
}

// The example displays the following output:
//      February 1, 2010
//      February 3, 2010
//      February 8, 2010

```

The regular expression pattern `(?<!(Saturday|Sunday))\b\w+ \d{1,2}, \d{4}\b` is interpreted as shown in the following table.

| Pattern | Description |
|--|---|
| <code>\b</code> | Begin the match at a word boundary. |
| <code>\w+</code> | Match one or more word characters followed by a white-space character. |
| <code>\d{1,2},</code> | Match either one or two decimal digits followed by a white-space character and a comma. |
| <code>\d{4}\b</code> | Match four decimal digits, and end the match at a word boundary. |
| <code>(?<!</code> <code>(Saturday Sunday))</code> | If the match is preceded by something other than the strings "Saturday" or "Sunday" followed by a space, the match is successful. |

Atomic groups

The following grouping construct represents an atomic group (known in some other regular expression engines as a nonbacktracking subexpression, an atomic

subexpression, or a once-only subexpression):

```
(?> subexpression )
```

Here, *subexpression* is any regular expression pattern.

Ordinarily, if a regular expression includes an optional or alternative matching pattern and a match does not succeed, the regular expression engine can branch in multiple directions to match an input string with a pattern. If a match is not found when it takes the first branch, the regular expression engine can back up or backtrack to the point where it took the first match and attempt the match using the second branch. This process can continue until all branches have been tried.

The `(?>subexpression)` language construct disables backtracking. The regular expression engine will match as many characters in the input string as it can. When no further match is possible, it will not backtrack to attempt alternate pattern matches. (That is, the subexpression matches only strings that would be matched by the subexpression alone; it does not attempt to match a string based on the subexpression and any subexpressions that follow it.)

This option is recommended if you know that backtracking will not succeed. Preventing the regular expression engine from performing unnecessary searching improves performance.

The following example illustrates how an atomic group modifies the results of a pattern match. The backtracking regular expression successfully matches a series of repeated characters followed by one more occurrence of the same character on a word boundary, but the nonbacktracking regular expression does not.

C#

```
using System;
using System.Text.RegularExpressions;

public class Example
{
    public static void Main()
    {
        string[] inputs = { "cccd.", "aaad", "aaaa" };
        string back = @"(\w)\1+\.\b";
        string noback = @"(?>(\w)\1+)\.\b";

        foreach (string input in inputs)
        {
            Match match1 = Regex.Match(input, back);
            Match match2 = Regex.Match(input, noback);
            Console.WriteLine("{0}: ", input);
```

```

        Console.Write("  Backtracking : ");
        if (match1.Success)
            Console.WriteLine(match1.Value);
        else
            Console.WriteLine("No match");

        Console.Write("  Nonbacktracking: ");
        if (match2.Success)
            Console.WriteLine(match2.Value);
        else
            Console.WriteLine("No match");
    }
}

// The example displays the following output:
//   cccd.:
//       Backtracking : cccd
//       Nonbacktracking: cccd
//   aaad:
//       Backtracking : aaad
//       Nonbacktracking: aaad
//   aaaa:
//       Backtracking : aaaa
//       Nonbacktracking: No match

```

The nonbacktracking regular expression `(?>(\w)\1+).\b` is defined as shown in the following table.

| Pattern | Description |
|-----------------------------|---|
| <code>(\w)</code> | Match a single word character and assign it to the first capturing group. |
| <code>\1+</code> | Match the value of the first captured substring one or more times. |
| <code>.</code> | Match any character. |
| <code>\b</code> | End the match on a word boundary. |
| <code>(?>(\w)\1+)</code> | Match one or more occurrences of a duplicated word character, but don't backtrack to match the last character on a word boundary. |

Grouping constructs and regular expression objects

Substrings that are matched by a regular expression capturing group are represented by [System.Text.RegularExpressions.Group](#) objects, which can be retrieved from the

`System.Text.RegularExpressions.GroupCollection` object that is returned by the `Match.Groups` property. The `GroupCollection` object is populated as follows:

- The first `Group` object in the collection (the object at index zero) represents the entire match.
- The next set of `Group` objects represent unnamed (numbered) capturing groups. They appear in the order in which they are defined in the regular expression, from left to right. The index values of these groups range from 1 to the number of unnamed capturing groups in the collection. (The index of a particular group is equivalent to its numbered backreference. For more information about backreferences, see [Backreference Constructs](#).)
- The final set of `Group` objects represent named capturing groups. They appear in the order in which they are defined in the regular expression, from left to right. The index value of the first named capturing group is one greater than the index of the last unnamed capturing group. If there are no unnamed capturing groups in the regular expression, the index value of the first named capturing group is one.

If you apply a quantifier to a capturing group, the corresponding `Group` object's `Capture.Value`, `Capture.Index`, and `Capture.Length` properties reflect the last substring that is captured by a capturing group. You can retrieve a complete set of substrings that are captured by groups that have quantifiers from the `CaptureCollection` object that is returned by the `Group.Captures` property.

The following example clarifies the relationship between the `Group` and `Capture` objects.

C#

```
using System;
using System.Text.RegularExpressions;

public class Example
{
    public static void Main()
    {
        string pattern = @"(\b(\w+)\W+)+";
        string input = "This is a short sentence.";
        Match match = Regex.Match(input, pattern);
        Console.WriteLine("Match: '{0}'", match.Value);
        for (int ctr = 1; ctr < match.Groups.Count; ctr++)
        {
            Console.WriteLine("    Group {0}: '{1}'", ctr,
match.Groups[ctr].Value);
            int capCtr = 0;
            foreach (Capture capture in match.Groups[ctr].Captures)
            {
                Console.WriteLine("        Capture {0}: '{1}'", capCtr,
capture.Value);
            }
        }
    }
}
```

```

        capCtr++;
    }
}
}

// The example displays the following output:
//      Match: 'This is a short sentence.'
//          Group 1: 'sentence.'
//              Capture 0: 'This '
//              Capture 1: 'is '
//              Capture 2: 'a '
//              Capture 3: 'short '
//              Capture 4: 'sentence.'
//          Group 2: 'sentence'
//              Capture 0: 'This'
//              Capture 1: 'is'
//              Capture 2: 'a'
//              Capture 3: 'short'
//              Capture 4: 'sentence'

```

The regular expression pattern `(\b(\w+)\W+)+` extracts individual words from a string. It is defined as shown in the following table.

| Pattern | Description |
|---------------------------|--|
| <code>\b</code> | Begin the match at a word boundary. |
| <code>(\w+)</code> | Match one or more word characters. Together, these characters form a word. This is the second capturing group. |
| <code>\W+</code> | Match one or more non-word characters. |
| <code>(\b(\w+)\W+)</code> | Match the pattern of one or more word characters followed by one or more non-word characters one or more times. This is the first capturing group. |

The second capturing group matches each word of the sentence. The first capturing group matches each word along with the punctuation and white space that follow the word. The [Group](#) object whose index is 2 provides information about the text matched by the second capturing group. The complete set of words captured by the capturing group are available from the [CaptureCollection](#) object returned by the [Group.Captures](#) property.

Quantifiers in Regular Expressions

Article • 08/12/2022

Quantifiers specify how many instances of a character, group, or character class must be present in the input for a match to be found. The following table lists the quantifiers supported by .NET:

| Greedy quantifier | Lazy quantifier | Description |
|-------------------|-----------------|--------------------------------|
| * | *? | Matches zero or more times. |
| + | +? | Matches one or more times. |
| ? | ?? | Matches zero or one time. |
| { n } | { n }? | Matches exactly n times. |
| { n , } | { n , }? | Matches at least n times. |
| { n , m } | { n , m }? | Matches from n to m times. |

The quantities `n` and `m` are integer constants. Ordinarily, quantifiers are greedy. They cause the regular expression engine to match as many occurrences of particular patterns as possible. Appending the `?` character to a quantifier makes it lazy. It causes the regular expression engine to match as few occurrences as possible. For a complete description of the difference between greedy and lazy quantifiers, see the section [Greedy and Lazy Quantifiers](#) later in this article.

ⓘ Important

Nesting quantifiers, such as the regular expression pattern `(a*)*`, can increase the number of comparisons that the regular expression engine must perform. The number of comparisons can increase as an exponential function of the number of characters in the input string. For more information about this behavior and its workarounds, see [Backtracking](#).

Regular Expression Quantifiers

The following sections list the quantifiers supported by .NET regular expressions:

ⓘ Note

If the *, +, ?, {, and } characters are encountered in a regular expression pattern, the regular expression engine interprets them as quantifiers or part of quantifier constructs unless they are included in a **character class**. To interpret these as literal characters outside a character class, you must escape them by preceding them with a backslash. For example, the string * in a regular expression pattern is interpreted as a literal asterisk ("*") character.

Match Zero or More Times: *

The * quantifier matches the preceding element zero or more times. It's equivalent to the {0,} quantifier. * is a greedy quantifier whose lazy equivalent is *?.

The following example illustrates this regular expression. Five of the nine digit-groups in the input string match the pattern and four (95, 929, 9219, and 9919) don't.

C#

```
string pattern = @"\b91*9*\b";
string input = "99 95 919 929 9119 9219 999 9919 91119";
foreach (Match match in Regex.Matches(input, pattern))
    Console.WriteLine("{0}' found at position {1}.", match.Value,
match.Index);

// The example displays the following output:
//      '99' found at position 0.
//      '919' found at position 6.
//      '9119' found at position 14.
//      '999' found at position 24.
//      '91119' found at position 33.
```

The regular expression pattern is defined as shown in the following table:

| Pattern | Description |
|---------|---|
| \b | Specifies that the match must start at a word boundary. |
| 91* | Matches a 9 followed by zero or more 1 characters. |
| 9* | Matches zero or more 9 characters. |
| \b | Specifies that the match must end at a word boundary. |

Match One or More Times: +

The `+` quantifier matches the preceding element one or more times. It's equivalent to `{1,}`. `+` is a greedy quantifier whose lazy equivalent is `+?`.

For example, the regular expression `\ban+\w*?\b` tries to match entire words that begin with the letter `a` followed by one or more instances of the letter `n`. The following example illustrates this regular expression. The regular expression matches the words `an`, `annual`, `announcement`, and `antique`, and correctly fails to match `autumn` and `all`.

C#

```
string pattern = @"\ban+\w*?\b";

string input = "Autumn is a great time for an annual announcement to all
antique collectors.";
foreach (Match match in Regex.Matches(input, pattern,
RegexOptions.IgnoreCase))
    Console.WriteLine("{0}' found at position {1}.", match.Value,
match.Index);

// The example displays the following output:
//      'an' found at position 27.
//      'annual' found at position 30.
//      'announcement' found at position 37.
//      'antique' found at position 57.
```

The regular expression pattern is defined as shown in the following table:

| Pattern | Description |
|-------------------|--|
| <code>\b</code> | Start at a word boundary. |
| <code>an+</code> | Matches an <code>a</code> followed by one or more <code>n</code> characters. |
| <code>\w*?</code> | Matches a word character zero or more times but as few times as possible. |
| <code>\b</code> | End at a word boundary. |

Match Zero or One Time: ?

The `?` quantifier matches the preceding element zero or one time. It's equivalent to `{0,1}`. `?` is a greedy quantifier whose lazy equivalent is `??`.

For example, the regular expression `\ban?\b` tries to match entire words that begin with the letter `a` followed by zero or one instance of the letter `n`. In other words, it tries to match the words `a` and `an`. The following example illustrates this regular expression:

C#

```
string pattern = @"\ban?\b";
string input = "An amiable animal with a large snout and an animated nose.";
foreach (Match match in Regex.Matches(input, pattern,
RegexOptions.IgnoreCase))
    Console.WriteLine("{0}' found at position {1}.", match.Value,
match.Index);

// The example displays the following output:
//      'An' found at position 0.
//      'a' found at position 23.
//      'an' found at position 42.
```

The regular expression pattern is defined as shown in the following table:

| Pattern | Description |
|---------|---|
| \b | Start at a word boundary. |
| an? | Matches an a followed by zero or one n character. |
| \b | End at a word boundary. |

Match Exactly n Times: {n}

The {n} quantifier matches the preceding element exactly *n* times, where *n* is any integer. {n} is a greedy quantifier whose lazy equivalent is {n}?.

For example, the regular expression \b\d+\,\d{3}\b tries to match a word boundary followed by one or more decimal digits followed by three decimal digits followed by a word boundary. The following example illustrates this regular expression:

C#

```
string pattern = @"\b\d+\,\d{3}\b";
string input = "Sales totaled 103,524 million in January, " +
              "106,971 million in February, but only " +
              "943 million in March.";
foreach (Match match in Regex.Matches(input, pattern))
    Console.WriteLine("{0}' found at position {1}.", match.Value,
match.Index);

// The example displays the following output:
//      '103,524' found at position 14.
//      '106,971' found at position 45.
```

The regular expression pattern is defined as shown in the following table:

| Pattern | Description |
|---------|-------------------------------------|
| \b | Start at a word boundary. |
| \d+ | Matches one or more decimal digits. |
| \, | Matches a comma character. |
| \d{3} | Matches three decimal digits. |
| \b | End at a word boundary. |

Match at Least n Times: {n,}

The `{n,}` quantifier matches the preceding element at least n times, where n is any integer. `{n,}` is a greedy quantifier whose lazy equivalent is `{n,}?`.

For example, the regular expression `\b\d{2,}\b\D+` tries to match a word boundary followed by at least two digits followed by a word boundary and a non-digit character. The following example illustrates this regular expression. The regular expression fails to match the phrase `"7 days"` because it contains just one decimal digit, but it successfully matches the phrases `"10 weeks"` and `"300 years"`.

C#

```
string pattern = @"\b\d{2,}\b\D+";
string input = "7 days, 10 weeks, 300 years";
foreach (Match match in Regex.Matches(input, pattern))
    Console.WriteLine("{0}' found at position {1}.", match.Value,
match.Index);

// The example displays the following output:
//      '10 weeks, ' found at position 8.
//      '300 years' found at position 18.
```

The regular expression pattern is defined as shown in the following table:

| Pattern | Description |
|---------|--------------------------------------|
| \b | Start at a word boundary. |
| \d{2,} | Matches at least two decimal digits. |
| \b | Matches a word boundary. |

| Pattern | Description |
|---------|---|
| \D+ | Matches at least one non-decimal digit. |

Match Between n and m Times: {n,m}

The `{n,m}` quantifier matches the preceding element at least n times, but no more than m times, where n and m are integers. `{n,m}` is a greedy quantifier whose lazy equivalent is `{n,m}?`.

In the following example, the regular expression `(00\s){2,4}` tries to match between two and four occurrences of two zero digits followed by a space. The final portion of the input string includes this pattern five times rather than the maximum of four. However, only the initial portion of this substring (up to the space and the fifth pair of zeros) matches the regular expression pattern.

C#

```
string pattern = @"(00\s){2,4}";
string input = "0x00 FF 00 00 18 17 FF 00 00 00 21 00 00 00 00 00 00";
foreach (Match match in Regex.Matches(input, pattern))
    Console.WriteLine("{0} found at position {1}.", match.Value,
match.Index);

// The example displays the following output:
//      '00 00 ' found at position 8.
//      '00 00 00 ' found at position 23.
//      '00 00 00 00 ' found at position 35.
```

Match Zero or More Times (Lazy Match): *?

The `*?` quantifier matches the preceding element zero or more times but as few times as possible. It's the lazy counterpart of the greedy quantifier `*`.

In the following example, the regular expression `\b\w*?oo\w*?\b` matches all words that contain the string `oo`.

C#

```
string pattern = @"\b\w*?oo\w*?\b";
string input = "woof root root rob oof woo woe";
foreach (Match match in Regex.Matches(input, pattern,
RegexOptions.IgnoreCase))
    Console.WriteLine("{0} found at position {1}.", match.Value,
match.Index);
```

```
// The example displays the following output:
//      'woof' found at position 0.
//      'root' found at position 5.
//      'root' found at position 10.
//      'oof' found at position 19.
//      'woo' found at position 23.
```

The regular expression pattern is defined as shown in the following table:

| Pattern | Description |
|---------|---|
| \b | Start at a word boundary. |
| \w*? | Matches zero or more word characters but as few characters as possible. |
| oo | Matches the string oo. |
| \w*? | Matches zero or more word characters but as few characters as possible. |
| \b | End on a word boundary. |

Match One or More Times (Lazy Match): +?

The +? quantifier matches the preceding element one or more times but as few times as possible. It's the lazy counterpart of the greedy quantifier +.

For example, the regular expression \b\w+?\b matches one or more characters separated by word boundaries. The following example illustrates this regular expression:

C#

```
string pattern = @"\b\w+?\b";
string input = "Aa Bb Cc Dd Ee Ff";
foreach (Match match in Regex.Matches(input, pattern))
    Console.WriteLine("{0} found at position {1}.", match.Value,
match.Index);

// The example displays the following output:
//      'Aa' found at position 0.
//      'Bb' found at position 3.
//      'Cc' found at position 6.
//      'Dd' found at position 9.
//      'Ee' found at position 12.
//      'Ff' found at position 15.
```

Match Zero or One Time (Lazy Match): ??

The `??` quantifier matches the preceding element zero or one time but as few times as possible. It's the lazy counterpart of the greedy quantifier `?`.

For example, the regular expression `^\s*(System.)??Console.WriteLine(?)\(\??` attempts to match the strings `Console.Write` or `Console.WriteLine`. The string can also include `System.` before `Console`, and it can be followed by an opening parenthesis. The string must be at the beginning of a line, although it can be preceded by white space. The following example illustrates this regular expression:

C#

```
string pattern = @"^\s*(System.)??Console.WriteLine(?)\(\??";
string input = "System.Console.WriteLine(\"Hello!\")\n" +
               "Console.Write(\"Hello!\")\n" +
               "Console.WriteLine(\"Hello!\")\n" +
               "Console.ReadLine()\n" +
               "    Console.WriteLine";
foreach (Match match in Regex.Matches(input, pattern,
                                         RegexOptions.IgnorePatternWhitespace |
                                         RegexOptions.IgnoreCase |
                                         RegexOptions.Multiline))
    Console.WriteLine("{0}' found at position {1}.", match.Value,
                      match.Index);

// The example displays the following output:
//      'System.Console.WriteLine' found at position 0.
//      'Console.WriteLine' found at position 36.
//      'Console.ReadLine' found at position 61.
//      '    Console.WriteLine' found at position 110.
```

The regular expression pattern is defined as shown in the following table:

| Pattern | Description |
|-----------------------------------|---|
| <code>^</code> | Matches the start of the input stream. |
| <code>\s*</code> | Matches zero or more white-space characters. |
| <code>(System.)??</code> | Matches zero or one occurrence of the string <code>System.</code> . |
| <code>Console.WriteLine(?)</code> | Matches the string <code>Console.WriteLine</code> . |
| <code>\(\??</code> | Matches zero or one occurrence of the opening parenthesis. |

Match Exactly n Times (Lazy Match): {n}?

The `{n}?` quantifier matches the preceding element exactly `n` times, where `n` is any integer. It's the lazy counterpart of the greedy quantifier `{n}`.

In the following example, the regular expression `\b(\w{3,}?\.){2}?\w{3,}?\b` is used to identify a website address. The expression matches `www.microsoft.com` and `msdn.microsoft.com` but doesn't match `mywebsite` or `mycompany.com`.

C#

```
string pattern = @"\b(\w{3,}?\.){2}?\w{3,}?\b";
string input = "www.microsoft.com msdn.microsoft.com mywebsite
mycompany.com";
foreach (Match match in Regex.Matches(input, pattern))
    Console.WriteLine("{0}' found at position {1}.", match.Value,
match.Index);

// The example displays the following output:
//      'www.microsoft.com' found at position 0.
//      'msdn.microsoft.com' found at position 18.
```

The regular expression pattern is defined as shown in the following table:

| Pattern | Description |
|--------------------------|---|
| <code>\b</code> | Start at a word boundary. |
| <code>(\w{3,}?\.)</code> | Matches at least three word-characters but as few characters as possible, followed by a dot or period character. This pattern is the first capturing group. |
| <code>{2}?</code> | Matches the pattern in the first group two times but as few times as possible. |
| <code>\b</code> | End the match on a word boundary. |

Match at Least n Times (Lazy Match): `{n,}?`

The `{n,}?` quantifier matches the preceding element at least `n` times, where `n` is any integer but as few times as possible. It's the lazy counterpart of the greedy quantifier `{n,}`.

See the example for the `{n}?` quantifier in the previous section for an illustration. The regular expression in that example uses the `{n,}?` quantifier to match a string that has at least three characters followed by a period.

Match Between n and m Times (Lazy Match): `{n,m}?`

The `{n,m}?` quantifier matches the preceding element between `n` and `m` times, where `n` and `m` are integers but as few times as possible. It's the lazy counterpart of the greedy quantifier `{n,m}`.

In the following example, the regular expression `\b[A-Z](\w*\?\s*){1,10}[.!\?]` matches sentences that contain between 1 and 10 words. It matches all the sentences in the input string except for one sentence that contains 18 words.

C#

```
string pattern = @"\b[A-Z](\w*\?\s*){1,10}[.!\?]";
string input = "Hi. I am writing a short note. Its purpose is " +
                "to test a regular expression that attempts to find " +
                "sentences with ten or fewer words. Most sentences " +
                "in this note are short.";
foreach (Match match in Regex.Matches(input, pattern))
    Console.WriteLine("{0} found at position {1}.", match.Value,
match.Index);

// The example displays the following output:
//      'Hi.' found at position 0.
//      'I am writing a short note.' found at position 4.
//      'Most sentences in this note are short.' found at position 132.
```

The regular expression pattern is defined as shown in the following table:

| Pattern | Description |
|------------------------|---|
| <code>\b</code> | Start at a word boundary. |
| <code>[A-Z]</code> | Matches an uppercase character from A to Z. |
| <code>(\w*?\s*)</code> | Matches zero or more word characters, followed by one or more white-space characters but as few times as possible. This pattern is the first capturing group. |
| <code>{1,10}</code> | Matches the previous pattern between 1 and 10 times. |
| <code>[.!\?]</code> | Matches any one of the punctuation characters <code>.</code> , <code>!</code> , or <code>?</code> . |

Greedy and Lazy Quantifiers

Some quantifiers have two versions:

- A greedy version.

A greedy quantifier tries to match an element as many times as possible.

- A non-greedy (or lazy) version.

A non-greedy quantifier tries to match an element as few times as possible. You can turn a greedy quantifier into a lazy quantifier by adding a `?`.

Consider a regular expression that's intended to extract the last four digits from a string of numbers, such as a credit card number. The version of the regular expression that uses the `*` greedy quantifier is `\b.*([0-9]{4})\b`. However, if a string contains two numbers, this regular expression matches the last four digits of the second number only, as the following example shows:

```
C#  
  
string greedyPattern = @"\b.*([0-9]{4})\b";  
string input1 = "1112223333 3992991999";  
foreach (Match match in Regex.Matches(input1, greedyPattern))  
    Console.WriteLine("Account ending in *****{0}.", match.Groups[1].Value);  
  
// The example displays the following output:  
//      Account ending in *****1999.
```

The regular expression fails to match the first number because the `*` quantifier tries to match the previous element as many times as possible in the entire string, and so it finds its match at the end of the string.

This behavior isn't the desired one. Instead, you can use the `*?` lazy quantifier to extract digits from both numbers, as the following example shows:

```
C#  
  
string lazyPattern = @"\b.*?([0-9]{4})\b";  
string input2 = "1112223333 3992991999";  
foreach (Match match in Regex.Matches(input2, lazyPattern))  
    Console.WriteLine("Account ending in *****{0}.", match.Groups[1].Value);  
  
// The example displays the following output:  
//      Account ending in *****3333.  
//      Account ending in *****1999.
```

In most cases, regular expressions with greedy and lazy quantifiers return the same matches. They most commonly return different results when they're used with the wildcard `(.)` metacharacter, which matches any character.

Quantifiers and Empty Matches

The quantifiers `*`, `+`, and `{n,m}` and their lazy counterparts never repeat after an empty match when the minimum number of captures has been found. This rule prevents quantifiers from entering infinite loops on empty subexpression matches when the maximum number of possible group captures is infinite or near infinite.

For example, the following code shows the result of a call to the `Regex.Match` method with the regular expression pattern `(a?)*`, which matches zero or one `a` character zero or more times. The single capturing group captures each `a` and `String.Empty`, but there's no second empty match because the first empty match causes the quantifier to stop repeating.

C#

```
using System;
using System.Text.RegularExpressions;

public class Example
{
    public static void Main()
    {
        string pattern = "(a?)*";
        string input = "aaabbb";
        Match match = Regex.Match(input, pattern);
        Console.WriteLine("Match: '{0}' at index {1}",
                           match.Value, match.Index);
        if (match.Groups.Count > 1) {
            GroupCollection groups = match.Groups;
            for (int grpCtr = 1; grpCtr <= groups.Count - 1; grpCtr++) {
                Console.WriteLine("    Group {0}: '{1}' at index {2}",
                                  grpCtr,
                                  groups[grpCtr].Value,
                                  groups[grpCtr].Index);
                int captureCtr = 0;
                foreach (Capture capture in groups[grpCtr].Captures) {
                    captureCtr++;
                    Console.WriteLine("        Capture {0}: '{1}' at index {2}",
                                      captureCtr, capture.Value, capture.Index);
                }
            }
        }
    }
}

// The example displays the following output:
//      Match: 'aaa' at index 0
//          Group 1: '' at index 3
//              Capture 1: 'a' at index 0
//              Capture 2: 'a' at index 1
//              Capture 3: 'a' at index 2
//              Capture 4: '' at index 3
```

To see the practical difference between a capturing group that defines a minimum and a maximum number of captures and one that defines a fixed number of captures, consider the regular expression patterns `(a\1|(?(1)\1)){0,2}` and `(a\1|(?(1)\1)){2}`. Both regular expressions consist of a single capturing group, which is defined in the following table:

| Pattern | Description |
|--------------------|--|
| <code>(a\1</code> | Either matches <code>a</code> along with the value of the first captured group ... |
| <code> (?(1</code> | ... or tests whether the first captured group has been defined. The <code>(?(1)</code> construct doesn't define a capturing group. |
| <code>\1))</code> | If the first captured group exists, match its value. If the group doesn't exist, the group will match String.Empty . |

The first regular expression tries to match this pattern between zero and two times; the second, exactly two times. Because the first pattern reaches its minimum number of captures with its first capture of [String.Empty](#), it never repeats to try to match `a\1`. The `{0,2}` quantifier allows only empty matches in the last iteration. In contrast, the second regular expression does match `a` because it evaluates `a\1` a second time. The minimum number of iterations, 2, forces the engine to repeat after an empty match.

C#

```
using System;
using System.Text.RegularExpressions;

public class Example
{
    public static void Main()
    {
        string pattern, input;

        pattern = @"(a\1|(?(1)\1)){0,2}";
        input = "aaabbb";

        Console.WriteLine("Regex pattern: {0}", pattern);
        Match match = Regex.Match(input, pattern);
        Console.WriteLine("Match: '{0}' at position {1}.",
                          match.Value, match.Index);
        if (match.Groups.Count > 1) {
            for (int groupCtr = 1; groupCtr <= match.Groups.Count - 1;
groupCtr++)
            {
                Group group = match.Groups[groupCtr];
                Console.WriteLine("  Group: {0}: '{1}' at position {2}.",
                                  groupCtr, group.Value, group.Index);
                int captureCtr = 0;
```

```

        foreach (Capture capture in group.Captures) {
            captureCtr++;
            Console.WriteLine("    Capture: {0}: '{1}' at position
{2}.",
                                captureCtr, capture.Value, capture.Index);
        }
    }
}
Console.WriteLine();

pattern = @"(a\1|(?(1)\1)){2}";
Console.WriteLine("Regex pattern: {0}", pattern);
match = Regex.Match(input, pattern);
Console.WriteLine("Matched '{0}' at position {1}.",
                    match.Value, match.Index);
if (match.Groups.Count > 1) {
    for (int groupCtr = 1; groupCtr <= match.Groups.Count - 1;
groupCtr++)
    {
        Group group = match.Groups[groupCtr];
        Console.WriteLine("    Group: {0}: '{1}' at position {2}.",
                            groupCtr, group.Value, group.Index);
        int captureCtr = 0;
        foreach (Capture capture in group.Captures) {
            captureCtr++;
            Console.WriteLine("        Capture: {0}: '{1}' at position
{2}.",
                                captureCtr, capture.Value, capture.Index);
        }
    }
}
}

// The example displays the following output:
//     Regex pattern: (a\1|(?(1)\1)){0,2}
//     Match: '' at position 0.
//         Group: 1: '' at position 0.
//             Capture: 1: '' at position 0.

//
//     Regex pattern: (a\1|(?(1)\1)){2}
//     Matched 'a' at position 0.
//         Group: 1: 'a' at position 0.
//             Capture: 1: '' at position 0.
//             Capture: 2: 'a' at position 0.

```

Backreference Constructs in Regular Expressions

Article • 09/15/2021

Backreferences provide a convenient way to identify a repeated character or substring within a string. For example, if the input string contains multiple occurrences of an arbitrary substring, you can match the first occurrence with a capturing group, and then use a backreference to match subsequent occurrences of the substring.

ⓘ Note

A separate syntax is used to refer to named and numbered capturing groups in replacement strings. For more information, see [Substitutions](#).

.NET defines separate language elements to refer to numbered and named capturing groups. For more information about capturing groups, see [Grouping Constructs](#).

Numbered Backreferences

A numbered backreference uses the following syntax:

`\ number`

where *number* is the ordinal position of the capturing group in the regular expression. For example, `\4` matches the contents of the fourth capturing group. If *number* is not defined in the regular expression pattern, a parsing error occurs, and the regular expression engine throws an [ArgumentException](#). For example, the regular expression `\b(\w+)\s\1` is valid, because `(\w+)` is the first and only capturing group in the expression. On the other hand, `\b(\w+)\s\2` is invalid and throws an argument exception, because there is no capturing group numbered `\2`. In addition, if *number* identifies a capturing group in a particular ordinal position, but that capturing group has been assigned a numeric name different than its ordinal position, the regular expression parser also throws an [ArgumentException](#).

Note the ambiguity between octal escape codes (such as `\16`) and `\ number` backreferences that use the same notation. This ambiguity is resolved as follows:

- The expressions `\1` through `\9` are always interpreted as backreferences, and not as octal codes.

- If the first digit of a multidigit expression is 8 or 9 (such as `\80` or `\91`), the expression is interpreted as a literal.
- Expressions from `\10` and greater are considered backreferences if there is a backreference corresponding to that number; otherwise, they are interpreted as octal codes.
- If a regular expression contains a backreference to an undefined group number, a parsing error occurs, and the regular expression engine throws an [ArgumentException](#).

If the ambiguity is a problem, you can use the `\k<name>` notation, which is unambiguous and cannot be confused with octal character codes. Similarly, hexadecimal codes such as `\xdd` are unambiguous and cannot be confused with backreferences.

The following example finds doubled word characters in a string. It defines a regular expression, `(\w)\1`, which consists of the following elements.

| Element | Description |
|-------------------|--|
| <code>(\w)</code> | Match a word character and assign it to the first capturing group. |
| <code>\1</code> | Match the next character that is the same as the value of the first capturing group. |

C#

```
using System;
using System.Text.RegularExpressions;

public class Example
{
    public static void Main()
    {
        string pattern = @"(\w)\1";
        string input = "trellis llama webbing dresser swagger";
        foreach (Match match in Regex.Matches(input, pattern))
            Console.WriteLine("Found '{0}' at position {1}.",
                match.Value, match.Index);
    }
}
// The example displays the following output:
//      Found 'll' at position 3.
//      Found 'll' at position 8.
//      Found 'bb' at position 16.
//      Found 'ss' at position 25.
//      Found 'gg' at position 33.
```

Named Backreferences

A named backreference is defined by using the following syntax:

```
\k< name >
```

or:

```
\k' name '
```

where *name* is the name of a capturing group defined in the regular expression pattern. If *name* is not defined in the regular expression pattern, a parsing error occurs, and the regular expression engine throws an [ArgumentException](#).

The following example finds doubled word characters in a string. It defines a regular expression, `(?<char>\w)\k<char>`, which consists of the following elements.

| Element | Description |
|---|--|
| <code>(?</code> <code><char>\w)</code> | Match a word character and assign it to a capturing group named <code>char</code> . |
| <code>\k<char></code> | Match the next character that is the same as the value of the <code>char</code> capturing group. |

C#

```
using System;
using System.Text.RegularExpressions;

public class Example
{
    public static void Main()
    {
        string pattern = @"(?<char>\w)\k<char>";
        string input = "trellis llama webbing dresser swagger";
        foreach (Match match in Regex.Matches(input, pattern))
            Console.WriteLine("Found '{0}' at position {1}.",
                match.Value, match.Index);
    }
}
// The example displays the following output:
//      Found 'll' at position 3.
//      Found 'll' at position 8.
//      Found 'bb' at position 16.
//      Found 'ss' at position 25.
//      Found 'gg' at position 33.
```

Named numeric backreferences

In a named backreference with `\k<name>`, *name* can also be the string representation of a number. For example, the following example uses the regular expression `(?<2>\w)\k<2>` to find doubled word characters in a string. In this case, the example defines a capturing group that is explicitly named "2", and the backreference is correspondingly named "2".

```
C#  
  
using System;  
using System.Text.RegularExpressions;  
  
public class Example  
{  
    public static void Main()  
    {  
        string pattern = @"(?<2>\w)\k<2>";  
        string input = "trellis llama webbing dresser swagger";  
        foreach (Match match in Regex.Matches(input, pattern))  
            Console.WriteLine("Found '{0}' at position {1}.",  
                match.Value, match.Index);  
    }  
}  
// The example displays the following output:  
//     Found 'll' at position 3.  
//     Found 'll' at position 8.  
//     Found 'bb' at position 16.  
//     Found 'ss' at position 25.  
//     Found 'gg' at position 33.
```

If *name* is the string representation of a number, and no capturing group has that name, `\k<name>` is the same as the backreference `\number`, where *number* is the ordinal position of the capture. In the following example, there is a single capturing group named `char`. The backreference construct refers to it as `\k<1>`. As the output from the example shows, the call to the `Regex.IsMatch` succeeds because `char` is the first capturing group.

```
C#  
  
using System;  
using System.Text.RegularExpressions;  
  
public class Example  
{  
    public static void Main()  
    {  
        Console.WriteLine(Regex.IsMatch("aa", @"(?<char>\w)\k<1>"));  
        // Displays "True".  
    }  
}
```

```
}
```

However, if *name* is the string representation of a number and the capturing group in that position has been explicitly assigned a numeric name, the regular expression parser cannot identify the capturing group by its ordinal position. Instead, it throws an [ArgumentException](#). The only capturing group in the following example is named "2". Because the `\k` construct is used to define a backreference named "1", the regular expression parser is unable to identify the first capturing group and throws an exception.

```
C#
```

```
using System;
using System.Text.RegularExpressions;

public class Example
{
    public static void Main()
    {
        Console.WriteLine(Regex.IsMatch("aa", @"\(?<2>\w)\k<1>"));
        // Throws an ArgumentException.
    }
}
```

What Backreferences Match

A backreference refers to the most recent definition of a group (the definition most immediately to the left, when matching left to right). When a group makes multiple captures, a backreference refers to the most recent capture.

The following example includes a regular expression pattern, `(?<1>a)(?<1>\1b)*`, which redefines the `\1` named group. The following table describes each pattern in the regular expression.

| Pattern | Description |
|-------------------------------|--|
| <code>(?<1>a)</code> | Match the character "a" and assign the result to the capturing group named <code>1</code> . |
| <code>(?<1>\1b)*</code> | Match zero or more occurrences of the group named <code>1</code> along with a "b", and assign the result to the capturing group named <code>1</code> . |

```
C#
```

```

using System;
using System.Text.RegularExpressions;

public class Example
{
    public static void Main()
    {
        string pattern = @"(?<1>a)(?<1>\1b)*";
        string input = "aababb";
        foreach (Match match in Regex.Matches(input, pattern))
        {
            Console.WriteLine("Match: " + match.Value);
            foreach (Group group in match.Groups)
                Console.WriteLine("    Group: " + group.Value);
        }
    }
}

// The example displays the following output:
//      Group: aababb
//      Group: abb

```

In comparing the regular expression with the input string ("aababb"), the regular expression engine performs the following operations:

1. It starts at the beginning of the string, and successfully matches "a" with the expression `(?<1>a)`. The value of the `1` group is now "a".
2. It advances to the second character, and successfully matches the string "ab" with the expression `\1b`, or "ab". It then assigns the result, "ab" to `\1`.
3. It advances to the fourth character. The expression `(?<1>\1b)*` is to be matched zero or more times, so it successfully matches the string "abb" with the expression `\1b`. It assigns the result, "abb", back to `\1`.

In this example, `*` is a looping quantifier -- it is evaluated repeatedly until the regular expression engine cannot match the pattern it defines. Looping quantifiers do not clear group definitions.

If a group has not captured any substrings, a backreference to that group is undefined and never matches. This is illustrated by the regular expression pattern `\b(\p{Lu}{2})(\d{2})?(\p{Lu}{2})\b`, which is defined as follows:

| Pattern | Description |
|-----------------|-------------------------------------|
| <code>\b</code> | Begin the match on a word boundary. |

| Pattern | Description |
|-------------|---|
| (\p{Lu}{2}) | Match two uppercase letters. This is the first capturing group. |
| (\d{2})? | Match zero or one occurrence of two decimal digits. This is the second capturing group. |
| (\p{Lu}{2}) | Match two uppercase letters. This is the third capturing group. |
| \b | End the match on a word boundary. |

An input string can match this regular expression even if the two decimal digits that are defined by the second capturing group are not present. The following example shows that even though the match is successful, an empty capturing group is found between two successful capturing groups.

C#

```

using System;
using System.Text.RegularExpressions;

public class Example
{
    public static void Main()
    {
        string pattern = @"\b(\p{Lu}{2})(\d{2})?(\p{Lu}{2})\b";
        string[] inputs = { "AA22ZZ", "AABB" };
        foreach (string input in inputs)
        {
            Match match = Regex.Match(input, pattern);
            if (match.Success)
            {
                Console.WriteLine("Match in {0}: {1}", input, match.Value);
                if (match.Groups.Count > 1)
                {
                    for (int ctr = 1; ctr <= match.Groups.Count - 1; ctr++)
                    {
                        if (match.Groups[ctr].Success)
                            Console.WriteLine("Group {0}: {1}",
                                ctr, match.Groups[ctr].Value);
                        else
                            Console.WriteLine("Group {0}: <no match>", ctr);
                    }
                }
                Console.WriteLine();
            }
        }
    }
}

```

```
// The example displays the following output:  
//      Match in AA22ZZ: AA22ZZ  
//          Group 1: AA  
//          Group 2: 22  
//          Group 3: ZZ  
//  
//      Match in AABB: AABB  
//          Group 1: AA  
//          Group 2: <no match>  
//          Group 3: BB
```

Alternation Constructs in Regular Expressions

Article • 01/14/2022

Alternation constructs modify a regular expression to enable either/or or conditional matching. .NET supports three alternation constructs:

- Pattern matching with |
- Conditional matching with (?(expression)yes|no)
- Conditional matching based on a valid captured group

Pattern Matching with |

You can use the vertical bar (|) character to match any one of a series of patterns, where the | character separates each pattern.

Like the positive character class, the | character can be used to match any one of a number of single characters. The following example uses both a positive character class and either/or pattern matching with the | character to locate occurrences of the words "gray" or "grey" in a string. In this case, the | character produces a regular expression that is more verbose.

C#

```
using System;
using System.Text.RegularExpressions;

public class Example
{
    public static void Main()
    {
        // Regular expression using character class.
        string pattern1 = @"\bgr[ae]y\b";
        // Regular expression using either/or.
        string pattern2 = @"\bgr(a|e)y\b";

        string input = "The gray wolf blended in among the grey rocks.";
        foreach (Match match in Regex.Matches(input, pattern1))
            Console.WriteLine("{0} found at position {1}",
                match.Value, match.Index);
        Console.WriteLine();
        foreach (Match match in Regex.Matches(input, pattern2))
            Console.WriteLine("{0} found at position {1}",
                match.Value, match.Index);
    }
}
```

```

}

// The example displays the following output:
//      'gray' found at position 4
//      'grey' found at position 35
//
//      'gray' found at position 4
//      'grey' found at position 35

```

The regular expression that uses the `|` character, `\bgr(a|e)y\b`, is interpreted as shown in the following table:

| Pattern | Description |
|--------------------|---------------------------------|
| <code>\b</code> | Start at a word boundary. |
| <code>gr</code> | Match the characters "gr". |
| <code>(a e)</code> | Match either an "a" or an "e". |
| <code>y\b</code> | Match a "y" on a word boundary. |

The `|` character can also be used to perform an either/or match with multiple characters or subexpressions, which can include any combination of character literals and regular expression language elements. (The character class does not provide this functionality.) The following example uses the `|` character to extract either a U.S. Social Security Number (SSN), which is a 9-digit number with the format *ddd-dd-dddd*, or a U.S. Employer Identification Number (EIN), which is a 9-digit number with the format *dd-ddddddd*.

C#

```

using System;
using System.Text.RegularExpressions;

public class Example
{
    public static void Main()
    {
        string pattern = @"\b(\d{2}-\d{7}|\d{3}-\d{2}-\d{4})\b";
        string input = "01-9999999 020-333333 777-88-9999";
        Console.WriteLine("Matches for {0}:", pattern);
        foreach (Match match in Regex.Matches(input, pattern))
            Console.WriteLine("  {0} at position {1}", match.Value,
match.Index);
    }
}

// The example displays the following output:
//      Matches for \b(\d{2}-\d{7}|\d{3}-\d{2}-\d{4})\b:

```

```
//          01-9999999 at position 0
//          777-88-9999 at position 22
```

The regular expression `\b(\d{2}-\d{7}|\d{3}-\d{2}-\d{4})\b` is interpreted as shown in the following table:

| Pattern | Description |
|--|--|
| <code>\b</code> | Start at a word boundary. |
| <code>(\d{2}-\d{7} \d{3}-\d{2}-\d{4})</code> | Match either of the following: two decimal digits followed by a hyphen followed by seven decimal digits; or three decimal digits, a hyphen, two decimal digits, another hyphen, and four decimal digits. |
| <code>\b</code> | End the match at a word boundary. |

Conditional matching with an expression

This language element attempts to match one of two patterns depending on whether it can match an initial pattern. Its syntax is:

```
(?(<code>expression</code>) yes )
```

or

```
(?(<code>expression</code>) yes | no )
```

where *expression* is the initial pattern to match, *yes* is the pattern to match if *expression* is matched, and *no* is the optional pattern to match if *expression* is not matched (if a *no* pattern is not provided, it's equivalent to an empty *no*). The regular expression engine treats *expression* as a zero-width assertion; that is, the regular expression engine does not advance in the input stream after it evaluates *expression*. Therefore, this construct is equivalent to the following:

```
(?(<code>?= expression</code>) yes | no )
```

where `(?= expression)` is a zero-width assertion construct. (For more information, see [Grouping Constructs](#).) Because the regular expression engine interprets *expression* as an anchor (a zero-width assertion), *expression* must either be a zero-width assertion (for more information, see [Anchors](#)) or a subexpression that is also contained in *yes*. Otherwise, the *yes* pattern cannot be matched.

 **Note**

If *expression* is a named or numbered capturing group, the alternation construct is interpreted as a capture test; for more information, see the next section, **Conditional Matching Based on a Valid Capture Group**. In other words, the regular expression engine does not attempt to match the captured substring, but instead tests for the presence or absence of the group.

The following example is a variation of the example that appears in the [Either/Or Pattern Matching with |](#) section. It uses conditional matching to determine whether the first three characters after a word boundary are two digits followed by a hyphen. If they are, it attempts to match a U.S. Employer Identification Number (EIN). If not, it attempts to match a U.S. Social Security Number (SSN).

C#

```
using System;
using System.Text.RegularExpressions;

public class Example
{
    public static void Main()
    {
        string pattern = @"\b(?:(\d{2}-)\d{2}-\d{7}|\d{3}-\d{2}-\d{4})\b";
        string input = "01-9999999 020-333333 777-88-9999";
        Console.WriteLine("Matches for {0}:", pattern);
        foreach (Match match in Regex.Matches(input, pattern))
            Console.WriteLine("    {0} at position {1}", match.Value,
match.Index);
    }
}
// The example displays the following output:
//      Matches for \b(?:(\d{2}-)\d{2}-\d{7}|\d{3}-\d{2}-\d{4})\b:
//          01-9999999 at position 0
//          777-88-9999 at position 22
```

The regular expression pattern `\b(?:(\d{2}-)\d{2}-\d{7}|\d{3}-\d{2}-\d{4})\b` is interpreted as shown in the following table:

| Pattern | Description |
|--------------------------|--|
| <code>\b</code> | Start at a word boundary. |
| <code>(?:(\d{2}-)</code> | Determine whether the next three characters consist of two digits followed by a hyphen. |
| <code>\d{2}-\d{7}</code> | If the previous pattern matches, match two digits followed by a hyphen followed by seven digits. |

| Pattern | Description |
|-------------------|--|
| \d{3}-\d{2}-\d{4} | If the previous pattern does not match, match three decimal digits, a hyphen, two decimal digits, another hyphen, and four decimal digits. |
| \b | Match a word boundary. |

Conditional matching based on a valid captured group

This language element attempts to match one of two patterns depending on whether it has matched a specified capturing group. Its syntax is:

(?(\ *name*) *yes*)

or

(?(\ *name*) *yes* | *no*)

or

(?(\ *number*) *yes*)

or

(?(\ *number*) *yes* | *no*)

where *name* is the name and *number* is the number of a capturing group, *yes* is the expression to match if *name* or *number* has a match, and *no* is the optional expression to match if it does not (if a *no* pattern is not provided, it's equivalent to an empty *no*).

If *name* does not correspond to the name of a capturing group that is used in the regular expression pattern, the alternation construct is interpreted as an expression test, as explained in the previous section. Typically, this means that *expression* evaluates to `false`. If *number* does not correspond to a numbered capturing group that is used in the regular expression pattern, the regular expression engine throws an [ArgumentException](#).

The following example is a variation of the example that appears in the [Either/Or Pattern Matching with |](#) section. It uses a capturing group named `n2` that consists of two digits followed by a hyphen. The alternation construct tests whether this capturing group has been matched in the input string. If it has, the alternation construct attempts to match the last seven digits of a nine-digit U.S. Employer Identification Number (EIN). If it has not, it attempts to match a nine-digit U.S. Social Security Number (SSN).

C#

```
using System;
using System.Text.RegularExpressions;

public class Example
{
    public static void Main()
    {
        string pattern = @"\b(?:<n2>\d{2}-)?(?:n2)\d{7}|\d{3}-\d{2}-\d{4})\b";
        string input = "01-9999999 020-333333 777-88-9999";
        Console.WriteLine("Matches for {0}:", pattern);
        foreach (Match match in Regex.Matches(input, pattern))
            Console.WriteLine("    {0} at position {1}", match.Value,
match.Index);
    }
}
// The example displays the following output:
//      Matches for \b(?:<n2>\d{2}-)?(?:n2)\d{7}|\d{3}-\d{2}-\d{4})\b:
//          01-9999999 at position 0
//          777-88-9999 at position 22
```

The regular expression pattern `\b(?:<n2>\d{2}-)?(?:n2)\d{7}|\d{3}-\d{2}-\d{4})\b` is interpreted as shown in the following table:

| Pattern | Description |
|------------------------------------|--|
| <code>\b</code> | Start at a word boundary. |
| <code>(?:<n2>\d{2}-)?</code> | Match zero or one occurrence of two digits followed by a hyphen. Name this capturing group <code>n2</code> . |
| <code>(?:n2)</code> | Test whether <code>n2</code> was matched in the input string. |
| <code>\d{7}</code> | If <code>n2</code> was matched, match seven decimal digits. |
| <code> \d{3}-\d{2}-\d{4}</code> | If <code>n2</code> was not matched, match three decimal digits, a hyphen, two decimal digits, another hyphen, and four decimal digits. |
| <code>\b</code> | Match a word boundary. |

A variation of this example that uses a numbered group instead of a named group is shown in the following example. Its regular expression pattern is `\b(\d{2}-)?(?:1)\d{7}|\d{3}-\d{2}-\d{4})\b`.

C#

```
using System;
using System.Text.RegularExpressions;
```

```
public class Example
{
    public static void Main()
    {
        string pattern = @"\b(\d{2}-)?(?:1)\d{7}|\d{3}-\d{2}-\d{4})\b";
        string input = "01-9999999 020-333333 777-88-9999";
        Console.WriteLine("Matches for {0}:", pattern);
        foreach (Match match in Regex.Matches(input, pattern))
            Console.WriteLine("  {0} at position {1}", match.Value,
match.Index);
    }
}
// The example display the following output:
//      Matches for \b(\d{2}-)?(?:1)\d{7}|\d{3}-\d{2}-\d{4})\b:
//      01-9999999 at position 0
//      777-88-9999 at position 22
```

Substitutions in Regular Expressions

Article • 09/15/2021

Substitutions are language elements that are recognized only within replacement patterns. They use a regular expression pattern to define all or part of the text that is to replace matched text in the input string. The replacement pattern can consist of one or more substitutions along with literal characters. Replacement patterns are provided to overloads of the [Regex.Replace](#) method that have a `replacement` parameter and to the [Match.Result](#) method. The methods replace the matched pattern with the pattern that is defined by the `replacement` parameter.

.NET defines the substitution elements listed in the following table.

| Substitution | Description |
|--------------------------|---|
| <code>\$ number</code> | Includes the last substring matched by the capturing group that is identified by <i>number</i> , where <i>number</i> is a decimal value, in the replacement string. For more information, see Substituting a Numbered Group . |
| <code> \${ name }</code> | Includes the last substring matched by the named group that is designated by <code>(?<i>name</i>)</code> in the replacement string. For more information, see Substituting a Named Group . |
| <code> \$\$</code> | Includes a single "\$" literal in the replacement string. For more information, see Substituting a "\$" Symbol . |
| <code> \$&</code> | Includes a copy of the entire match in the replacement string. For more information, see Substituting the Entire Match . |
| <code> \$`</code> | Includes all the text of the input string before the match in the replacement string. For more information, see Substituting the Text before the Match . |
| <code> \$'</code> | Includes all the text of the input string after the match in the replacement string. For more information, see Substituting the Text after the Match . |
| <code> \$+</code> | Includes the last group captured in the replacement string. For more information, see Substituting the Last Captured Group . |
| <code> \$_</code> | Includes the entire input string in the replacement string. For more information, see Substituting the Entire Input String . |

Substitution Elements and Replacement Patterns

Substitutions are the only special constructs recognized in a replacement pattern. None of the other regular expression language elements, including character escapes and the period (.), which matches any character, are supported. Similarly, substitution language elements are recognized only in replacement patterns and are never valid in regular expression patterns.

The only character that can appear either in a regular expression pattern or in a substitution is the \$ character, although it has a different meaning in each context. In a regular expression pattern, \$ is an anchor that matches the end of the string. In a replacement pattern, \$ indicates the beginning of a substitution.

Note

For functionality similar to a replacement pattern within a regular expression, use a backreference. For more information about backreferences, see [Backreference Constructs](#).

Substituting a Numbered Group

The \$*number* language element includes the last substring matched by the *number* capturing group in the replacement string, where *number* is the index of the capturing group. For example, the replacement pattern \${1} indicates that the matched substring is to be replaced by the first captured group. For more information about numbered capturing groups, see [Grouping Constructs](#).

All digits that follow \$ are interpreted as belonging to the *number* group. If this is not your intent, you can substitute a named group instead. For example, you can use the replacement string \${1}1 instead of \${1}1 to define the replacement string as the value of the first captured group along with the number "1". For more information, see [Substituting a Named Group](#).

Capturing groups that are not explicitly assigned names using the (?<*name*>) syntax are numbered from left to right starting at one. Named groups are also numbered from left to right, starting at one greater than the index of the last unnamed group. For example, in the regular expression (\w)(?<digit>\d), the index of the digit named group is 2.

If *number* does not specify a valid capturing group defined in the regular expression pattern, \${*number*} is interpreted as a literal character sequence that is used to replace each match.

The following example uses the `$number` substitution to strip the currency symbol from a decimal value. It removes currency symbols found at the beginning or end of a monetary value, and recognizes the two most common decimal separators ("." and ",").

C#

```
using System;
using System.Text.RegularExpressions;

public class Example
{
    public static void Main()
    {
        string pattern = @"\p{Sc}*(\s?\d+[.,]?\d*)\p{Sc}*";
        string replacement = "$1";
        string input = "$16.32 12.19 €16.29 €18.29 €18,29";
        string result = Regex.Replace(input, pattern, replacement);
        Console.WriteLine(result);
    }
}
// The example displays the following output:
//      16.32 12.19 16.29 18.29  18,29
```

The regular expression pattern `\p{Sc}*(\s?\d+[.,]?\d*)\p{Sc}* is defined as shown in the following table.`

| Pattern | Description |
|------------------------------------|--|
| <code>\p{Sc}*</code> | Match zero or more currency symbol characters. |
| <code>\s?</code> | Match zero or one white-space characters. |
| <code>\d+</code> | Match one or more decimal digits. |
| <code>[.,]?</code> | Match zero or one period or comma. |
| <code>\d*</code> | Match zero or more decimal digits. |
| <code>(\s?\d+ [.,]?\d*)</code> | Match a white space followed by one or more decimal digits, followed by zero or one period or comma, followed by zero or more decimal digits. This is the first capturing group. Because the replacement pattern is <code>\$1</code> , the call to the <code>Regex.Replace</code> method replaces the entire matched substring with this captured group. |

Substituting a Named Group

The `${name}` language element substitutes the last substring matched by the `name` capturing group, where `name` is the name of a capturing group defined by the `(?)`

`<name>`) language element. For more information about named capturing groups, see [Grouping Constructs](#).

If *name* doesn't specify a valid named capturing group defined in the regular expression pattern but consists of digits, `${name}` is interpreted as a numbered group.

If *name* specifies neither a valid named capturing group nor a valid numbered capturing group defined in the regular expression pattern, `${name}` is interpreted as a literal character sequence that is used to replace each match.

The following example uses the `${name}` substitution to strip the currency symbol from a decimal value. It removes currency symbols found at the beginning or end of a monetary value, and recognizes the two most common decimal separators ("." and ",").

C#

```
using System;
using System.Text.RegularExpressions;

public class Example
{
    public static void Main()
    {
        string pattern = @"\p{Sc}*(?<amount>\s?\d+[.,]?\d*)\p{Sc}*";
        string replacement = "${amount}";
        string input = "$16.32 12.19 £16.29 €18.29 €18,29";
        string result = Regex.Replace(input, pattern, replacement);
        Console.WriteLine(result);
    }
}
// The example displays the following output:
//      16.32 12.19 16.29 18.29  18,29
```

The regular expression pattern `\p{Sc}*(?<amount>\s?\d[.,]?\d*)\p{Sc}*` is defined as shown in the following table.

| Pattern | Description |
|----------------------|--|
| <code>\p{Sc}*</code> | Match zero or more currency symbol characters. |
| <code>\s?</code> | Match zero or one white-space characters. |
| <code>\d+</code> | Match one or more decimal digits. |
| <code>[.,]?</code> | Match zero or one period or comma. |
| <code>\d*</code> | Match zero or more decimal digits. |

| Pattern | Description |
|------------------------------------|---|
| (? <amount>\s?\d[.,]?\d*)</amount> | Match a white space, followed by one or more decimal digits, followed by zero or one period or comma, followed by zero or more decimal digits. This is the capturing group named <code>amount</code> . Because the replacement pattern is <code> \${amount}</code> , the call to the Regex.Replace method replaces the entire matched substring with this captured group. |

Substituting a "\$" Character

The `$$` substitution inserts a literal "\$" character in the replaced string.

The following example uses the [NumberFormatInfo](#) object to determine the current culture's currency symbol and its placement in a currency string. It then builds both a regular expression pattern and a replacement pattern dynamically. If the example is run on a computer whose current culture is en-US, it generates the regular expression pattern `\b(\d+)(\.(\d+))?` and the replacement pattern `$$ $1$2`. The replacement pattern replaces the matched text with a currency symbol and a space followed by the first and second captured groups.

C#

```
using System;
using System.Globalization;
using System.Text.RegularExpressions;

public class Example
{
    public static void Main()
    {
        // Define array of decimal values.
        string[] values= { "16.35", "19.72", "1234", "0.99"};
        // Determine whether currency precedes (True) or follows (False)
        number.
        bool precedes = NumberFormatInfo.CurrentInfo.CurrencyPositivePattern %
        2 == 0;
        // Get decimal separator.
        string cSeparator =
        NumberFormatInfo.CurrentInfo.CurrencyDecimalSeparator;
        // Get currency symbol.
        string symbol = NumberFormatInfo.CurrentInfo.CurrencySymbol;
        // If symbol is a "$", add an extra "$".
        if (symbol == "$") symbol = " $$";

        // Define regular expression pattern and replacement string.
        string pattern = @"\b(\d+)" + cSeparator + @"(\d+)?";
        string replacement = "$1$2";
        replacement = precedes ? symbol + " " + replacement : replacement + "
```

```

    " + symbol;
    foreach (string value in values)
        Console.WriteLine("{0} --> {1}", value, Regex.Replace(value,
pattern, replacement));
    }
}
// The example displays the following output:
//      16.35 --> $ 16.35
//      19.72 --> $ 19.72
//      1234 --> $ 1234
//      0.99 --> $ 0.99

```

The regular expression pattern `\b(\d+)(\.(.\d+))?` is defined as shown in the following table.

| Pattern | Description |
|-----------------------|---|
| <code>\b</code> | Start the match at the beginning of a word boundary. |
| <code>(\d+)</code> | Match one or more decimal digits. This is the first capturing group. |
| <code>\.</code> | Match a period (the decimal separator). |
| <code>(\d+)</code> | Match one or more decimal digits. This is the third capturing group. |
| <code>(\.\d+)?</code> | Match zero or one occurrence of a period followed by one or more decimal digits. This is the second capturing group. |

Substituting the Entire Match

The `$&` substitution includes the entire match in the replacement string. Often, it is used to add a substring to the beginning or end of the matched string. For example, the `($&)` replacement pattern adds parentheses to the beginning and end of each match. If there is no match, the `$&` substitution has no effect.

The following example uses the `$&` substitution to add quotation marks at the beginning and end of book titles stored in a string array.

```

C#
using System;
using System.Text.RegularExpressions;

public class Example
{
    public static void Main()
    {
        string pattern = @"^(\w+\s?)+$";

```

```

        string[] titles = { "A Tale of Two Cities",
                            "The Hound of the Baskervilles",
                            "The Protestant Ethic and the Spirit of
                            Capitalism",
                            "The Origin of Species" };
        string replacement = "\"$&\"";
        foreach (string title in titles)
            Console.WriteLine(Regex.Replace(title, pattern, replacement));
    }
}

// The example displays the following output:
//      "A Tale of Two Cities"
//      "The Hound of the Baskervilles"
//      "The Protestant Ethic and the Spirit of Capitalism"
//      "The Origin of Species"

```

The regular expression pattern `^(\w+\s?)+$` is defined as shown in the following table.

| Pattern | Description |
|------------------------|--|
| <code>^</code> | Start the match at the beginning of the input string. |
| <code>(\w+\s?)+</code> | Match the pattern of one or more word characters followed by zero or one white-space characters one or more times. |
| <code>\$</code> | Match the end of the input string. |

The `"$&"` replacement pattern adds a literal quotation mark to the beginning and end of each match.

Substituting the Text Before the Match

The `$`` substitution replaces the matched string with the entire input string before the match. That is, it duplicates the input string up to the match while removing the matched text. Any text that follows the matched text is unchanged in the result string. If there are multiple matches in an input string, the replacement text is derived from the original input string, rather than from the string in which text has been replaced by earlier matches. (The example provides an illustration.) If there is no match, the `$`` substitution has no effect.

The following example uses the regular expression pattern `\d+` to match a sequence of one or more decimal digits in the input string. The replacement string `$`` replaces these digits with the text that precedes the match.

```

using System;
using System.Text.RegularExpressions;

public class Example
{
    public static void Main()
    {
        string input = "aa1bb2cc3dd4ee5";
        string pattern = @"\d+";
        string substitution = "$`";
        Console.WriteLine("Matches:");
        foreach (Match match in Regex.Matches(input, pattern))
            Console.WriteLine("    {0} at position {1}", match.Value,
match.Index);

        Console.WriteLine("Input string: {0}", input);
        Console.WriteLine("Output string: " +
                        Regex.Replace(input, pattern, substitution));
    }
}

// The example displays the following output:
//     Matches:
//         1 at position 2
//         2 at position 5
//         3 at position 8
//         4 at position 11
//         5 at position 14
//     Input string: aa1bb2cc3dd4ee5
//     Output string: aaaabbbaa1bbccaa1bb2ccddaa1bb2cc3ddeaa1bb2cc3dd4ee

```

In this example, the input string "aa1bb2cc3dd4ee5" contains five matches. The following table illustrates how the `$`` substitution causes the regular expression engine to replace each match in the input string. Inserted text is shown in bold in the results column.

| Match | Position | String before match | Result string |
|--------------|-----------------|--------------------------------|--|
| 1 | 2 | aa | aaaabb2cc3dd4ee5 |
| 2 | 5 | aa1bb | aaaabbbaa 1bbcc 3dd4ee5 |
| 3 | 8 | aa1bb2cc | aaaabbbaa1bbccaa 1bb2ccdd 4ee5 |
| 4 | 11 | aa1bb2cc3dd | aaaabbbaa1bbccaa1bb2ccddaa 1bb2cc3dde 5 |
| 5 | 14 | aa1bb2cc3dd4ee | aaaabbbaa1bbccaa1bb2ccddaa1bb2cc3ddeaa 1bb2cc3dd4ee |

Substituting the Text After the Match

The `$'` substitution replaces the matched string with the entire input string after the match. That is, it duplicates the input string after the match while removing the matched text. Any text that precedes the matched text is unchanged in the result string. If there is no match, the `$'` substitution has no effect.

The following example uses the regular expression pattern `\d+` to match a sequence of one or more decimal digits in the input string. The replacement string `$'` replaces these digits with the text that follows the match.

C#

```
using System;
using System.Text.RegularExpressions;

public class Example
{
    public static void Main()
    {
        string input = "aa1bb2cc3dd4ee5";
        string pattern = @"\d+";
        string substitution = "$'";
        Console.WriteLine("Matches:");
        foreach (Match match in Regex.Matches(input, pattern))
            Console.WriteLine("  {0} at position {1}", match.Value,
match.Index);
        Console.WriteLine("Input string: {0}", input);
        Console.WriteLine("Output string: " +
                           Regex.Replace(input, pattern, substitution));
    }
}
// The example displays the following output:
//   Matches:
//     1 at position 2
//     2 at position 5
//     3 at position 8
//     4 at position 11
//     5 at position 14
//   Input string: aa1bb2cc3dd4ee5
//   Output string: aabb2cc3dd4ee5bbcc3dd4ee5ccdd4ee5ddee5ee
```

In this example, the input string `"aa1bb2cc3dd4ee5"` contains five matches. The following table illustrates how the `$'` substitution causes the regular expression engine to replace each match in the input string. Inserted text is shown in bold in the results column.

| Match | Position | String after match | Result string |
|-------|----------|--------------------|------------------------------------|
| 1 | 2 | bb2cc3dd4ee5 | aabb2cc3dd4ee5bb2cc3dd4ee5 |
| 2 | 5 | cc3dd4ee5 | aabb2cc3dd4ee5bbcc3dd4ee5cc3dd4ee5 |

| Match | Position | String after match | Result string |
|-------|----------|--------------------|---|
| 3 | 8 | dd4ee5 | aabb2cc3dd4ee5bbcc3dd4ee5ccdd 4ee5dd4ee5 |
| 4 | 11 | ee5 | aabb2cc3dd4ee5bbcc3dd4ee5ccdd4ee5ddee 5ee5 |
| 5 | 14 | String.Empty | aabb2cc3dd4ee5bbcc3dd4ee5ccdd4ee5ddee 5ee5 |

Substituting the Last Captured Group

The `$+` substitution replaces the matched string with the last captured group. If there are no captured groups or if the value of the last captured group is `String.Empty`, the `$+` substitution has no effect.

The following example identifies duplicate words in a string and uses the `$+` substitution to replace them with a single occurrence of the word. The `RegexOptions.IgnoreCase` option is used to ensure that words that differ in case but that are otherwise identical are considered duplicates.

```
C#
using System;
using System.Text.RegularExpressions;

public class Example
{
    public static void Main()
    {
        string pattern = @"\b(\w+)\s\1\b";
        string substitution = "$+";
        string input = "The the dog jumped over the fence fence.";
        Console.WriteLine(Regex.Replace(input, pattern, substitution,
            RegexOptions.IgnoreCase));
    }
}
// The example displays the following output:
//      The dog jumped over the fence.
```

The regular expression pattern `\b(\w+)\s\1\b` is defined as shown in the following table.

| Pattern | Description |
|--------------------|---|
| <code>\b</code> | Begin the match at a word boundary. |
| <code>(\w+)</code> | Match one or more word characters. This is the first capturing group. |
| <code>\s</code> | Match a white-space character. |

| Pattern | Description |
|---------|-----------------------------------|
| \1 | Match the first captured group. |
| \b | End the match at a word boundary. |

Substituting the Entire Input String

The `$_` substitution replaces the matched string with the entire input string. That is, it removes the matched text and replaces it with the entire string, including the matched text.

The following example matches one or more decimal digits in the input string. It uses the `$_` substitution to replace them with the entire input string.

```
C#
using System;
using System.Text.RegularExpressions;

public class Example
{
    public static void Main()
    {
        string input = "ABC123DEF456";
        string pattern = @"\d+";
        string substitution = "$_";
        Console.WriteLine("Original string: {0}", input);
        Console.WriteLine("String with substitution: {0}",
                          Regex.Replace(input, pattern, substitution));
    }
}
// The example displays the following output:
//      Original string: ABC123DEF456
//      String with substitution: ABCABC123DEF456DEFABC123DEF456
```

In this example, the input string `"ABC123DEF456"` contains two matches. The following table illustrates how the `$_` substitution causes the regular expression engine to replace each match in the input string. Inserted text is shown in bold in the results column.

| Match | Position | Match | Result string |
|-------|----------|-------|--------------------------------|
| 1 | 3 | 123 | ABCABC123DEF456DEF456 |
| 2 | 5 | 456 | ABCABC123DEF456DEFABC123DEF456 |

Regular expression options

Article • 05/12/2023

By default, the comparison of an input string with any literal characters in a regular expression pattern is case-sensitive, white space in a regular expression pattern is interpreted as literal white-space characters, and capturing groups in a regular expression are named implicitly as well as explicitly. You can modify these and several other aspects of default regular expression behavior by specifying regular expression options. Some of these options, which are listed in the following table, can be included inline as part of the regular expression pattern, or they can be supplied to a [System.Text.RegularExpressions.Regex](#) class constructor or static pattern matching method as a [System.Text.RegularExpressions.RegexOptions](#) enumeration value.

| <code>RegexOptions</code> member | Inline character | Effect | More information |
|---|------------------|--|--|
| None | Not available | Use default behavior. | Default options |
| IgnoreCase | <code>i</code> | Use case-insensitive matching. | Case-insensitive matching |
| Multiline | <code>m</code> | Use multiline mode, where <code>^</code> and <code>\$</code> indicate the beginning and end of each line (instead of the beginning and end of the input string). | Multiline mode |
| Singleline | <code>s</code> | Use single-line mode, where the period <code>(.)</code> matches every character (instead of every character except <code>\n</code>). | Single-line mode |
| ExplicitCapture | <code>n</code> | Do not capture unnamed groups. The only valid captures are explicitly named or numbered groups of the form <code>(?<name> subexpression)</code> . | Explicit captures only |
| Compiled | Not available | Compile the regular expression to an assembly. | Compiled regular expressions |
| IgnorePatternWhitespace | <code>x</code> | Exclude unescaped white space from the pattern, and enable comments after a number sign <code>(#)</code> . | Ignore white space |

| RegexOptions member | Inline character | Effect | More information |
|----------------------------|-------------------------|---|--|
| RightToLeft | Not available | Change the search direction. Search moves from right to left instead of from left to right. | Right-to-left mode |
| ECMAScript | Not available | Enable ECMAScript-compliant behavior for the expression. | ECMAScript matching behavior |
| CultureInvariant | Not available | Ignore cultural differences in language. | Comparison using the invariant culture |
| NonBacktracking | Not available | Match using an approach that avoids backtracking and guarantees linear-time processing in the length of the input. (Available in .NET 7 and later versions.) | Nonbacktracking mode |

Specify options

You can specify options for regular expressions in one of three ways:

- In the `options` parameter of a [System.Text.RegularExpressions.Regex](#) class constructor or static (`Shared` in Visual Basic) pattern-matching method, such as `Regex(String, RegexOptions)` or `Regex.Match(String, String, RegexOptions)`. The `options` parameter is a bitwise OR combination of [System.Text.RegularExpressions.RegexOptions](#) enumerated values.

When options are supplied to a `Regex` instance by using the `options` parameter of a class constructor, the options are assigned to the `System.Text.RegularExpressions.RegexOptions` property. However, the `System.Text.RegularExpressions.RegexOptions` property does not reflect inline options in the regular expression pattern itself.

The following example provides an illustration. It uses the `options` parameter of the `Regex.Match(String, String, RegexOptions)` method to enable case-insensitive matching and to ignore pattern white space when identifying words that begin with the letter "d".

C#

```

string pattern = @"d \w+ \s";
string input = "Dogs are decidedly good pets.";
RegexOptions options = RegexOptions.IgnoreCase |
    RegexOptions.IgnorePatternWhitespace;

foreach (Match match in Regex.Matches(input, pattern, options))
    Console.WriteLine("{0}// found at index {1}.", match.Value,
        match.Index);
// The example displays the following output:
//      'Dogs // found at index 0.
//      'decidedly // found at index 9.

```

- By applying inline options in a regular expression pattern with the syntax `(?imnsx-imnsx)`. The option applies to the pattern from the point that the option is defined to either the end of the pattern or to the point at which the option is undefined by another inline option. Note that the [System.Text.RegularExpressions.RegexOptions](#) property of a [Regex](#) instance does not reflect these inline options. For more information, see the [Miscellaneous Constructs](#) topic.

The following example provides an illustration. It uses inline options to enable case-insensitive matching and to ignore pattern white space when identifying words that begin with the letter "d".

C#

```

string pattern = @"(?ix) d \w+ \s";
string input = "Dogs are decidedly good pets.";

foreach (Match match in Regex.Matches(input, pattern))
    Console.WriteLine("{0}// found at index {1}.", match.Value,
        match.Index);
// The example displays the following output:
//      'Dogs // found at index 0.
//      'decidedly // found at index 9.

```

- By applying inline options in a particular grouping construct in a regular expression pattern with the syntax `(?imnsx-imnsx: subexpression)`. No sign before a set of options turns the set on; a minus sign before a set of options turns the set off. (`(?` is a fixed part of the language construct's syntax that is required whether options are enabled or disabled.) The option applies only to that group. For more information, see [Grouping Constructs](#).

The following example provides an illustration. It uses inline options in a grouping construct to enable case-insensitive matching and to ignore pattern white space when identifying words that begin with the letter "d".

C#

```
string pattern = @"\b(?ix: d \w+)\s";
string input = "Dogs are decidedly good pets.";

foreach (Match match in Regex.Matches(input, pattern))
    Console.WriteLine("{0}// found at index {1}.", match.Value,
match.Index);
// The example displays the following output:
//      'Dogs // found at index 0.
//      'decidedly // found at index 9.
```

If options are specified inline, a minus sign (-) before an option or set of options turns off those options. For example, the inline construct (?ix-ms) turns on the [RegexOptions.IgnoreCase](#) and [RegexOptions.IgnorePatternWhitespace](#) options and turns off the [RegexOptions.Multiline](#) and [RegexOptions.Singleline](#) options. All regular expression options are turned off by default.

 **Note**

If the regular expression options specified in the `options` parameter of a constructor or method call conflict with the options specified inline in a regular expression pattern, the inline options are used.

The following five regular expression options can be set both with the `options` parameter and inline:

- [RegexOptions.IgnoreCase](#)
- [RegexOptions.Multiline](#)
- [RegexOptions.Singleline](#)
- [RegexOptions.ExplicitCapture](#)
- [RegexOptions.IgnorePatternWhitespace](#)

The following five regular expression options can be set using the `options` parameter but cannot be set inline:

- [RegexOptions.None](#)
- [RegexOptions.Compiled](#)
- [RegexOptions.RightToLeft](#)

- `RegexOptions.CultureInvariant`
- `RegexOptions.ECMAScript`

Determine options

You can determine which options were provided to a `Regex` object when it was instantiated by retrieving the value of the read-only `Regex.Options` property. This property is particularly useful for determining the options that are defined for a compiled regular expression created by the `Regex.CompileToAssembly` method.

To test for the presence of any option except `RegexOptions.None`, perform an AND operation with the value of the `Regex.Options` property and the `RegexOptions` value in which you are interested. Then test whether the result equals that `RegexOptions` value. The following example tests whether the `RegexOptions.IgnoreCase` option has been set.

C#

```
if ((rgx.Options & RegexOptions.IgnoreCase) == RegexOptions.IgnoreCase)
    Console.WriteLine("Case-insensitive pattern comparison.");
else
    Console.WriteLine("Case-sensitive pattern comparison.");
```

To test for `RegexOptions.None`, determine whether the value of the `Regex.Options` property is equal to `RegexOptions.None`, as the following example illustrates.

C#

```
if (rgx.Options == RegexOptions.None)
    Console.WriteLine("No options have been set.");
```

The following sections list the options supported by regular expression in .NET.

Default options

The `RegexOptions.None` option indicates that no options have been specified, and the regular expression engine uses its default behavior. This includes the following:

- The pattern is interpreted as a canonical rather than an ECMAScript regular expression.
- The regular expression pattern is matched in the input string from left to right.

- Comparisons are case-sensitive.
- The `^` and `$` language elements indicate the beginning and end of the input string. The end of the input string can be a trailing newline `\n` character.
- The `.` language element matches every character except `\n`.
- Any white space in a regular expression pattern is interpreted as a literal space character.
- The conventions of the current culture are used when comparing the pattern to the input string.
- Capturing groups in the regular expression pattern are implicit as well as explicit.

Note

The `RegexOptions.None` option has no inline equivalent. When regular expression options are applied inline, the default behavior is restored on an option-by-option basis, by turning a particular option off. For example, `(?i)` turns on case-insensitive comparison, and `(?-i)` restores the default case-sensitive comparison.

Because the `RegexOptions.None` option represents the default behavior of the regular expression engine, it is rarely explicitly specified in a method call. A constructor or static pattern-matching method without an `options` parameter is called instead.

Case-insensitive matching

The `IgnoreCase` option, or the `i` inline option, provides case-insensitive matching. By default, the casing conventions of the current culture are used.

The following example defines a regular expression pattern, `\bthe\w*\b`, that matches all words starting with "the". Because the first call to the `Match` method uses the default case-sensitive comparison, the output indicates that the string "The" that begins the sentence is not matched. It is matched when the `Match` method is called with options set to `IgnoreCase`.

C#

```
using System;
using System.Text.RegularExpressions;

public class Example
```

```

{
    public static void Main()
    {
        string pattern = @"\bthe\w*\b";
        string input = "The man then told them about that event.";
        foreach (Match match in Regex.Matches(input, pattern))
            Console.WriteLine("Found {0} at index {1}.", match.Value,
                match.Index);

        Console.WriteLine();
        foreach (Match match in Regex.Matches(input, pattern,
            RegexOptions.IgnoreCase))
            Console.WriteLine("Found {0} at index {1}.", match.Value,
                match.Index);
    }
}

// The example displays the following output:
//      Found then at index 8.
//      Found them at index 18.
//
//      Found The at index 0.
//      Found then at index 8.
//      Found them at index 18.

```

The following example modifies the regular expression pattern from the previous example to use inline options instead of the `options` parameter to provide case-insensitive comparison. The first pattern defines the case-insensitive option in a grouping construct that applies only to the letter "t" in the string "the". Because the option construct occurs at the beginning of the pattern, the second pattern applies the case-insensitive option to the entire regular expression.

C#

```

using System;
using System.Text.RegularExpressions;

public class CaseExample
{
    public static void Main()
    {
        string pattern = @"\b(?i:t)he\w*\b";
        string input = "The man then told them about that event.";
        foreach (Match match in Regex.Matches(input, pattern))
            Console.WriteLine("Found {0} at index {1}.", match.Value,
                match.Index);

        Console.WriteLine();
        pattern = @"(?i)\bthe\w*\b";
        foreach (Match match in Regex.Matches(input, pattern,
            RegexOptions.IgnoreCase))
            Console.WriteLine("Found {0} at index {1}.", match.Value,

```

```
match.Index);
    }
}

// The example displays the following output:
//      Found The at index 0.
//      Found then at index 8.
//      Found them at index 18.
//
//      Found The at index 0.
//      Found then at index 8.
//      Found them at index 18.
```

Multiline mode

The [RegexOptions.Multiline](#) option, or the `m` inline option, enables the regular expression engine to handle an input string that consists of multiple lines. It changes the interpretation of the `^` and `$` language elements so that they indicate the beginning and end of a line, instead of the beginning and end of the input string.

By default, `$` will be satisfied only at the end of the input string. If you specify the [RegexOptions.Multiline](#) option, it will be satisfied by either the newline character (`\n`) or the end of the input string.

In neither case does `$` recognize the carriage return/line feed character combination (`\r\n`). `$` always ignores any carriage return (`\r`). To end your match with either `\r\n` or `\n`, use the subexpression `\r?\$` instead of just `$`. Note that this will make the `\r` part of the match.

The following example extracts bowlers' names and scores and adds them to a [SortedList<TKey,TValue>](#) collection that sorts them in descending order. The [Matches](#) method is called twice. In the first method call, the regular expression is `^(\\w+)\\s(\\d+)$` and no options are set. As the output shows, because the regular expression engine cannot match the input pattern along with the beginning and end of the input string, no matches are found. In the second method call, the regular expression is changed to `^(\\w+)\\s(\\d+)\\r?$` and the options are set to [RegexOptions.Multiline](#). As the output shows, the names and scores are successfully matched, and the scores are displayed in descending order.

C#

```
using System;
using System.Collections.Generic;
using System.Text.RegularExpressions;
```

```

public class Multiline1Example
{
    public static void Main()
    {
        SortedList<int, string> scores = new SortedList<int, string>(new
DescendingComparer1<int>());

        string input = "Joe 164\n" +
                      "Sam 208\n" +
                      "Allison 211\n" +
                      "Gwen 171\n";
        string pattern = @"\^(\w+)\s(\d+)$";
        bool matched = false;

        Console.WriteLine("Without Multiline option:");
        foreach (Match match in Regex.Matches(input, pattern))
        {
            scores.Add(Int32.Parse(match.Groups[2].Value),
(string)match.Groups[1].Value);
            matched = true;
        }
        if (!matched)
            Console.WriteLine("    No matches.");
        Console.WriteLine();

        // Redefine pattern to handle multiple lines.
        pattern = @"\^(\w+)\s(\d+)\r*$";
        Console.WriteLine("With multiline option:");
        foreach (Match match in Regex.Matches(input, pattern,
RegexOptions.Multiline))
            scores.Add(Int32.Parse(match.Groups[2].Value),
(string)match.Groups[1].Value);

        // List scores in descending order.
        foreach (KeyValuePair<int, string> score in scores)
            Console.WriteLine("{0}: {1}", score.Value, score.Key);
    }
}

public class DescendingComparer1<T> : IComparer<T>
{
    public int Compare(T x, T y)
    {
        return Comparer<T>.Default.Compare(x, y) * -1;
    }
}
// The example displays the following output:
// Without Multiline option:
//     No matches.
//
// With multiline option:
// Allison: 211
// Sam: 208
// Gwen: 171
// Joe: 164

```

The regular expression pattern `^(\w+)\s(\d+)\r*$` is defined as shown in the following table.

| Pattern | Description |
|--------------------|---|
| <code>^</code> | Begin at the start of the line. |
| <code>(\w+)</code> | Match one or more word characters. This is the first capturing group. |
| <code>\s</code> | Match a white-space character. |
| <code>(\d+)</code> | Match one or more decimal digits. This is the second capturing group. |
| <code>\r?</code> | Match zero or one carriage return character. |
| <code>\$</code> | End at the end of the line. |

The following example is equivalent to the previous one, except that it uses the inline option `(?m)` to set the multiline option.

C#

```
using System;
using System.Collections.Generic;
using System.Text.RegularExpressions;

public class Multiline2Example
{
    public static void Main()
    {
        SortedList<int, string> scores = new SortedList<int, string>(new
DescendingComparer<int>());

        string input = "Joe 164\n" +
                      "Sam 208\n" +
                      "Allison 211\n" +
                      "Gwen 171\n";
        string pattern = @"(?m)^(\w+)\s(\d+)\r*$";

        foreach (Match match in Regex.Matches(input, pattern,
RegexOptions.Multiline))
            scores.Add(Convert.ToInt32(match.Groups[2].Value),
match.Groups[1].Value);

        // List scores in descending order.
        foreach (KeyValuePair<int, string> score in scores)
            Console.WriteLine("{0}: {1}", score.Value, score.Key);
    }
}
```

```
public class DescendingComparer<T> : IComparer<T>
{
    public int Compare(T x, T y)
    {
        return Comparer<T>.Default.Compare(x, y) * -1;
    }
}
// The example displays the following output:
//    Allison: 211
//    Sam: 208
//    Gwen: 171
//    Joe: 164
```

Single-line mode

The [RegexOptions.Singleline](#) option, or the `s` inline option, causes the regular expression engine to treat the input string as if it consists of a single line. It does this by changing the behavior of the period (`.`) language element so that it matches every character, instead of matching every character except for the newline character `\n`.

The following example illustrates how the behavior of the `.` language element changes when you use the [RegexOptions.Singleline](#) option. The regular expression `^.+` starts at the beginning of the string and matches every character. By default, the match ends at the end of the first line; the regular expression pattern matches the carriage return character `\r`, but it does not match `\n`. Because the [RegexOptions.Singleline](#) option interprets the entire input string as a single line, it matches every character in the input string, including `\n`.

C#

```
using System;
using System.Text.RegularExpressions;

public class Example
{
    public static void Main()
    {
        string pattern = "^.+";
        string input = "This is one line and" + Environment.NewLine + "this is
the second.";
        foreach (Match match in Regex.Matches(input, pattern))
            Console.WriteLine(Regex.Escape(match.Value));

        Console.WriteLine();
        foreach (Match match in Regex.Matches(input, pattern,
RegexOptions.Singleline))
            Console.WriteLine(Regex.Escape(match.Value));
```

```
    }
}

// The example displays the following output:
//      This\ is\ one\ line\ and\r
//
//      This\ is\ one\ line\ and\r\nthis\ is\ the\ second\.
```

The following example is equivalent to the previous one, except that it uses the inline option `(?s)` to enable single-line mode.

```
C#

using System;
using System.Text.RegularExpressions;

public class SingleLineExample
{
    public static void Main()
    {
        string pattern = "(?s)^.+";
        string input = "This is one line and" + Environment.NewLine + "this
is the second.";

        foreach (Match match in Regex.Matches(input, pattern))
            Console.WriteLine(Regex.Escape(match.Value));
    }
}
// The example displays the following output:
//      This\ is\ one\ line\ and\r\nthis\ is\ the\ second\.
```

Explicit captures only

By default, capturing groups are defined by the use of parentheses in the regular expression pattern. Named groups are assigned a name or number by the `(?subexpression)` language option, whereas unnamed groups are accessible by index. In the [GroupCollection](#) object, unnamed groups precede named groups.

Grouping constructs are often used only to apply quantifiers to multiple language elements, and the captured substrings are of no interest. For example, if the following regular expression:

```
\b\((?((\w+),?\s?)+[\.\!?\])\)?
```

is intended only to extract sentences that end with a period, exclamation point, or question mark from a document, only the resulting sentence (which is represented by the [Match](#) object) is of interest. The individual words in the collection are not.

Capturing groups that are not subsequently used can be expensive, because the regular expression engine must populate both the [GroupCollection](#) and [CaptureCollection](#) collection objects. As an alternative, you can use either the [RegexOptions.ExplicitCapture](#) option or the `n` inline option to specify that the only valid captures are explicitly named or numbered groups that are designated by the `(?<name> subexpression)` construct.

The following example displays information about the matches returned by the `\b\((?((\w+),?\s?)+[\.\!?])\)?` regular expression pattern when the [Match](#) method is called with and without the [RegexOptions.ExplicitCapture](#) option. As the output from the first method call shows, the regular expression engine fully populates the [GroupCollection](#) and [CaptureCollection](#) collection objects with information about captured substrings. Because the second method is called with `options` set to [RegexOptions.ExplicitCapture](#), it does not capture information on groups.

C#

```
using System;
using System.Text.RegularExpressions;

public class Explicit1Example
{
    public static void Main()
    {
        string input = "This is the first sentence. Is it the beginning " +
                      "of a literary masterpiece? I think not. Instead, " +
                      "it is a nonsensical paragraph.";
        string pattern = @"\b\((?((\w+),?\s?)+[\.\!?])\)?";
        Console.WriteLine("With implicit captures:");
        foreach (Match match in Regex.Matches(input, pattern))
        {
            Console.WriteLine("The match: {0}", match.Value);
            int groupCtr = 0;
            foreach (Group group in match.Groups)
            {
                Console.WriteLine("    Group {0}: {1}", groupCtr,
group.Value);
                groupCtr++;
                int captureCtr = 0;
                foreach (Capture capture in group.Captures)
                {
                    Console.WriteLine("        Capture {0}: {1}", captureCtr,
capture.Value);
                    captureCtr++;
                }
            }
        }
        Console.WriteLine();
        Console.WriteLine("With explicit captures only:");
        foreach (Match match in Regex.Matches(input, pattern,
RegexOptions.ExplicitCapture))
```

```
    {
        Console.WriteLine("The match: {0}", match.Value);
        int groupCtr = 0;
        foreach (Group group in match.Groups)
        {
            Console.WriteLine("    Group {0}: {1}", groupCtr,
group.Value);
            groupCtr++;
            int captureCtr = 0;
            foreach (Capture capture in group.Captures)
            {
                Console.WriteLine("        Capture {0}: {1}", captureCtr,
capture.Value);
                captureCtr++;
            }
        }
    }
}

// The example displays the following output:
//   With implicit captures:
//     The match: This is the first sentence.
//       Group 0: This is the first sentence.
//         Capture 0: This is the first sentence.
//       Group 1: sentence
//         Capture 0: This
//         Capture 1: is
//         Capture 2: the
//         Capture 3: first
//         Capture 4: sentence
//       Group 2: sentence
//         Capture 0: This
//         Capture 1: is
//         Capture 2: the
//         Capture 3: first
//         Capture 4: sentence
//     The match: Is it the beginning of a literary masterpiece?
//       Group 0: Is it the beginning of a literary masterpiece?
//         Capture 0: Is it the beginning of a literary masterpiece?
//       Group 1: masterpiece
//         Capture 0: Is
//         Capture 1: it
//         Capture 2: the
//         Capture 3: beginning
//         Capture 4: of
//         Capture 5: a
//         Capture 6: literary
//         Capture 7: masterpiece
//       Group 2: masterpiece
//         Capture 0: Is
//         Capture 1: it
//         Capture 2: the
//         Capture 3: beginning
//         Capture 4: of
//         Capture 5: a
```

```

//           Capture 6: literary
//           Capture 7: masterpiece
// The match: I think not.
//           Group 0: I think not.
//           Capture 0: I think not.
//           Group 1: not
//           Capture 0: I
//           Capture 1: think
//           Capture 2: not
//           Group 2: not
//           Capture 0: I
//           Capture 1: think
//           Capture 2: not
// The match: Instead, it is a nonsensical paragraph.
//           Group 0: Instead, it is a nonsensical paragraph.
//           Capture 0: Instead, it is a nonsensical paragraph.
//           Group 1: paragraph
//           Capture 0: Instead,
//           Capture 1: it
//           Capture 2: is
//           Capture 3: a
//           Capture 4: nonsensical
//           Capture 5: paragraph
//           Group 2: paragraph
//           Capture 0: Instead
//           Capture 1: it
//           Capture 2: is
//           Capture 3: a
//           Capture 4: nonsensical
//           Capture 5: paragraph
//
// With explicit captures only:
// The match: This is the first sentence.
//           Group 0: This is the first sentence.
//           Capture 0: This is the first sentence.
// The match: Is it the beginning of a literary masterpiece?
//           Group 0: Is it the beginning of a literary masterpiece?
//           Capture 0: Is it the beginning of a literary masterpiece?
// The match: I think not.
//           Group 0: I think not.
//           Capture 0: I think not.
// The match: Instead, it is a nonsensical paragraph.
//           Group 0: Instead, it is a nonsensical paragraph.
//           Capture 0: Instead, it is a nonsensical paragraph.

```

The regular expression pattern `\b\((?((?>\w+),?\s?)*)+[\.\!?\]\)\?` is defined as shown in the following table.

| Pattern | Description |
|-----------------|---|
| <code>\b</code> | Begin at a word boundary. |
| <code>\(</code> | Match zero or one occurrences of the opening parenthesis ("("). |

| Pattern | Description |
|---------------|---|
| (?>\w+),? | Match one or more word characters, followed by zero or one commas. Do not backtrack when matching word characters. |
| \s? | Match zero or one white-space characters. |
| ((\w+),?\s?)+ | Match the combination of one or more word characters, zero or one commas, and zero or one white-space characters one or more times. |
| [.\,!?]\\\)? | Match any of the three punctuation symbols, followed by zero or one closing parentheses (""). |

You can also use the `(?n)` inline element to suppress automatic captures. The following example modifies the previous regular expression pattern to use the `(?n)` inline element instead of the [RegexOptions.ExplicitCapture](#) option.

C#

```
using System;
using System.Text.RegularExpressions;

public class Explicit2Example
{
    public static void Main()
    {
        string input = "This is the first sentence. Is it the beginning " +
                      "of a literary masterpiece? I think not. Instead, " +
                      "it is a nonsensical paragraph.";
        string pattern = @"(?n)\b\((?(>\w+),?\s?)+[\.\,!?]\\\)?";

        foreach (Match match in Regex.Matches(input, pattern))
        {
            Console.WriteLine("The match: {0}", match.Value);
            int groupCtr = 0;
            foreach (Group group in match.Groups)
            {
                Console.WriteLine("    Group {0}: {1}", groupCtr,
group.Value);
                groupCtr++;
                int captureCtr = 0;
                foreach (Capture capture in group.Captures)
                {
                    Console.WriteLine("        Capture {0}: {1}", captureCtr,
capture.Value);
                    captureCtr++;
                }
            }
        }
    }
}

// The example displays the following output:
//      The match: This is the first sentence.
```

```
//      Group 0: This is the first sentence.
//      Capture 0: This is the first sentence.
//      The match: Is it the beginning of a literary masterpiece?
//      Group 0: Is it the beginning of a literary masterpiece?
//      Capture 0: Is it the beginning of a literary masterpiece?
//      The match: I think not.
//      Group 0: I think not.
//      Capture 0: I think not.
//      The match: Instead, it is a nonsensical paragraph.
//      Group 0: Instead, it is a nonsensical paragraph.
//      Capture 0: Instead, it is a nonsensical paragraph.
```

Finally, you can use the inline group element `(?n:)` to suppress automatic captures on a group-by-group basis. The following example modifies the previous pattern to suppress unnamed captures in the outer group, `((?>\w+),?\s?)`. Note that this suppresses unnamed captures in the inner group as well.

C#

```
using System;
using System.Text.RegularExpressions;

public class Explicit3Example
{
    public static void Main()
    {
        string input = "This is the first sentence. Is it the beginning " +
                      "of a literary masterpiece? I think not. Instead, " +
                      "it is a nonsensical paragraph.";
        string pattern = @"\b\((?:(?n:(?>\w+),?\s?)+[\.\!?\])\)?";

        foreach (Match match in Regex.Matches(input, pattern))
        {
            Console.WriteLine("The match: {0}", match.Value);
            int groupCtr = 0;
            foreach (Group group in match.Groups)
            {
                Console.WriteLine("  Group {0}: {1}", groupCtr,
group.Value);
                groupCtr++;
                int captureCtr = 0;
                foreach (Capture capture in group.Captures)
                {
                    Console.WriteLine("    Capture {0}: {1}", captureCtr,
capture.Value);
                    captureCtr++;
                }
            }
        }
    }
} // The example displays the following output:
```

```
//      The match: This is the first sentence.
//          Group 0: This is the first sentence.
//              Capture 0: This is the first sentence.
//      The match: Is it the beginning of a literary masterpiece?
//          Group 0: Is it the beginning of a literary masterpiece?
//              Capture 0: Is it the beginning of a literary masterpiece?
//      The match: I think not.
//          Group 0: I think not.
//              Capture 0: I think not.
//      The match: Instead, it is a nonsensical paragraph.
//          Group 0: Instead, it is a nonsensical paragraph.
//              Capture 0: Instead, it is a nonsensical paragraph.
```

Compiled regular expressions

Note

Where possible, use [source generated regular expressions](#) instead of compiling regular expressions using the [RegexOptions.Compiled](#) option. Source generation can help your app start faster, run more quickly and be more trimmable. To learn when source generation is possible, see [When to use it](#).

By default, regular expressions in .NET are interpreted. When a [Regex](#) object is instantiated or a static [Regex](#) method is called, the regular expression pattern is parsed into a set of custom opcodes, and an interpreter uses these opcodes to run the regular expression. This involves a tradeoff: The cost of initializing the regular expression engine is minimized at the expense of run-time performance.

You can use compiled instead of interpreted regular expressions by using the [RegexOptions.Compiled](#) option. In this case, when a pattern is passed to the regular expression engine, it is parsed into a set of opcodes and then converted to Microsoft intermediate language (MSIL), which can be passed directly to the common language runtime. Compiled regular expressions maximize run-time performance at the expense of initialization time.

Note

A regular expression can be compiled only by supplying the [RegexOptions.Compiled](#) value to the `options` parameter of a [Regex](#) class constructor or a static pattern-matching method. It is not available as an inline option.

You can use compiled regular expressions in calls to both static and instance regular expressions. In static regular expressions, the [RegexOptions.Compiled](#) option is passed to the `options` parameter of the regular expression pattern-matching method. In instance regular expressions, it is passed to the `options` parameter of the [Regex](#) class constructor. In both cases, it results in enhanced performance.

However, this improvement in performance occurs only under the following conditions:

- A [Regex](#) object that represents a particular regular expression is used in multiple calls to regular expression pattern-matching methods.
- The [Regex](#) object is not allowed to go out of scope, so it can be reused.
- A static regular expression is used in multiple calls to regular expression pattern-matching methods. (The performance improvement is possible because regular expressions used in static method calls are cached by the regular expression engine.)

 **Note**

The [RegexOptions.Compiled](#) option is unrelated to the [Regex.CompileToAssembly](#) method, which creates a special-purpose assembly that contains predefined compiled regular expressions.

Ignore white space

By default, white space in a regular expression pattern is significant; it forces the regular expression engine to match a white-space character in the input string. Because of this, the regular expression "`\b\w+\s`" and "`\b\w+`" are roughly equivalent regular expressions. In addition, when the number sign (#) is encountered in a regular expression pattern, it is interpreted as a literal character to be matched.

The [RegexOptions.IgnorePatternWhitespace](#) option, or the `x` inline option, changes this default behavior as follows:

- Unescaped white space in the regular expression pattern is ignored. To be part of a regular expression pattern, white-space characters must be escaped (for example, as `\s` or "`\` ").
- The number sign (#) is interpreted as the beginning of a comment, rather than as a literal character. All text in the regular expression pattern from the `#` character to

either the next `\n` character or to the end of the string, is interpreted as a comment.

However, in the following cases, white-space characters in a regular expression aren't ignored, even if you use the [RegexOptions.IgnorePatternWhitespace](#) option:

- White space within a character class is always interpreted literally. For example, the regular expression pattern `[.,;:]` matches any single white-space character, period, comma, semicolon, or colon.
- White space isn't allowed within a bracketed quantifier, such as `{ n }`, `{ n , }`, and `{ n , m }`. For example, the regular expression pattern `\d{1, 3}` fails to match any sequences of digits from one to three digits because it contains a white-space character.
- White space isn't allowed within a character sequence that introduces a language element. For example:
 - The language element `(?: subexpression)` represents a noncapturing group, and the `(?:` portion of the element can't have embedded spaces. The pattern `(? : subexpression)` throws an [ArgumentException](#) at run time because the regular expression engine can't parse the pattern, and the pattern `(? : subexpression)` fails to match *subexpression*.
 - The language element `\p{ name }`, which represents a Unicode category or named block, can't include embedded spaces in the `\p{` portion of the element. If you do include a white space, the element throws an [ArgumentException](#) at run time.

Enabling this option helps simplify regular expressions that are often difficult to parse and to understand. It improves readability, and makes it possible to document a regular expression.

The following example defines the following regular expression pattern:

```
\b \((? ( (?>\w+) ,?\s? )+ [\.\!?] \)? # Matches an entire sentence.
```

This pattern is similar to the pattern defined in the [Explicit Captures Only](#) section, except that it uses the [RegexOptions.IgnorePatternWhitespace](#) option to ignore pattern white space.

C#

```

using System;
using System.Text.RegularExpressions;

public class Whitespace1Example
{
    public static void Main()
    {
        string input = "This is the first sentence. Is it the beginning " +
                      "of a literary masterpiece? I think not. Instead, " +
                      "it is a nonsensical paragraph.";
        string pattern = @"\b \(? ( (?>\w+),?\s? )+ [\.\!?\] \)? # Matches an
entire sentence./";

        foreach (Match match in Regex.Matches(input, pattern,
RegexOptions.IgnorePatternWhitespace))
            Console.WriteLine(match.Value);
    }
}

// The example displays the following output:
//      This is the first sentence.
//      Is it the beginning of a literary masterpiece?
//      I think not.
//      Instead, it is a nonsensical paragraph.

```

The following example uses the inline option `(?x)` to ignore pattern white space.

C#

```

using System;
using System.Text.RegularExpressions;

public class Whitespace2Example
{
    public static void Main()
    {
        string input = "This is the first sentence. Is it the beginning " +
                      "of a literary masterpiece? I think not. Instead, " +
                      "it is a nonsensical paragraph.";
        string pattern = @"(?x)\b \(? ( (?>\w+),?\s? )+ [\.\!?\] \)? # 
Matches an entire sentence./";

        foreach (Match match in Regex.Matches(input, pattern))
            Console.WriteLine(match.Value);
    }
}

// The example displays the following output:
//      This is the first sentence.
//      Is it the beginning of a literary masterpiece?
//      I think not.
//      Instead, it is a nonsensical paragraph.

```

Right-to-left mode

By default, the regular expression engine searches from left to right. You can reverse the search direction by using the [RegexOptions.RightToLeft](#) option. The right-to-left search automatically begins at the last character position of the string. For pattern-matching methods that include a starting position parameter, such as [Regex.Match\(String, Int32\)](#), the specified starting position is the index of the rightmost character position at which the search is to begin.

ⓘ Note

Right-to-left pattern mode is available only by supplying the [RegexOptions.RightToLeft](#) value to the `options` parameter of a [Regex](#) class constructor or static pattern-matching method. It is not available as an inline option.

Example

The regular expression `\bb\w+\s` matches words with two or more characters that begin with the letter "b" and are followed by a white-space character. In the following example, the input string consists of three words that include one or more "b" characters. The first and second words begin with "b" and the third word ends with "b". As the output from the right-to-left search example shows, only the first and second words match the regular expression pattern, with the second word being matched first.

C#

```
using System;
using System.Text.RegularExpressions;

public class RTL1Example
{
    public static void Main()
    {
        string pattern = @"\bb\w+\s";
        string input = "build band tab";
        foreach (Match match in Regex.Matches(input, pattern,
RegexOptions.RightToLeft))
            Console.WriteLine("{0} found at position {1}.",
match.Value,
match.Index);
    }
}
// The example displays the following output:
```

```
//      'band ' found at position 6.  
//      'build ' found at position 0.
```

Evaluation order

The [RegexOptions.RightToLeft](#) option changes the search direction and also reverses the order in which the regular expression pattern is evaluated. In a right-to-left search, the search pattern is read from right to left. This distinction is important because it can affect things like capture groups and [backreferences](#). For example, the expression `Regex.Match("abcabc", @"\1(abc)", RegexOptions.RightToLeft)` finds a match `abcabc`, but in a left-to-right search (`Regex.Match("abcabc", @"\1(abc)", RegexOptions.None)`), no match is found. That's because the `(abc)` element must be evaluated before the numbered capturing group element `(\1)` for a match to be found.

Lookahead and lookbehind assertions

The location of a match for a lookahead `((?=subexpression))` or lookbehind `((?<=subexpression))` assertion doesn't change in a right-to-left search. The lookahead assertions look to the right of the current match location; the lookbehind assertions look to the left of the current match location.

Tip

Whether a search is right-to-left or not, lookbehinds are implemented using a right-to-left search starting at the current match location.

For example, the regular expression `(?<=\d{1,2}\s)\w+, \s\d{4}` uses the lookbehind assertion to test for a date that precedes a month name. The regular expression then matches the month and the year. For information on lookahead and lookbehind assertions, see [Grouping Constructs](#).

C#

```
using System;  
using System.Text.RegularExpressions;  
  
public class RTL2Example  
{  
    public static void Main()  
    {  
        string[] inputs = { "1 May, 1917", "June 16, 2003" };  
        string pattern = @"(?<=\d{1,2}\s)\w+, \s\d{4}";
```

```

foreach (string input in inputs)
{
    Match match = Regex.Match(input, pattern,
    RegexOptions.RightToLeft);
    if (match.Success)
        Console.WriteLine("The date occurs in {0}.", match.Value);
    else
        Console.WriteLine("{0} does not match.", input);
}
}

// The example displays the following output:
//      The date occurs in May, 1917.
//      June 16, 2003 does not match.

```

The regular expression pattern is defined as shown in the following table.

| Pattern | Description |
|--------------------|---|
| (? =<\d{1,2}\s) | The beginning of the match must be preceded by one or two decimal digits followed by a space. |
| \w+ | Match one or more word characters. |
| , | Match one comma character. |
| \s | Match a white-space character. |
| \d{4} | Match four decimal digits. |

ECMAScript matching behavior

By default, the regular expression engine uses canonical behavior when matching a regular expression pattern to input text. However, you can instruct the regular expression engine to use ECMAScript matching behavior by specifying the [RegexOptions.ESCAPE](#) option.

ⓘ Note

ECMAScript-compliant behavior is available only by supplying the [RegexOptions.ESCAPE](#) value to the `options` parameter of a [Regex](#) class constructor or static pattern-matching method. It is not available as an inline option.

The `RegexOptions.ESCAPE` option can be combined only with the `RegexOptions.IgnoreCase` and `RegexOptions.Multiline` options. The use of any other option in a regular expression results in an `ArgumentOutOfRangeException`.

The behavior of ECMAScript and canonical regular expressions differs in three areas: character class syntax, self-referencing capturing groups, and octal versus backreference interpretation.

- Character class syntax. Because canonical regular expressions support Unicode whereas ECMAScript does not, character classes in ECMAScript have a more limited syntax, and some character class language elements have a different meaning. For example, ECMAScript does not support language elements such as the Unicode category or block elements `\p` and `\P`. Similarly, the `\w` element, which matches a word character, is equivalent to the `[a-zA-Z_0-9]` character class when using ECMAScript and `[\p{L}\p{Lu}\p{Lt}\p{Lo}\p{Nd}\p{Pc}\p{Lm}]` when using canonical behavior. For more information, see [Character Classes](#).

The following example illustrates the difference between canonical and ECMAScript pattern matching. It defines a regular expression, `\b(\w+\s*)+`, that matches words followed by white-space characters. The input consists of two strings, one that uses the Latin character set and the other that uses the Cyrillic character set. As the output shows, the call to the `Regex.IsMatch(String, String, RegexOptions)` method that uses ECMAScript matching fails to match the Cyrillic words, whereas the method call that uses canonical matching does match these words.

```
C#  
  
using System;  
using System.Text.RegularExpressions;  
  
public class EcmaScriptExample  
{  
    public static void Main()  
    {  
        string[] values = { "целый мир", "the whole world" };  
        string pattern = @"\b(\w+\s*)+";  
        foreach (var value in values)  
        {  
            Console.Write("Canonical matching: ");  
            if (Regex.IsMatch(value, pattern))  
                Console.WriteLine("{0} matches the pattern.", value);  
            else  
                Console.WriteLine("{0} does not match the pattern.",  
value);  
  
            Console.Write("ECMAScript matching: ");  
        }  
    }  
}
```

```

        if (Regex.IsMatch(value, pattern, RegexOptions.ECMAScript))
            Console.WriteLine("'{0}' matches the pattern.", value);
        else
            Console.WriteLine("{0} does not match the pattern.",
value);
        Console.WriteLine();
    }
}

// The example displays the following output:
//      Canonical matching: 'целый мир' matches the pattern.
//      ECMAScript matching: целый мир does not match the pattern.
//
//      Canonical matching: 'the whole world' matches the pattern.
//      ECMAScript matching: 'the whole world' matches the pattern.

```

- Self-referencing capturing groups. A regular expression capture class with a backreference to itself must be updated with each capture iteration. As the following example shows, this feature enables the regular expression `((a+)(\1) ?)+` to match the input string " aa aaaa aaaaaa " when using ECMAScript, but not when using canonical matching.

C#

```

using System;
using System.Text.RegularExpressions;

public class EcmaScript2Example
{
    static string pattern;

    public static void Main()
    {
        string input = "aa aaaa aaaaaa ";
        pattern = @"\((a+)(\1) ?)+";

        // Match input using canonical matching.
        AnalyzeMatch(Regex.Match(input, pattern));

        // Match input using ECMAScript.
        AnalyzeMatch(Regex.Match(input, pattern,
RegexOptions.ECMAScript));
    }

    private static void AnalyzeMatch(Match m)
    {
        if (m.Success)
        {
            Console.WriteLine("'{0}' matches {1} at position {2}.",
pattern, m.Value, m.Index);
            int grpCtr = 0;
            foreach (Group grp in m.Groups)

```

```

    {
        Console.WriteLine("    {0}: '{1}'", grpCtr, grp.Value);
        grpCtr++;
        int capCtr = 0;
        foreach (Capture cap in grp.Captures)
        {
            Console.WriteLine("        {0}: '{1}'", capCtr,
cap.Value);
            capCtr++;
        }
    }
    else
    {
        Console.WriteLine("No match found.");
    }
    Console.WriteLine();
}
// The example displays the following output:
// No match found.
//
//     '((a+)(\1) ?)+' matches aa aaaa aaaaaa at position 0.
//         0: 'aa aaaa aaaaaa '
//             0: 'aa aaaa aaaaaa '
//                 1: 'aaaaaa '
//                     0: 'aa '
//                         1: 'aaa '
//                             2: 'aaaaaa '
//                                 2: 'aa'
//                                     0: 'aa'
//                                         1: 'aa'
//                                             2: 'aa'
//                                                 3: 'aaa '
//                                                     0: ''
//                                                         1: 'aa '
//                                                             2: 'aaaa '

```

The regular expression is defined as shown in the following table.

| Pattern | Description |
|----------------|--|
| (a+) | Match the letter "a" one or more times. This is the second capturing group. |
| (\1) | Match the substring captured by the first capturing group. This is the third capturing group. |
| ? | Match zero or one space characters. |
| ((a+)(\1) ?)+ | Match the pattern of one or more "a" characters followed by a string that matches the first capturing group followed by zero or one space characters one or more times. This is the first capturing group. |

- Resolution of ambiguities between octal escapes and backreferences. The following table summarizes the differences in octal versus backreference interpretation by canonical and ECMAScript regular expressions.

| Regular expression | Canonical behavior | ECMAScript behavior |
|--|---|---|
| \0 followed by 0 to 2 octal digits | Interpret as an octal. For example, \044 is always interpreted as an octal value and means "\$". | Same behavior. |
| \ followed by a digit from 1 to 9, followed by no additional decimal digits, | Interpret as a backreference. For example, \9 always means backreference 9, even if a ninth capturing group does not exist. If the capturing group does not exist, the regular expression parser throws an ArgumentException . | If a single decimal digit capturing group exists, backreference to that digit. Otherwise, interpret the value as a literal. |
| \ followed by a digit from 1 to 9, followed by additional decimal digits | Interpret the digits as a decimal value. If that capturing group exists, interpret the expression as a backreference. Otherwise, interpret the leading octal digits up to octal 377; that is, consider only the low 8 bits of the value. Interpret the remaining digits as literals. For example, in the expression \3000, if capturing group 300 exists, interpret as backreference 300; if capturing group 300 does not exist, interpret as octal 300 followed by 0. | Interpret as a backreference by converting as many digits as possible to a decimal value that can refer to a capture. If no digits can be converted, interpret as an octal by using the leading octal digits up to octal 377; interpret the remaining digits as literals. |

Compare using the invariant culture

By default, when the regular expression engine performs case-insensitive comparisons, it uses the casing conventions of the current culture to determine equivalent uppercase and lowercase characters.

However, this behavior is undesirable for some types of comparisons, particularly when comparing user input to the names of system resources, such as passwords, files, or URLs. The following example illustrates such a scenario. The code is intended to block access to any resource whose URL is prefaced with FILE://. The regular expression attempts a case-insensitive match with the string by using the regular expression \$FILE://. However, when the current system culture is tr-TR (Turkish-Türkiye), "I" is not

the uppercase equivalent of "i". As a result, the call to the [Regex.IsMatch](#) method returns `false`, and access to the file is allowed.

C#

```
CultureInfo defaultCulture = Thread.CurrentThread.CurrentCulture;
Thread.CurrentThread.CurrentCulture = new CultureInfo("tr-TR");

string input = "file://c:/Documents.MyReport.doc";
string pattern = "FILE://";

Console.WriteLine("Culture-sensitive matching ({0} culture)...",
                  Thread.CurrentThread.CurrentCulture.Name);
if (Regex.IsMatch(input, pattern, RegexOptions.IgnoreCase))
    Console.WriteLine("URLs that access files are not allowed.");
else
    Console.WriteLine("Access to {0} is allowed.", input);

Thread.CurrentThread.CurrentCulture = defaultCulture;
// The example displays the following output:
//     Culture-sensitive matching (tr-TR culture)...
//     Access to file://c:/Documents.MyReport.doc is allowed.
```

① Note

For more information about string comparisons that are case-sensitive and that use the invariant culture, see [Best Practices for Using Strings](#).

Instead of using the case-insensitive comparisons of the current culture, you can specify the [RegexOptions.CultureInvariant](#) option to ignore cultural differences in language and to use the conventions of the invariant culture.

① Note

Comparison using the invariant culture is available only by supplying the [RegexOptions.CultureInvariant](#) value to the `options` parameter of a [Regex](#) class constructor or static pattern-matching method. It is not available as an inline option.

The following example is identical to the previous example, except that the static [Regex.IsMatch\(String, String, RegexOptions\)](#) method is called with options that include [RegexOptions.CultureInvariant](#). Even when the current culture is set to Turkish (Türkiye), the regular expression engine is able to successfully match "FILE" and "file" and block access to the file resource.

C#

```
CultureInfo defaultCulture = Thread.CurrentThread.CurrentCulture;
Thread.CurrentThread.CurrentCulture = new CultureInfo("tr-TR");

string input = "file:///c:/Documents.MyReport.doc";
string pattern = "FILE://";

Console.WriteLine("Culture-insensitive matching...");
if (Regex.IsMatch(input, pattern,
    RegexOptions.IgnoreCase | RegexOptions.CultureInvariant))
    Console.WriteLine("URLs that access files are not allowed.");
else
    Console.WriteLine("Access to {0} is allowed.", input);

Thread.CurrentThread.CurrentCulture = defaultCulture;
// The example displays the following output:
//     Culture-insensitive matching...
//     URLs that access files are not allowed.
```

Nonbacktracking mode

By default, .NET's regex engine uses *backtracking* to try to find pattern matches. A backtracking engine is one that tries to match one pattern, and if that fails, goes backs and tries to match an alternate pattern, and so on. A backtracking engine is very fast for typical cases, but slows down as the number of pattern alternations increases, which can lead to *catastrophic backtracking*. The [RegexOptions.NonBacktracking](#) option, which was introduced in .NET 7, doesn't use backtracking and avoids that worst-case scenario. Its goal is to provide consistently good behavior, regardless of the input being searched.

The [RegexOptions.NonBacktracking](#) option doesn't support everything the other built-in engines support. In particular, the option can't be used in conjunction with [RegexOptions.RightToLeft](#) or [RegexOptions.ECMAScript](#). It also doesn't allow for the following constructs in the pattern:

- Atomic groups
- Backreferences
- Balancing groups
- Conditionals
- Lookarounds
- Start anchors (`\G`)

[RegexOptions.NonBacktracking](#) also has a subtle difference with regards to execution. If a capture group is in a loop, most (non-.NET) regex engines only provide the last matched value for that capture. However, .NET's regex engine tracks all values that are

captured inside a loop and provides access to them. The `RegexOptions.NonBacktracking` option is like most other regex implementations and only supports providing the final capture.

For more information about backtracking, see [Backtracking in regular expressions](#).

Miscellaneous Constructs in Regular Expressions

Article • 10/06/2022

Regular expressions in .NET include three miscellaneous language constructs. One lets you enable or disable particular matching options in the middle of a regular expression pattern. The remaining two let you include comments in a regular expression.

Inline Options

You can set or disable specific pattern matching options for part of a regular expression by using the syntax

```
(?imnsx-imnsx)
```

You list the options you want to enable after the question mark, and the options you want to disable after the minus sign. The following table describes each option. For more information about each option, see [Regular Expression Options](#).

| Option | Description |
|--------|---|
| i | Case-insensitive matching. |
| m | Multiline mode. |
| n | Explicit captures only. (Parentheses do not act as capturing groups.) |
| s | Single-line mode. |
| x | Ignore unescaped white space, and allow x-mode comments. |

Any change in regular expression options defined by the `(?imnsx-imnsx)` construct remains in effect until the end of the enclosing group.

Note

The `(?imnsx-imnsx: subexpression)` grouping construct provides identical functionality for a subexpression. For more information, see [Grouping Constructs](#).

The following example uses the `i`, `n`, and `x` options to enable case insensitivity and explicit captures, and to ignore white space in the regular expression pattern in the

middle of a regular expression.

C#

```
using System;
using System.Text.RegularExpressions;

public class Example
{
    public static void Main()
    {
        string pattern;
        string input = "double dare double Double a Drooling dog The Dreaded
Deep";

        pattern = @"\b(D\w+)\s(d\w+)\b";
        // Match pattern using default options.
        foreach (Match match in Regex.Matches(input, pattern))
        {
            Console.WriteLine(match.Value);
            if (match.Groups.Count > 1)
                for (int ctr = 1; ctr < match.Groups.Count; ctr++)
                    Console.WriteLine("    Group {0}: {1}", ctr,
match.Groups[ctr].Value);
        }
        Console.WriteLine();

        // Change regular expression pattern to include options.
        pattern = @"\b(D\w+)(?ixn) \s (d\w+) \b";
        // Match new pattern with options.
        foreach (Match match in Regex.Matches(input, pattern))
        {
            Console.WriteLine(match.Value);
            if (match.Groups.Count > 1)
                for (int ctr = 1; ctr < match.Groups.Count; ctr++)
                    Console.WriteLine("    Group {0}: '{1}'", ctr,
match.Groups[ctr].Value);
        }
    }
}

// The example displays the following output:
//      Drooling dog
//          Group 1: Drooling
//          Group 2: dog
//
//      Drooling dog
//          Group 1: 'Drooling'
//      Dreaded Deep
//          Group 1: 'Dreaded'
```

The example defines two regular expressions. The first, `\b(D\w+)\s(d\w+)\b`, matches two consecutive words that begin with an uppercase "D" and a lowercase "d". The

second regular expression, `\b(D\w+)(?ixn) \s (d\w+) \b`, uses inline options to modify this pattern, as described in the following table. A comparison of the results confirms the effect of the `(?ixn)` construct.

| Pattern | Description |
|---------------------|---|
| <code>\b</code> | Start at a word boundary. |
| <code>(D\w+)</code> | Match a capital "D" followed by one or more word characters. This is the first capture group. |
| <code>(?ixn)</code> | From this point on, make comparisons case-insensitive, make only explicit captures, and ignore white space in the regular expression pattern. |
| <code>\s</code> | Match a white-space character. |
| <code>(d\w+)</code> | Match an uppercase or lowercase "d" followed by one or more word characters. This group is not captured because the <code>n</code> (explicit capture) option was enabled. |
| <code>\b</code> | Match a word boundary. |

Inline Comment

The `(?# comment)` construct lets you include an inline comment in a regular expression. The regular expression engine does not use any part of the comment in pattern matching, although the comment is included in the string that is returned by the [Regex.ToString](#) method. The comment ends at the first closing parenthesis.

The following example repeats the first regular expression pattern from the example in the previous section. It adds two inline comments to the regular expression to indicate whether the comparison is case-sensitive. The regular expression pattern, `\b((?# case-sensitive comparison)D\w+)\s(?ixn)((?#case-insensitive comparison)d\w+)\b`, is defined as follows.

| Pattern | Description |
|---|---|
| <code>\b</code> | Start at a word boundary. |
| <code>(?# case-sensitive comparison)</code> | A comment. It does not affect pattern-matching behavior. |
| <code>(D\w+)</code> | Match a capital "D" followed by one or more word characters. This is the first capturing group. |
| <code>\s</code> | Match a white-space character. |

| Pattern | Description |
|---------------------------------|---|
| (?ixn) | From this point on, make comparisons case-insensitive, make only explicit captures, and ignore white space in the regular expression pattern. |
| (?#case-insensitive comparison) | A comment. It does not affect pattern-matching behavior. |
| (d\w+) | Match an uppercase or lowercase "d" followed by one or more word characters. This is the second capture group. |
| \b | Match a word boundary. |

C#

```

using System;
using System.Text.RegularExpressions;

public class Example
{
    public static void Main()
    {
        string pattern = @"\b((?# case-sensitive comparison)D\w+)\s(?ixn)((?#
#case-insensitive comparison)d\w+)\b";
        Regex rgx = new Regex(pattern);
        string input = "double dare double Double a Drooling dog The Dreaded
Deep";

        Console.WriteLine("Pattern: " + pattern.ToString());
        // Match pattern using default options.
        foreach (Match match in rgx.Matches(input))
        {
            Console.WriteLine(match.Value);
            if (match.Groups.Count > 1)
            {
                for (int ctr = 1; ctr < match.Groups.Count; ctr++)
                    Console.WriteLine("    Group {0}: {1}", ctr,
match.Groups[ctr].Value);
            }
        }
    }
}
// The example displays the following output:
//      Pattern: \b((?# case-sensitive comparison)D\w+)\s(?ixn)((?#
#case-
insensitive comp
//      arison)d\w+)\b
//      Drooling dog
//          Group 1: Drooling
//      Dreaded Deep
//          Group 1: Dreaded

```

End-of-Line Comment

A number sign (#) marks an x-mode comment, which starts at the unescaped # character at the end of the regular expression pattern and continues until the end of the line. To use this construct, you must either enable the `x` option (through inline options) or supply the `RegexOptions.IgnorePatternWhitespace` value to the `option` parameter when instantiating the `Regex` object or calling a static `Regex` method.

The following example illustrates the end-of-line comment construct. It determines whether a string is a composite format string that includes at least one format item. The following table describes the constructs in the regular expression pattern:

```
\{\ \d+(-*\d+)*(\:\w{1,4}?)*\}\(?x) # Looks for a composite format item.
```

| Pattern | Description |
|---|--|
| <code>\{</code> | Match an opening brace. |
| <code>\d+</code> | Match one or more decimal digits. |
| <code>(,-*\d+)*</code> | Match zero or one occurrence of a comma, followed by an optional minus sign, followed by one or more decimal digits. |
| <code>(\:\w{1,4}?)*</code> | Match zero or one occurrence of a colon, followed by one to four, but as few as possible, white-space characters. |
| <code>\}</code> | Match a closing brace. |
| <code>(?x)</code> | Enable the ignore pattern white-space option so that the end-of-line comment will be recognized. |
| <code># Looks for a composite format item.</code> | An end-of-line comment. |

C#

```
using System;
using System.Text.RegularExpressions;

public class Example
{
    public static void Main()
    {
        string pattern = @"\{\ \d+(-*\d+)*(\:\w{1,4}?)*\}\(?x) # Looks for a
composite format item.";
        string input = "{0,-3:F}";
        Console.WriteLine('{0}:', input);
        if (Regex.IsMatch(input, pattern))
            Console.WriteLine("    contains a composite format item.");
    }
}
```

```
        else
            Console.WriteLine("    does not contain a composite format item.");
    }
}
// The example displays the following output:
//      '{0,-3:F}':
//      contains a composite format item.
```

Note that, instead of providing the `(?x)` construct in the regular expression, the comment could also have been recognized by calling the [Regex.IsMatch\(String, String, RegexOptions\)](#) method and passing it the [RegexOptions.IgnorePatternWhitespace](#) enumeration value.

Best practices for regular expressions in .NET

Article • 10/03/2023

The regular expression engine in .NET is a powerful, full-featured tool that processes text based on pattern matches rather than on comparing and matching literal text. In most cases, it performs pattern matching rapidly and efficiently. However, in some cases, the regular expression engine can appear to be slow. In extreme cases, it can even appear to stop responding as it processes a relatively small input over the course of hours or even days.

This article outlines some of the best practices that developers can adopt to ensure that their regular expressions achieve optimal performance.

Warning

When using `System.Text.RegularExpressions` to process untrusted input, pass a timeout. A malicious user can provide input to `RegularExpressions`, causing a [Denial-of-Service attack ↗](#). ASP.NET Core framework APIs that use `RegularExpressions` pass a timeout.

Consider the input source

In general, regular expressions can accept two types of input: constrained or unconstrained. Constrained input is a text that originates from a known or reliable source and follows a predefined format. Unconstrained input is a text that originates from an unreliable source, such as a web user, and might not follow a predefined or expected format.

Regular expression patterns are often written to match valid input. That is, developers examine the text that they want to match and then write a regular expression pattern that matches it. Developers then determine whether this pattern requires correction or further elaboration by testing it with multiple valid input items. When the pattern matches all presumed valid inputs, it's declared to be production-ready, and can be included in a released application. This approach makes a regular expression pattern suitable for matching constrained input. However, it doesn't make it suitable for matching unconstrained input.

To match unconstrained input, a regular expression must handle three kinds of text efficiently:

- Text that matches the regular expression pattern.
- Text that doesn't match the regular expression pattern.
- Text that nearly matches the regular expression pattern.

The last text type is especially problematic for a regular expression that has been written to handle constrained input. If that regular expression also relies on extensive [backtracking](#), the regular expression engine can spend an inordinate amount of time (in some cases, many hours or days) processing seemingly innocuous text.

Warning

The following example uses a regular expression that's prone to excessive backtracking and that's likely to reject valid email addresses. You shouldn't use it in an email validation routine. If you would like a regular expression that validates email addresses, see [How to: Verify that Strings Are in Valid Email Format](#).

For example, consider a commonly used but problematic regular expression for validating the alias of an email address. The regular expression `@[0-9A-Z]([-.\\w]*[0-9A-Z])*$` is written to process what is considered to be a valid email address. A valid email address consists of an alphanumeric character, followed by zero or more characters that can be alphanumeric, periods, or hyphens. The regular expression must end with an alphanumeric character. However, as the following example shows, although this regular expression handles valid input easily, its performance is inefficient when it's processing nearly valid input:

C#

```
using System;
using System.Diagnostics;
using System.Text.RegularExpressions;

public class Example
{
    public static void Main()
    {
        Stopwatch sw;
        string[] addresses = { "AAAAAAA@contoso.com",
                               "AAAAAAAAAaaaaaaaaa!@contoso.com" };
        // The following regular expression should not actually be used to
        // validate an email address.
        string pattern = @"@[0-9A-Z]([-.\\w]*[0-9A-Z])*$";
        string input;
```

```

        foreach (var address in addresses) {
            string mailBox = address.Substring(0, address.IndexOf("@"));
            int index = 0;
            for (int ctr = mailBox.Length - 1; ctr >= 0; ctr--) {
                index++;

                input = mailBox.Substring(ctr, index);
                sw = Stopwatch.StartNew();
                Match m = Regex.Match(input, pattern, RegexOptions.IgnoreCase);
                sw.Stop();
                if (m.Success)
                    Console.WriteLine("{0,2}. Matched '{1,25}' in {2}",
                                      index, m.Value, sw.Elapsed);
                else
                    Console.WriteLine("{0,2}. Failed  '{1,25}' in {2}",
                                      index, input, sw.Elapsed);
            }
            Console.WriteLine();
        }
    }

// The example displays output similar to the following:
//      1. Matched '          A' in 00:00:00.0007122
//      2. Matched '         AA' in 00:00:00.0000282
//      3. Matched '        AAA' in 00:00:00.0000042
//      4. Matched '       AAAA' in 00:00:00.0000038
//      5. Matched '      AAAAA' in 00:00:00.0000042
//      6. Matched '     AAAAAA' in 00:00:00.0000042
//      7. Matched '    AAAAAAA' in 00:00:00.0000042
//      8. Matched '   AAAAAAAA' in 00:00:00.0000087
//      9. Matched '  AAAAAAAAA' in 00:00:00.0000045
//     10. Matched ' AAAAAAAAAA' in 00:00:00.0000045
//     11. Matched 'AAAAAAA" in 00:00:00.0000045
//
//      1. Failed  '          !' in 00:00:00.0000447
//      2. Failed  '         a!' in 00:00:00.0000071
//      3. Failed  '        aa!' in 00:00:00.0000071
//      4. Failed  '       aaa!' in 00:00:00.0000061
//      5. Failed  '      aaaa!' in 00:00:00.0000081
//      6. Failed  '     aaaaa!' in 00:00:00.0000126
//      7. Failed  '    aaaaaa!' in 00:00:00.0000359
//      8. Failed  '   aaaaaaa!' in 00:00:00.0000414
//      9. Failed  '  aaaaaaaa!' in 00:00:00.0000758
//     10. Failed  ' aaaaaaaaa!' in 00:00:00.0001462
//     11. Failed  'aaaaaaa" in 00:00:00.0002885
//     12. Failed  'Aaaaaaaaaaa!' in 00:00:00.0005780
//     13. Failed  'AAaaaaaaaaaa!' in 00:00:00.0011628
//     14. Failed  'AAAaaaaaaaaaa!' in 00:00:00.0022851
//     15. Failed  'AAAAaaaaaaaaaa!' in 00:00:00.0045864
//     16. Failed  'AAAAAaaaaaaaaaa!' in 00:00:00.0093168
//     17. Failed  'AAAAAAaaaaaaaaaa!' in 00:00:00.0185993
//     18. Failed  'AAAAAAAaaaaaaaaaa!' in 00:00:00.0366723
//     19. Failed  'AAAAAAAaaaaaaaaaa!' in 00:00:00.1370108

```

```
// 20. Failed 'AAAAAAAAaaaaaaa!' in 00:00:00.1553966
// 21. Failed 'AAAAAAAAAaaaaaaaa!' in 00:00:00.3223372
```

As the output from the preceding example shows, the regular expression engine processes the valid email alias in about the same time interval regardless of its length. On the other hand, when the nearly valid email address has more than five characters, processing time approximately doubles for each extra character in the string. Therefore, a nearly valid 28-character string would take over an hour to process, and a nearly valid 33-character string would take nearly a day to process.

Because this regular expression was developed solely by considering the format of input to be matched, it fails to take account of input that doesn't match the pattern. This oversight, in turn, can allow unconstrained input that nearly matches the regular expression pattern to significantly degrade performance.

To solve this problem, you can do the following:

- When developing a pattern, you should consider how backtracking might affect the performance of the regular expression engine, particularly if your regular expression is designed to process unconstrained input. For more information, see the [Take Charge of Backtracking](#) section.
- Thoroughly test your regular expression using invalid, near-valid, and valid input. You can use [Rex ↗](#) to randomly generate input for a particular regular expression. [Rex ↗](#) is a regular expression exploration tool from Microsoft Research.

Handle object instantiation appropriately

At the heart of .NET's regular expression object model, is the [System.Text.RegularExpressions.Regex](#) class, which represents the regular expression engine. Often, the single greatest factor that affects regular expression performance is the way in which the [Regex](#) engine is used. Defining a regular expression involves tightly coupling the regular expression engine with a regular expression pattern. That coupling process, whether it involves instantiating a [Regex](#) object by passing its constructor a regular expression pattern or calling a static method by passing it the regular expression pattern and the string to be analyzed, is by necessity an expensive one.

ⓘ Note

For a detailed discussion of the performance implications of using interpreted and compiled regular expressions, see [Optimizing Regular Expression Performance, Part II: Taking Charge of Backtracking](#) in the BCL Team blog.

You can couple the regular expression engine with a particular regular expression pattern and then use the engine to match the text in several ways:

- You can call a static pattern-matching method, such as [Regex.Match\(String, String\)](#). This method doesn't require instantiation of a regular expression object.
- You can instantiate a [Regex](#) object and call an instance pattern-matching method of an interpreted regular expression, which is the default method for binding the regular expression engine to a regular expression pattern. It results when a [Regex](#) object is instantiated without an `options` argument that includes the [Compiled](#) flag.
- You can instantiate a [Regex](#) object and call an instance pattern-matching method of a compiled regular expression. Regular expression objects represent compiled patterns when a [Regex](#) object is instantiated with an `options` argument that includes the [Compiled](#) flag.
- You can create a special-purpose [Regex](#) object that's tightly coupled with a particular regular expression pattern, compile it, and save it to a standalone assembly. You can call the [Regex.CompileToAssembly](#) method to compile and save it.

The particular way in which you call regular expression matching methods can affect your application's performance. The following sections discuss when to use static method calls, interpreted regular expressions, and compiled regular expressions to improve your application's performance.

 **Important**

The form of the method call (static, interpreted, compiled) affects performance if the same regular expression is used repeatedly in method calls, or if an application makes extensive use of regular expression objects.

Static regular expressions

Static regular expression methods are recommended as an alternative to repeatedly instantiating a regular expression object with the same regular expression. Unlike

regular expression patterns used by regular expression objects, either the operation codes or the compiled Microsoft intermediate language (MSIL) from patterns used in static method calls is cached internally by the regular expression engine.

For example, an event handler frequently calls another method to validate user input. This example is reflected in the following code, in which a [Button](#) control's [Click](#) event is used to call a method named `IsValidCurrency`, which checks whether the user has entered a currency symbol followed by at least one decimal digit.

C#

```
public void OKButton_Click(object sender, EventArgs e)
{
    if (! String.IsNullOrEmpty(sourceCurrency.Text))
        if (RegexLib.IsValidCurrency(sourceCurrency.Text))
            PerformConversion();
        else
            status.Text = "The source currency value is invalid.";
}
```

An inefficient implementation of the `IsValidCurrency` method is shown in the following example:

① Note

Each method call reinstatiates a [Regex](#) object with the same pattern. This, in turn, means that the regular expression pattern must be recompiled each time the method is called.

C#

```
using System;
using System.Text.RegularExpressions;

public class RegexLib
{
    public static bool IsValidCurrency(string currencyValue)
    {
        string pattern = @"\p{Sc}+\s*\d+";
        Regex currencyRegex = new Regex(pattern);
        return currencyRegex.IsMatch(currencyValue);
    }
}
```

You should replace the preceding inefficient code with a call to the static [Regex.IsMatch\(String, String\)](#) method. This approach eliminates the need to instantiate a

[Regex](#) object each time you want to call a pattern-matching method, and enables the regular expression engine to retrieve a compiled version of the regular expression from its cache.

```
C#  
  
using System;  
using System.Text.RegularExpressions;  
  
public class RegexLib  
{  
    public static bool IsValidCurrency(string currencyValue)  
    {  
        string pattern = @"\p{Sc}+\s*\d+";  
        return Regex.IsMatch(currencyValue, pattern);  
    }  
}
```

By default, the last 15 most recently used static regular expression patterns are cached. For applications that require a larger number of cached static regular expressions, the size of the cache can be adjusted by setting the [Regex.CacheSize](#) property.

The regular expression `\p{Sc}+\s*\d+` that's used in this example verifies that the input string has a currency symbol and at least one decimal digit. The pattern is defined as shown in the following table:

| Pattern | Description |
|----------------------|--|
| <code>\p{Sc}+</code> | Matches one or more characters in the Unicode Symbol, Currency category. |
| <code>\s*</code> | Matches zero or more white-space characters. |
| <code>\d+</code> | Matches one or more decimal digits. |

Interpreted vs. compiled regular expressions

Regular expression patterns that aren't bound to the regular expression engine through the specification of the [Compiled](#) option are interpreted. When a regular expression object is instantiated, the regular expression engine converts the regular expression to a set of operation codes. When an instance method is called, the operation codes are converted to MSIL and executed by the JIT compiler. Similarly, when a static regular expression method is called and the regular expression can't be found in the cache, the regular expression engine converts the regular expression to a set of operation codes and stores them in the cache. It then converts these operation codes to MSIL so that the JIT compiler can execute them. Interpreted regular expressions reduce startup time at

the cost of slower execution time. Because of this process, they're best used when the regular expression is used in a small number of method calls, or if the exact number of calls to regular expression methods is unknown but is expected to be small. As the number of method calls increases, the performance gain from reduced startup time is outstripped by the slower execution speed.

Regular expression patterns that are bound to the regular expression engine through the specification of the [Compiled](#) option are compiled. Therefore, when a regular expression object is instantiated, or when a static regular expression method is called and the regular expression can't be found in the cache, the regular expression engine converts the regular expression to an intermediary set of operation codes. These codes are then converted to MSIL. When a method is called, the JIT compiler executes the MSIL. In contrast to interpreted regular expressions, compiled regular expressions increase startup time but execute individual pattern-matching methods faster. As a result, the performance benefit that results from compiling the regular expression increases in proportion to the number of regular expression methods called.

To summarize, we recommend that you use interpreted regular expressions when you call regular expression methods with a specific regular expression relatively infrequently. You should use compiled regular expressions when you call regular expression methods with a specific regular expression relatively frequently. It's difficult to determine the exact threshold at which the slower execution speeds of interpreted regular expressions outweigh gains from their reduced startup time, or the threshold at which the slower startup times of compiled regular expressions outweigh gains from their faster execution speeds. It depends on various factors, including the complexity of the regular expression and the specific data that it processes. To determine whether interpreted or compiled regular expressions offer the best performance for your particular application scenario, you can use the [Stopwatch](#) class to compare their execution times.

The following example compares the performance of compiled and interpreted regular expressions when reading the first 10 sentences and when reading all the sentences in the text of Theodore Dreiser's *The Financier*. As the output from the example shows, when only 10 calls are made to regular expression matching methods, an interpreted regular expression offers better performance than a compiled regular expression. However, a compiled regular expression offers better performance when a large number of calls (in this case, over 13,000) are made.

C#

```
using System;
using System.Diagnostics;
using System.IO;
using System.Text.RegularExpressions;
```

```
public class Example
{
    public static void Main()
    {
        string pattern = @"\b(\w+((\r?\n)|,\s))*\w+[.?;!]";
        Stopwatch sw;
        Match match;
        int ctr;

        StreamReader inFile = new StreamReader(@".\Dreiser_TheFinancier.txt");
        string input = inFile.ReadToEnd();
        inFile.Close();

        // Read first ten sentences with interpreted regex.
        Console.WriteLine("10 Sentences with Interpreted Regex:");
        sw = Stopwatch.StartNew();
        Regex int10 = new Regex(pattern, RegexOptions.Singleline);
        match = int10.Match(input);
        for (ctr = 0; ctr <= 9; ctr++) {
            if (match.Success)
                // Do nothing with the match except get the next match.
                match = match.NextMatch();
            else
                break;
        }
        sw.Stop();
        Console.WriteLine("    {0} matches in {1}", ctr, sw.Elapsed);

        // Read first ten sentences with compiled regex.
        Console.WriteLine("10 Sentences with Compiled Regex:");
        sw = Stopwatch.StartNew();
        Regex comp10 = new Regex(pattern,
                                RegexOptions.Singleline | RegexOptions.Compiled);
        match = comp10.Match(input);
        for (ctr = 0; ctr <= 9; ctr++) {
            if (match.Success)
                // Do nothing with the match except get the next match.
                match = match.NextMatch();
            else
                break;
        }
        sw.Stop();
        Console.WriteLine("    {0} matches in {1}", ctr, sw.Elapsed);

        // Read all sentences with interpreted regex.
        Console.WriteLine("All Sentences with Interpreted Regex:");
        sw = Stopwatch.StartNew();
        Regex intAll = new Regex(pattern, RegexOptions.Singleline);
        match = intAll.Match(input);
        int matches = 0;
        while (match.Success) {
            matches++;
            // Do nothing with the match except get the next match.
            match = match.NextMatch();
        }
    }
}
```

```

        }
        sw.Stop();
        Console.WriteLine("    {0:N0} matches in {1}", matches, sw.Elapsed);

        // Read all sentences with compiled regex.
        Console.WriteLine("All Sentences with Compiled Regex:");
        sw = Stopwatch.StartNew();
        Regex compAll = new Regex(pattern,
            RegexOptions.Singleline | RegexOptions.Compiled);
        match = compAll.Match(input);
        matches = 0;
        while (match.Success) {
            matches++;
            // Do nothing with the match except get the next match.
            match = match.NextMatch();
        }
        sw.Stop();
        Console.WriteLine("    {0:N0} matches in {1}", matches, sw.Elapsed);
    }
}

// The example displays the following output:
//      10 Sentences with Interpreted Regex:
//          10 matches in 00:00:00.0047491
//      10 Sentences with Compiled Regex:
//          10 matches in 00:00:00.0141872
//      All Sentences with Interpreted Regex:
//          13,443 matches in 00:00:01.1929928
//      All Sentences with Compiled Regex:
//          13,443 matches in 00:00:00.7635869

//
//      >compare1
//      10 Sentences with Interpreted Regex:
//          10 matches in 00:00:00.0046914
//      10 Sentences with Compiled Regex:
//          10 matches in 00:00:00.0143727
//      All Sentences with Interpreted Regex:
//          13,443 matches in 00:00:01.1514100
//      All Sentences with Compiled Regex:
//          13,443 matches in 00:00:00.7432921

```

The regular expression pattern used in the example, `\b(\w+((\r?\n)|,\s))*\w+[.?:;!]`, is defined as shown in the following table:

| Pattern | Description |
|-------------------------|---|
| <code>\b</code> | Begin the match at a word boundary. |
| <code>\w+</code> | Matches one or more word characters. |
| <code>(\r?\n) ,?</code> | Matches either zero or one carriage return followed by a newline character, or zero or one comma followed by a white-space character. |
| <code>\s</code> | |

| Pattern | Description |
|----------------------|---|
| (\w+((\r?\n) ,?\s))* | Matches zero or more occurrences of one or more word characters that are followed either by zero or one carriage return and a newline character, or by zero or one comma followed by a white-space character. |
| \w+ | Matches one or more word characters. |
| [.?;:] | Matches a period, question mark, colon, semicolon, or exclamation point. |

Regular expressions: Compiled to an assembly

.NET also enables you to create an assembly that contains compiled regular expressions. This capability moves the performance hit of regular expression compilation from run time to design time. However, it also involves some additional work. You must define the regular expressions in advance and compile them to an assembly. The compiler can then reference this assembly when compiling source code that uses the assembly's regular expressions. Each compiled regular expression in the assembly is represented by a class that derives from [Regex](#).

To compile regular expressions to an assembly, you call the [Regex.CompileToAssembly\(RegexCompilationInfo\[\], AssemblyName\)](#) method and pass it an array of [RegexCompilationInfo](#) objects and an [AssemblyName](#) object. The [RegexCompilationInfo](#) objects represent the regular expressions to be compiled, and the [AssemblyName](#) object that contains information about the assembly to be created.

We recommend that you compile regular expressions to an assembly in the following situations:

- If you're a component developer who wants to create a library of reusable regular expressions.
- If you expect your regular expression's pattern-matching methods to be called an indeterminate number of times—anywhere from once or twice to thousands or tens of thousands of times. Unlike compiled or interpreted regular expressions, regular expressions that are compiled to separate assemblies offer performance that's consistent regardless of the number of method calls.

If you're using compiled regular expressions to optimize performance, you shouldn't use reflection to create the assembly, load the regular expression engine, and execute its pattern-matching methods. Avoiding reflection requires that you don't build regular expression patterns dynamically, and that you specify any pattern-matching options, such as case-insensitive pattern matching, at the time the assembly is created. It also

requires that you separate the code that creates the assembly from the code that uses the regular expression.

The following example shows how to create an assembly that contains a compiled regular expression. It creates an assembly named `RegexLib.dll` with a single regular expression class, `SentencePattern`. This class contains the sentence-matching regular expression pattern used in the [Interpreted vs. Compiled Regular Expressions](#) section.

```
C#  
  
using System;  
using System.Reflection;  
using System.Text.RegularExpressions;  
  
public class Example  
{  
    public static void Main()  
    {  
        RegexCompilationInfo SentencePattern =  
            new RegexCompilationInfo(@"\b(\w+((\r?\n)|,?  
\s))*\w+[.:;!]",  
                RegexOptions.Multiline,  
                "SentencePattern",  
                "Utilities.RegularExpressions",  
                true);  
        RegexCompilationInfo[] regexes = { SentencePattern };  
        AssemblyName assemName = new AssemblyName("RegexLib,  
Version=1.0.0.1001, Culture=neutral, PublicKeyToken=null");  
        Regex.CompileToAssembly(regexes, assemName);  
    }  
}
```

When the example is compiled to an executable and run, it creates an assembly named `RegexLib.dll`. A `Utilities.RegularExpressions.SentencePattern` class derived from `Regex` represents the regular expression. The following example then uses the compiled regular expression to extract the sentences from the text of Theodore Dreiser's *The Financier*:

```
C#  
  
using System;  
using System.IO;  
using System.Text.RegularExpressions;  
using Utilities.RegularExpressions;  
  
public class Example  
{  
    public static void Main()  
    {
```

```
{  
    SentencePattern pattern = new SentencePattern();  
    StreamReader inFile = new StreamReader(@".\Dreiser_TheFinancier.txt");  
    string input = inFile.ReadToEnd();  
    inFile.Close();  
  
    MatchCollection matches = pattern.Matches(input);  
    Console.WriteLine("Found {0:N0} sentences.", matches.Count);  
}  
}  
// The example displays the following output:  
//      Found 13,443 sentences.
```

Take charge of backtracking

Ordinarily, the regular expression engine uses linear progression to move through an input string and compare it to a regular expression pattern. However, when indeterminate quantifiers such as `*`, `+`, and `?` are used in a regular expression pattern, the regular expression engine might give up a portion of successful partial matches and return to a previously saved state in order to search for a successful match for the entire pattern. This process is known as backtracking.

Tip

For more information on backtracking, see [Details of regular expression behavior](#) and [Backtracking](#). For detailed discussions of backtracking, see the [Regular Expression Improvements in .NET 7](#) and [Optimizing Regular Expression Performance](#) blog posts.

Support for backtracking gives regular expressions power and flexibility. It also places the responsibility for controlling the operation of the regular expression engine in the hands of regular expression developers. Because developers are often not aware of this responsibility, their misuse of backtracking or reliance on excessive backtracking often plays the most significant role in degrading regular expression performance. In a worst-case scenario, execution time can double for each additional character in the input string. In fact, by using backtracking excessively, it's easy to create the programmatic equivalent of an endless loop if input nearly matches the regular expression pattern. The regular expression engine might take hours or even days to process a relatively short input string.

Often, applications pay a performance penalty for using backtracking even though backtracking isn't essential for a match. For example, the regular expression

`\b\p{Lu}\w*\b` matches all words that begin with an uppercase character, as the following table shows:

| Pattern | Description |
|---------------------|---------------------------------------|
| <code>\b</code> | Begin the match at a word boundary. |
| <code>\p{Lu}</code> | Matches an uppercase character. |
| <code>\w*</code> | Matches zero or more word characters. |
| <code>\b</code> | End the match at a word boundary. |

Because a word boundary isn't the same as, or a subset of, a word character, there's no possibility that the regular expression engine will cross a word boundary when matching word characters. Therefore for this regular expression, backtracking can never contribute to the overall success of any match. It can only degrade performance because the regular expression engine is forced to save its state for each successful preliminary match of a word character.

If you determine that backtracking isn't necessary, you can disable it in a couple of ways:

- By setting the [RegexOptions.NonBacktracking](#) option (introduced in .NET 7). For more information, see [Nonbacktracking mode](#).
- By using the `(?>subexpression)` language element, known as an atomic group. The following example parses an input string by using two regular expressions. The first, `\b\p{Lu}\w*\b`, relies on backtracking. The second, `\b\p{Lu}(?>\w*)\b`, disables backtracking. As the output from the example shows, they both produce the same result:

```
C#  
  
using System;  
using System.Text.RegularExpressions;  
  
public class Example  
{  
    public static void Main()  
    {  
        string input = "This this word Sentence name Capital";  
        string pattern = @"\b\p{Lu}\w*\b";  
        foreach (Match match in Regex.Matches(input, pattern))  
            Console.WriteLine(match.Value);  
  
        Console.WriteLine();  
  
        pattern = @"\b\p{Lu}(?>\w*)\b";
```

```

        foreach (Match match in Regex.Matches(input, pattern))
            Console.WriteLine(match.Value);
    }
}

// The example displays the following output:
//      This
//      Sentence
//      Capital
//
//      This
//      Sentence
//      Capital

```

In many cases, backtracking is essential for matching a regular expression pattern to input text. However, excessive backtracking can severely degrade performance and create the impression that an application has stopped responding. In particular, this problem arises when quantifiers are nested and the text that matches the outer subexpression is a subset of the text that matches the inner subexpression.

Warning

In addition to avoiding excessive backtracking, you should use the timeout feature to ensure that excessive backtracking doesn't severely degrade regular expression performance. For more information, see the [Use time-out values](#) section.

For example, the regular expression pattern `^[0-9A-Z]([-.\\w]*[0-9A-Z])*\\$` is intended to match a part number that consists of at least one alphanumeric character. Any additional characters can consist of an alphanumeric character, a hyphen, an underscore, or a period, though the last character must be alphanumeric. A dollar sign terminates the part number. In some cases, this regular expression pattern can exhibit poor performance because quantifiers are nested, and because the subexpression `[0-9A-Z]` is a subset of the subexpression `[-.\\w]*`.

In these cases, you can optimize regular expression performance by removing the nested quantifiers and replacing the outer subexpression with a zero-width lookahead or lookbehind assertion. Lookahead and lookbehind assertions are anchors. They don't move the pointer in the input string but instead look ahead or behind to check whether a specified condition is met. For example, the part number regular expression can be rewritten as `^[0-9A-Z][-.\\w]*(?<=[0-9A-Z])\\$`. This regular expression pattern is defined as shown in the following table:

| Pattern | Description |
|----------------|---|
| <code>^</code> | Begin the match at the beginning of the input string. |

| Pattern | Description |
|----------------|---|
| [0-9A-Z] | Match an alphanumeric character. The part number must consist of at least this character. |
| [-.\w]* | Match zero or more occurrences of any word character, hyphen, or period. |
| \\$ | Match a dollar sign. |
| (?<=[0-9A-Z]) | Look behind the ending dollar sign to ensure that the previous character is alphanumeric. |
| \$ | End the match at the end of the input string. |

The following example illustrates the use of this regular expression to match an array containing possible part numbers:

```
C#
using System;
using System.Text.RegularExpressions;

public class Example
{
    public static void Main()
    {
        string pattern = @"^([0-9A-Z][ -.\w]*(?<=[0-9A-Z]))\$$";
        string[] partNos = { "A1C$", "A4", "A4$", "A1603D$", "A1603D#" };

        foreach (var input in partNos) {
            Match match = Regex.Match(input, pattern);
            if (match.Success)
                Console.WriteLine(match.Value);
            else
                Console.WriteLine("Match not found.");
        }
    }
}
// The example displays the following output:
//      A1C$
//      Match not found.
//      A4$
//      A1603D$
//      Match not found.
```

The regular expression language in .NET includes the following language elements that you can use to eliminate nested quantifiers. For more information, see [Grouping constructs](#).

| Language element | Description |
|--------------------------------------|--|
| <code>(?= subexpression)</code> | Zero-width positive lookahead. Looks ahead of the current position to determine whether <code>subexpression</code> matches the input string. |
| <code>(?! subexpression)</code> | Zero-width negative lookahead. Looks ahead of the current position to determine whether <code>subexpression</code> doesn't match the input string. |
| <code>(?=< subexpression)</code> | Zero-width positive lookbehind. Looks behind the current position to determine whether <code>subexpression</code> matches the input string. |
| <code>(?<! subexpression)</code> | Zero-width negative lookbehind. Looks behind the current position to determine whether <code>subexpression</code> doesn't match the input string. |

Use time-out values

If your regular expressions processes input that nearly matches the regular expression pattern, it can often rely on excessive backtracking, which impacts its performance significantly. In addition to carefully considering your use of backtracking and testing the regular expression against near-matching input, you should always set a time-out value to minimize the effect of excessive backtracking, if it occurs.

The regular expression time-out interval defines the period of time that the regular expression engine will look for a single match before it times out. Depending on the regular expression pattern and the input text, the execution time might exceed the specified time-out interval, but it won't spend more time backtracking than the specified time-out interval. The default time-out interval is [Regex.InfiniteMatchTimeout](#), which means that the regular expression won't time out. You can override this value and define a time-out interval as follows:

- Call the [Regex\(String, RegexOptions, TimeSpan\)](#) constructor to provide a time-out value when you instantiate a [Regex](#) object.
- Call a static pattern matching method, such as [Regex.Match\(String, String, RegexOptions, TimeSpan\)](#) or [Regex.Replace\(String, String, String, RegexOptions, TimeSpan\)](#), that includes a `matchTimeout` parameter.
- Call the constructor that has a parameter of type [TimeSpan](#) for compiled regular expressions that are created by calling the [Regex.CompileToAssembly](#) method.
- Set a process-wide or AppDomain-wide value with code such as

```
AppDomain.CurrentDomain.SetData("REGEX_DEFAULT_MATCH_TIMEOUT",
    TimeSpan.FromMilliseconds(100));
```

If you've defined a time-out interval and a match isn't found at the end of that interval, the regular expression method throws a [RegexMatchTimeoutException](#) exception. In your exception handler, you can choose to retry the match with a longer time-out interval, abandon the match attempt and assume that there's no match, or abandon the match attempt and log the exception information for future analysis.

The following example defines a `GetWordData` method that instantiates a regular expression with a time-out interval of 350 milliseconds to calculate the number of words and average number of characters in a word in a text document. If the matching operation times out, the time-out interval is increased by 350 milliseconds and the `Regex` object is reinstated. If the new time-out interval exceeds one second, the method rethrows the exception to the caller.

C#

```
using System;
using System.Collections.Generic;
using System.IO;
using System.Text.RegularExpressions;

public class Example
{
    public static void Main()
    {
        RegexUtilities util = new RegexUtilities();
        string title = "Doyle - The Hound of the Baskervilles.txt";
        try {
            var info = util.GetWordData(title);
            Console.WriteLine("Words: {0:N0}", info.Item1);
            Console.WriteLine("Average Word Length: {0:N2} characters",
info.Item2);
        }
        catch (IOException e) {
            Console.WriteLine("IOException reading file '{0}'", title);
            Console.WriteLine(e.Message);
        }
        catch (RegexMatchTimeoutException e) {
            Console.WriteLine("The operation timed out after {0:N0}
milliseconds",
e.MatchTimeout.TotalMilliseconds);
        }
    }

    public class RegexUtilities
    {
        public Tuple<int, double> GetWordData(string filename)
        {
            const int MAX_TIMEOUT = 1000; // Maximum timeout interval in
milliseconds.
            const int INCREMENT = 350; // Milliseconds increment of timeout.
```

```
    List<string> exclusions = new List<string>( new string[] { "a", "an",
"the" });
    int[] wordLengths = new int[29];           // Allocate an array of more
than ample size.
    string input = null;
    StreamReader sr = null;
    try {
        sr = new StreamReader(filename);
        input = sr.ReadToEnd();
    }
    catch (FileNotFoundException e) {
        string msg = String.Format("Unable to find the file '{0}'",
filename);
        throw new IOException(msg, e);
    }
    catch (IOException e) {
        throw new IOException(e.Message, e);
    }
    finally {
        if (sr != null) sr.Close();
    }

    int timeoutInterval = INCREMENT;
    bool init = false;
    Regex rgx = null;
    Match m = null;
    int indexPos = 0;
    do {
        try {
            if (! init) {
                rgx = new Regex(@"\b\w+\b", RegexOptions.None,
                    TimeSpan.FromMilliseconds(timeoutInterval));
                m = rgx.Match(input, indexPos);
                init = true;
            }
            else {
                m = m.NextMatch();
            }
            if (m.Success) {
                if ( !exclusions.Contains(m.Value.ToLower()))
                    wordLengths[m.Value.Length]++;
            }
            indexPos += m.Length + 1;
        }
    }
    catch (RegexMatchTimeoutException e) {
        if (e.MatchTimeout.TotalMilliseconds < MAX_TIMEOUT) {
            timeoutInterval += INCREMENT;
            init = false;
        }
        else {
            // Rethrow the exception.
            throw;
        }
    }
}
```

```

        }

    } while (m.Success);

    // If regex completed successfully, calculate number of words and
    // average length.
    int nWords = 0;
    long totalLength = 0;

    for (int ctr = wordLengths.GetLowerBound(0); ctr <=
wordLengths.GetUpperBound(0); ctr++) {
        nWords += wordLengths[ctr];
        totalLength += ctr * wordLengths[ctr];
    }
    return new Tuple<int, double>(nWords, totalLength/nWords);
}
}

```

Capture only when necessary

Regular expressions in .NET support grouping constructs, which let you group a regular expression pattern into one or more subexpressions. The most commonly used grouping constructs in .NET regular expression language are `(subexpression)`, which defines a numbered capturing group, and `(?name)subexpression`, which defines a named capturing group. Grouping constructs are essential for creating backreferences and for defining a subexpression to which a quantifier is applied.

However, the use of these language elements has a cost. They cause the [GroupCollection](#) object returned by the [Match.Groups](#) property to be populated with the most recent unnamed or named captures. If a single grouping construct has captured multiple substrings in the input string, they also populate the [CaptureCollection](#) object returned by the [Group.Captures](#) property of a particular capturing group with multiple [Capture](#) objects.

Often, grouping constructs are used in a regular expression only so that quantifiers can be applied to them. The groups captured by these subexpressions aren't used later. For example, the regular expression `\b(\w+[,]?|\s?)+[.?!]` is designed to capture an entire sentence. The following table describes the language elements in this regular expression pattern and their effect on the [Match](#) object's [Match.Groups](#) and [Group.Captures](#) collections:

| Pattern | Description |
|------------------|--------------------------------------|
| <code>\b</code> | Begin the match at a word boundary. |
| <code>\w+</code> | Matches one or more word characters. |

| Pattern | Description |
|------------------------|--|
| [;,]? | Matches zero or one comma or semicolon. |
| \s? | Matches zero or one white-space character. |
| (\w+ [;,]? \s?)+ | Matches one or more occurrences of one or more word characters followed by an optional comma or semicolon followed by an optional white-space character. This pattern defines the first capturing group, which is necessary so that the combination of multiple word characters (that is, a word) followed by an optional punctuation symbol will be repeated until the regular expression engine reaches the end of a sentence. |
| [.?!] | Matches a period, question mark, or exclamation point. |

As the following example shows, when a match is found, both the [GroupCollection](#) and [CaptureCollection](#) objects are populated with captures from the match. In this case, the capturing group `(\w+[,]?[\s?])` exists so that the `+` quantifier can be applied to it, which enables the regular expression pattern to match each word in a sentence. Otherwise, it would match the last word in a sentence.

C#

```
using System;
using System.Text.RegularExpressions;

public class Example
{
    public static void Main()
    {
        string input = "This is one sentence. This is another.";
        string pattern = @"\b(\w+[,]?[\s?])+[.?!]";

        foreach (Match match in Regex.Matches(input, pattern)) {
            Console.WriteLine("Match: '{0}' at index {1}.",
                match.Value, match.Index);
            int grpCtr = 0;
            foreach (Group grp in match.Groups) {
                Console.WriteLine("    Group {0}: '{1}' at index {2}.",
                    grpCtr, grp.Value, grp.Index);
                int capCtr = 0;
                foreach (Capture cap in grp.Captures) {
                    Console.WriteLine("        Capture {0}: '{1}' at {2}.",
                        capCtr, cap.Value, cap.Index);
                    capCtr++;
                }
                grpCtr++;
            }
            Console.WriteLine();
        }
    }
}
```

```

}

// The example displays the following output:
//      Match: 'This is one sentence.' at index 0.
//          Group 0: 'This is one sentence.' at index 0.
//              Capture 0: 'This is one sentence.' at 0.
//          Group 1: 'sentence' at index 12.
//              Capture 0: 'This ' at 0.
//              Capture 1: 'is ' at 5.
//              Capture 2: 'one ' at 8.
//              Capture 3: 'sentence' at 12.
//
//      Match: 'This is another.' at index 22.
//          Group 0: 'This is another.' at index 22.
//              Capture 0: 'This is another.' at 22.
//          Group 1: 'another' at index 30.
//              Capture 0: 'This ' at 22.
//              Capture 1: 'is ' at 27.
//              Capture 2: 'another' at 30.

```

When you use subexpressions only to apply quantifiers to them and you aren't interested in the captured text, you should disable group captures. For example, the `(?:subexpression)` language element prevents the group to which it applies from capturing matched substrings. In the following example, the regular expression pattern from the previous example is changed to `\b(?:\w+[,]?\s?)+[.?!]`. As the output shows, it prevents the regular expression engine from populating the [GroupCollection](#) and [CaptureCollection](#) collections:

C#

```

using System;
using System.Text.RegularExpressions;

public class Example
{
    public static void Main()
    {
        string input = "This is one sentence. This is another.";
        string pattern = @"\b(?:\w+[, ]?\s?)+[.?!]";

        foreach (Match match in Regex.Matches(input, pattern)) {
            Console.WriteLine("Match: '{0}' at index {1}.",
                match.Value, match.Index);
            int grpCtr = 0;
            foreach (Group grp in match.Groups) {
                Console.WriteLine("    Group {0}: '{1}' at index {2}.",
                    grpCtr, grp.Value, grp.Index);
                int capCtr = 0;
                foreach (Capture cap in grp.Captures) {
                    Console.WriteLine("        Capture {0}: '{1}' at {2}.",
                        capCtr, cap.Value, cap.Index);
                    capCtr++;
                }
            }
        }
    }
}

```

```

        }
        grpCtr++;
    }
    Console.WriteLine();
}
}

// The example displays the following output:
//      Match: 'This is one sentence.' at index 0.
//          Group 0: 'This is one sentence.' at index 0.
//              Capture 0: 'This is one sentence.' at 0.
//
//      Match: 'This is another.' at index 22.
//          Group 0: 'This is another.' at index 22.
//              Capture 0: 'This is another.' at 22.

```

You can disable captures in one of the following ways:

- Use the `(?:subexpression)` language element. This element prevents the capture of matched substrings in the group to which it applies. It doesn't disable substring captures in any nested groups.
- Use the [ExplicitCapture](#) option. It disables all unnamed or implicit captures in the regular expression pattern. When you use this option, only substrings that match named groups defined with the `(?<name>subexpression)` language element can be captured. The [ExplicitCapture](#) flag can be passed to the `options` parameter of a [Regex](#) class constructor or to the `options` parameter of a [Regex](#) static matching method.
- Use the `n` option in the `(?imnsx)` language element. This option disables all unnamed or implicit captures from the point in the regular expression pattern at which the element appears. Captures are disabled either until the end of the pattern or until the `(-n)` option enables unnamed or implicit captures. For more information, see [Miscellaneous Constructs](#).
- Use the `n` option in the `(?imnsx:subexpression)` language element. This option disables all unnamed or implicit captures in `subexpression`. Captures by any unnamed or implicit nested capturing groups are disabled as well.

The Regular Expression Object Model

Article • 09/15/2021

This topic describes the object model used in working with .NET regular expressions. It contains the following sections:

- [The Regular Expression Engine](#)
- [The MatchCollection and Match Objects](#)
- [The Group Collection](#)
- [The Captured Group](#)
- [The Capture Collection](#)
- [The Individual Capture](#)

The Regular Expression Engine

The regular expression engine in .NET is represented by the [Regex](#) class. The regular expression engine is responsible for parsing and compiling a regular expression, and for performing operations that match the regular expression pattern with an input string. The engine is the central component in the .NET regular expression object model.

You can use the regular expression engine in either of two ways:

- By calling the static methods of the [Regex](#) class. The method parameters include the input string and the regular expression pattern. The regular expression engine caches regular expressions that are used in static method calls, so repeated calls to static regular expression methods that use the same regular expression offer relatively good performance.
- By instantiating a [Regex](#) object, by passing a regular expression to the class constructor. In this case, the [Regex](#) object is immutable (read-only) and represents a regular expression engine that is tightly coupled with a single regular expression. Because regular expressions used by [Regex](#) instances are not cached, you should not instantiate a [Regex](#) object multiple times with the same regular expression.

You can call the methods of the [Regex](#) class to perform the following operations:

- Determine whether a string matches a regular expression pattern.
- Extract a single match or the first match.

- Extract all matches.
- Replace a matched substring.
- Split a single string into an array of strings.

These operations are described in the following sections.

Matching a Regular Expression Pattern

The `Regex.IsMatch` method returns `true` if the string matches the pattern, or `false` if it does not. The `IsMatch` method is often used to validate string input. For example, the following code ensures that a string matches a valid social security number in the United States.

C#

```
using System;
using System.Text.RegularExpressions;

public class Example
{
    public static void Main()
    {
        string[] values = { "111-22-3333", "111-2-3333" };
        string pattern = @"^\d{3}-\d{2}-\d{4}$";
        foreach (string value in values) {
            if (Regex.IsMatch(value, pattern))
                Console.WriteLine("{0} is a valid SSN.", value);
            else
                Console.WriteLine("{0}: Invalid", value);
        }
    }
}
// The example displays the following output:
//      111-22-3333 is a valid SSN.
//      111-2-3333: Invalid
```

The regular expression pattern `^\d{3}-\d{2}-\d{4}$` is interpreted as shown in the following table.

| Pattern | Description |
|--------------------|--|
| <code>^</code> | Match the beginning of the input string. |
| <code>\d{3}</code> | Match three decimal digits. |
| <code>-</code> | Match a hyphen. |

| Pattern | Description |
|---------|------------------------------------|
| \d{2} | Match two decimal digits. |
| - | Match a hyphen. |
| \d{4} | Match four decimal digits. |
| \$ | Match the end of the input string. |

Extracting a Single Match or the First Match

The [Regex.Match](#) method returns a [Match](#) object that contains information about the first substring that matches a regular expression pattern. If the [Match.Success](#) property returns `true`, indicating that a match was found, you can retrieve information about subsequent matches by calling the [Match.NextMatch](#) method. These method calls can continue until the [Match.Success](#) property returns `false`. For example, the following code uses the [Regex.Match\(String, String\)](#) method to find the first occurrence of a duplicated word in a string. It then calls the [Match.NextMatch](#) method to find any additional occurrences. The example examines the [Match.Success](#) property after each method call to determine whether the current match was successful and whether a call to the [Match.NextMatch](#) method should follow.

C#

```

using System;
using System.Text.RegularExpressions;

public class Example
{
    public static void Main()
    {
        string input = "This is a a farm that that raises dairy cattle.";
        string pattern = @"\b(\w+)\W+(\1)\b";
        Match match = Regex.Match(input, pattern);
        while (match.Success)
        {
            Console.WriteLine("Duplicate '{0}' found at position {1}.",
                match.Groups[1].Value, match.Groups[2].Index);
            match = match.NextMatch();
        }
    }
}
// The example displays the following output:
//      Duplicate 'a' found at position 10.
//      Duplicate 'that' found at position 22.

```

The regular expression pattern `\b(\w+)\W+(\1)\b` is interpreted as shown in the following table.

| Pattern | Description |
|--------------------|---|
| <code>\b</code> | Begin the match on a word boundary. |
| <code>(\w+)</code> | Match one or more word characters. This is the first capturing group. |
| <code>\W+</code> | Match one or more non-word characters. |
| <code>(\1)</code> | Match the first captured string. This is the second capturing group. |
| <code>\b</code> | End the match on a word boundary. |

Extracting All Matches

The [Regex.Matches](#) method returns a [MatchCollection](#) object that contains information about all matches that the regular expression engine found in the input string. For example, the previous example could be rewritten to call the [Matches](#) method instead of the [Match](#) and [NextMatch](#) methods.

C#

```
using System;
using System.Text.RegularExpressions;

public class Example
{
    public static void Main()
    {
        string input = "This is a a farm that that raises dairy cattle.";
        string pattern = @"\b(\w+)\W+(\1)\b";
        foreach (Match match in Regex.Matches(input, pattern))
            Console.WriteLine("Duplicate '{0}' found at position {1}.",
                match.Groups[1].Value, match.Groups[2].Index);
    }
}
// The example displays the following output:
//      Duplicate 'a' found at position 10.
//      Duplicate 'that' found at position 22.
```

Replacing a Matched Substring

The [Regex.Replace](#) method replaces each substring that matches the regular expression pattern with a specified string or regular expression pattern, and returns the entire input

string with replacements. For example, the following code adds a U.S. currency symbol before a decimal number in a string.

```
C#  
  
using System;  
using System.Text.RegularExpressions;  
  
public class Example  
{  
    public static void Main()  
    {  
        string pattern = @"\b\d+\.\d{2}\b";  
        string replacement = "$$$&";  
        string input = "Total Cost: 103.64";  
        Console.WriteLine(Regex.Replace(input, pattern, replacement));  
    }  
}  
// The example displays the following output:  
//      Total Cost: $103.64
```

The regular expression pattern `\b\d+\.\d{2}\b` is interpreted as shown in the following table.

| Pattern | Description |
|--------------------|-------------------------------------|
| <code>\b</code> | Begin the match at a word boundary. |
| <code>\d+</code> | Match one or more decimal digits. |
| <code>\.</code> | Match a period. |
| <code>\d{2}</code> | Match two decimal digits. |
| <code>\b</code> | End the match at a word boundary. |

The replacement pattern `$$$&` is interpreted as shown in the following table.

| Pattern | Replacement string |
|----------------------|---------------------------------|
| <code>\$\$</code> | The dollar sign (\$) character. |
| <code>\$&</code> | The entire matched substring. |

Splitting a Single String into an Array of Strings

The `Regex.Split` method splits the input string at the positions defined by a regular expression match. For example, the following code places the items in a numbered list

into a string array.

C#

```
using System;
using System.Text.RegularExpressions;

public class Example
{
    public static void Main()
    {
        string input = "1. Eggs 2. Bread 3. Milk 4. Coffee 5. Tea";
        string pattern = @"\b\d{1,2}\.\s";
        foreach (string item in Regex.Split(input, pattern))
        {
            if (!String.IsNullOrEmpty(item))
                Console.WriteLine(item);
        }
    }
}
// The example displays the following output:
//      Eggs
//      Bread
//      Milk
//      Coffee
//      Tea
```

The regular expression pattern `\b\d{1,2}\.\s` is interpreted as shown in the following table.

| Pattern | Description |
|----------------------|-------------------------------------|
| <code>\b</code> | Begin the match at a word boundary. |
| <code>\d{1,2}</code> | Match one or two decimal digits. |
| <code>\.</code> | Match a period. |
| <code>\s</code> | Match a white-space character. |

The MatchCollection and Match Objects

Regex methods return two objects that are part of the regular expression object model: the [MatchCollection](#) object, and the [Match](#) object.

The Match Collection

The `Regex.Matches` method returns a `MatchCollection` object that contains `Match` objects that represent all the matches that the regular expression engine found, in the order in which they occur in the input string. If there are no matches, the method returns a `MatchCollection` object with no members. The `MatchCollection.Item[]` property lets you access individual members of the collection by index, from zero to one less than the value of the `MatchCollection.Count` property. `Item[]` is the collection's indexer (in C#) and default property (in Visual Basic).

By default, the call to the `Regex.Matches` method uses lazy evaluation to populate the `MatchCollection` object. Access to properties that require a fully populated collection, such as the `MatchCollection.Count` and `MatchCollection.Item[]` properties, may involve a performance penalty. As a result, we recommend that you access the collection by using the `IEnumerator` object that is returned by the `MatchCollection.GetEnumerator` method. Individual languages provide constructs, such as `For Each` in Visual Basic and `foreach` in C#, that wrap the collection's `IEnumerator` interface.

The following example uses the `Regex.Matches(String)` method to populate a `MatchCollection` object with all the matches found in an input string. The example enumerates the collection, copies the matches to a string array, and records the character positions in an integer array.

C#

```
using System;
using System.Collections.Generic;
using System.Text.RegularExpressions;

public class Example
{
    public static void Main()
    {
        MatchCollection matches;
        List<string> results = new List<string>();
        List<int> matchposition = new List<int>();

        // Create a new Regex object and define the regular expression.
        Regex r = new Regex("abc");
        // Use the Matches method to find all matches in the input string.
        matches = r.Matches("123abc4abcd");
        // Enumerate the collection to retrieve all matches and positions.
        foreach (Match match in matches)
        {
            // Add the match string to the string array.
            results.Add(match.Value);
            // Record the character position where the match was found.
            matchposition.Add(match.Index);
        }
        // List the results.
    }
}
```

```

        for (int ctr = 0; ctr < results.Count; ctr++)
            Console.WriteLine("{0}' found at position {1}.",
                               results[ctr], matchposition[ctr]);
    }
}
// The example displays the following output:
//      'abc' found at position 3.
//      'abc' found at position 7.

```

The Match

The [Match](#) class represents the result of a single regular expression match. You can access [Match](#) objects in two ways:

- By retrieving them from the [MatchCollection](#) object that is returned by the [Regex.Matches](#) method. To retrieve individual [Match](#) objects, iterate the collection by using a `foreach` (in C#) or `For Each...Next` (in Visual Basic) construct, or use the [MatchCollection.Item\[\]](#) property to retrieve a specific [Match](#) object either by index or by name. You can also retrieve individual [Match](#) objects from the collection by iterating the collection by index, from zero to one less than the number of objects in the collection. However, this method does not take advantage of lazy evaluation, because it accesses the [MatchCollection.Count](#) property.

The following example retrieves individual [Match](#) objects from a [MatchCollection](#) object by iterating the collection using the `foreach` OR `For Each...Next` construct. The regular expression simply matches the string "abc" in the input string.

C#

```

using System;
using System.Text.RegularExpressions;

public class Example
{
    public static void Main()
    {
        string pattern = "abc";
        string input = "abc123abc456abc789";
        foreach (Match match in Regex.Matches(input, pattern))
            Console.WriteLine("{0} found at position {1}.",
                               match.Value, match.Index);
    }
}
// The example displays the following output:
//      abc found at position 0.
//      abc found at position 6.
//      abc found at position 12.

```

- By calling the `Regex.Match` method, which returns a `Match` object that represents the first match in a string or a portion of a string. You can determine whether the match has been found by retrieving the value of the `Match.Success` property. To retrieve `Match` objects that represent subsequent matches, call the `Match.NextMatch` method repeatedly, until the `Success` property of the returned `Match` object is `false`.

The following example uses the `Regex.Match(String, String)` and `Match.NextMatch` methods to match the string "abc" in the input string.

```
C#  
  
using System;  
using System.Text.RegularExpressions;  
  
public class Example  
{  
    public static void Main()  
    {  
        string pattern = "abc";  
        string input = "abc123abc456abc789";  
        Match match = Regex.Match(input, pattern);  
        while (match.Success)  
        {  
            Console.WriteLine("{0} found at position {1}.",  
                match.Value, match.Index);  
            match = match.NextMatch();  
        }  
    }  
}  
// The example displays the following output:  
//      abc found at position 0.  
//      abc found at position 6.  
//      abc found at position 12.
```

Two properties of the `Match` class return collection objects:

- The `Match.Groups` property returns a `GroupCollection` object that contains information about the substrings that match capturing groups in the regular expression pattern.
- The `Match.Captures` property returns a `CaptureCollection` object that is of limited use. The collection is not populated for a `Match` object whose `Success` property is `false`. Otherwise, it contains a single `Capture` object that has the same information as the `Match` object.

For more information about these objects, see [The Group Collection](#) and [The Capture Collection](#) sections later in this topic.

Two additional properties of the [Match](#) class provide information about the match. The `Match.Value` property returns the substring in the input string that matches the regular expression pattern. The `Match.Index` property returns the zero-based starting position of the matched string in the input string.

The [Match](#) class also has two pattern-matching methods:

- The [Match.NextMatch](#) method finds the match after the match represented by the current [Match](#) object, and returns a [Match](#) object that represents that match.
- The [Match.Result](#) method performs a specified replacement operation on the matched string and returns the result.

The following example uses the [Match.Result](#) method to prepend a \$ symbol and a space before every number that includes two fractional digits.

C#

```
using System;
using System.Text.RegularExpressions;

public class Example
{
    public static void Main()
    {
        string pattern = @"\b\d+(,\d{3})*\.\d{2}\b";
        string input = "16.32\n194.03\n1,903,672.08";

        foreach (Match match in Regex.Matches(input, pattern))
            Console.WriteLine(match.Result("$$ $&"));
    }
}
// The example displays the following output:
//      $ 16.32
//      $ 194.03
//      $ 1,903,672.08
```

The regular expression pattern `\b\d+(,\d{3})*\.\d{2}\b` is defined as shown in the following table.

| Pattern | Description |
|------------------|-------------------------------------|
| <code>\b</code> | Begin the match at a word boundary. |
| <code>\d+</code> | Match one or more decimal digits. |

| Pattern | Description |
|-----------|---|
| (,\d{3})* | Match zero or more occurrences of a comma followed by three decimal digits. |
| \. | Match the decimal point character. |
| \d{2} | Match two decimal digits. |
| \b | End the match at a word boundary. |

The replacement pattern `$$ $&` indicates that the matched substring should be replaced by a dollar sign (\$) symbol (the `$$` pattern), a space, and the value of the match (the `$&` pattern).

[Back to top](#)

The Group Collection

The `Match.Groups` property returns a `GroupCollection` object that contains `Group` objects that represent captured groups in a single match. The first `Group` object in the collection (at index 0) represents the entire match. Each object that follows represents the results of a single capturing group.

You can retrieve individual `Group` objects in the collection by using the `GroupCollection.Item[]` property. You can retrieve unnamed groups by their ordinal position in the collection, and retrieve named groups either by name or by ordinal position. Unnamed captures appear first in the collection, and are indexed from left to right in the order in which they appear in the regular expression pattern. Named captures are indexed after unnamed captures, from left to right in the order in which they appear in the regular expression pattern. To determine what numbered groups are available in the collection returned for a particular regular expression matching method, you can call the instance `Regex.GetGroupNumbers` method. To determine what named groups are available in the collection, you can call the instance `Regex.GetGroupNames` method. Both methods are particularly useful in general-purpose routines that analyze the matches found by any regular expression.

The `GroupCollection.Item[]` property is the indexer of the collection in C# and the collection object's default property in Visual Basic. This means that individual `Group` objects can be accessed by index (or by name, in the case of named groups) as follows:

C#

```
Group group = match.Groups[ctr];
```

The following example defines a regular expression that uses grouping constructs to capture the month, day, and year of a date.

```
C#  
  
using System;  
using System.Text.RegularExpressions;  
  
public class Example  
{  
    public static void Main()  
    {  
        string pattern = @"\b(\w+)\s(\d{1,2}),\s(\d{4})\b";  
        string input = "Born: July 28, 1989";  
        Match match = Regex.Match(input, pattern);  
        if (match.Success)  
            for (int ctr = 0; ctr < match.Groups.Count; ctr++)  
                Console.WriteLine("Group {0}: {1}", ctr,  
match.Groups[ctr].Value);  
    }  
}  
// The example displays the following output:  
//      Group 0: July 28, 1989  
//      Group 1: July  
//      Group 2: 28  
//      Group 3: 1989
```

The regular expression pattern `\b(\w+)\s(\d{1,2}),\s(\d{4})\b` is defined as shown in the following table.

| Pattern | Description |
|------------------------|---|
| <code>\b</code> | Begin the match at a word boundary. |
| <code>(\w+)</code> | Match one or more word characters. This is the first capturing group. |
| <code>\s</code> | Match a white-space character. |
| <code>(\d{1,2})</code> | Match one or two decimal digits. This is the second capturing group. |
| <code>,</code> | Match a comma. |
| <code>\s</code> | Match a white-space character. |
| <code>(\d{4})</code> | Match four decimal digits. This is the third capturing group. |
| <code>\b</code> | End the match on a word boundary. |

[Back to top](#)

The Captured Group

The [Group](#) class represents the result from a single capturing group. Group objects that represent the capturing groups defined in a regular expression are returned by the [Item\[\]](#) property of the [GroupCollection](#) object returned by the [Match.Groups](#) property. The [Item\[\]](#) property is the indexer (in C#) and the default property (in Visual Basic) of the [Group](#) class. You can also retrieve individual members by iterating the collection using the `foreach` or `For Each` construct. For an example, see the previous section.

The following example uses nested grouping constructs to capture substrings into groups. The regular expression pattern `(a(b))c` matches the string "abc". It assigns the substring "ab" to the first capturing group, and the substring "b" to the second capturing group.

C#

```
var matchposition = new List<int>();
var results = new List<string>();
// Define substrings abc, ab, b.
var r = new Regex("(a(b))c");
Match m = r.Match("abdabc");
for (int i = 0; m.Groups[i].Value != ""; i++)
{
    // Add groups to string array.
    results.Add(m.Groups[i].Value);
    // Record character position.
    matchposition.Add(m.Groups[i].Index);
}

// Display the capture groups.
for (int ctr = 0; ctr < results.Count; ctr++)
    Console.WriteLine("{0} at position {1}",
                      results[ctr], matchposition[ctr]);
// The example displays the following output:
//      abc at position 3
//      ab at position 3
//      b at position 4
```

The following example uses named grouping constructs to capture substrings from a string that contains data in the format "DATANAME:VALUE", which the regular expression splits at the colon (:).

C#

```
var r = new Regex(@"^(?<name>\w+):(?:<value>\w+)");
Match m = r.Match("Section1:119900");
Console.WriteLine(m.Groups["name"].Value);
Console.WriteLine(m.Groups["value"].Value);
```

```
// The example displays the following output:  
//      Section1  
//      119900
```

The regular expression pattern `^(?<name>\w+):(?<value>\w+)` is defined as shown in the following table.

| Pattern | Description |
|----------------------------------|---|
| <code>^</code> | Begin the match at the beginning of the input string. |
| <code>(?<name>\w+)</code> | Match one or more word characters. The name of this capturing group is <code>name</code> . |
| <code>:</code> | Match a colon. |
| <code>(?<value>\w+)</code> | Match one or more word characters. The name of this capturing group is <code>value</code> . |

The properties of the [Group](#) class provide information about the captured group: The `Group.Value` property contains the captured substring, the `Group.Index` property indicates the starting position of the captured group in the input text, the `Group.Length` property contains the length of the captured text, and the `Group.Success` property indicates whether a substring matched the pattern defined by the capturing group.

Applying quantifiers to a group (for more information, see [Quantifiers](#)) modifies the relationship of one capture per capturing group in two ways:

- If the `*` or `*?` quantifier (which specifies zero or more matches) is applied to a group, a capturing group may not have a match in the input string. When there is no captured text, the properties of the [Group](#) object are set as shown in the following table.

| Group property | Value |
|----------------------|---------------------------|
| <code>Success</code> | <code>false</code> |
| <code>Value</code> | <code>String.Empty</code> |
| <code>Length</code> | 0 |

The following example provides an illustration. In the regular expression pattern `aaa(bbb)*ccc`, the first capturing group (the substring "bbb") can be matched zero or more times. Because the input string "aaaccc" matches the pattern, the capturing group does not have a match.

C#

```

using System;
using System.Text.RegularExpressions;

public class Example
{
    public static void Main()
    {
        string pattern = "aaa(bbb)*ccc";
        string input = "aaaccc";
        Match match = Regex.Match(input, pattern);
        Console.WriteLine("Match value: {0}", match.Value);
        if (match.Groups[1].Success)
            Console.WriteLine("Group 1 value: {0}",
        match.Groups[1].Value);
        else
            Console.WriteLine("The first capturing group has no match.");
    }
}
// The example displays the following output:
//      Match value: aaaccc
//      The first capturing group has no match.

```

- Quantifiers can match multiple occurrences of a pattern that is defined by a capturing group. In this case, the `Value` and `Length` properties of a `Group` object contain information only about the last captured substring. For example, the following regular expression matches a single sentence that ends in a period. It uses two grouping constructs: The first captures individual words along with a white-space character; the second captures individual words. As the output from the example shows, although the regular expression succeeds in capturing an entire sentence, the second capturing group captures only the last word.

C#

```

using System;
using System.Text.RegularExpressions;

public class Example
{
    public static void Main()
    {
        string pattern = @"\b((\w+)\s?)+\.?";
        string input = "This is a sentence. This is another sentence.";
        Match match = Regex.Match(input, pattern);
        if (match.Success)
        {
            Console.WriteLine("Match: " + match.Value);
            Console.WriteLine("Group 2: " + match.Groups[2].Value);
        }
    }
}

```

```
// The example displays the following output:  
//      Match: This is a sentence.  
//      Group 2: sentence
```

[Back to top](#)

The Capture Collection

The [Group](#) object contains information only about the last capture. However, the entire set of captures made by a capturing group is still available from the [CaptureCollection](#) object that is returned by the [Group.Captures](#) property. Each member of the collection is a [Capture](#) object that represents a capture made by that capturing group, in the order in which they were captured (and, therefore, in the order in which the captured strings were matched from left to right in the input string). You can retrieve individual [Capture](#) objects from the collection in either of two ways:

- By iterating through the collection using a construct such as `foreach` (in C#) or `For Each` (in Visual Basic).
- By using the [CaptureCollection.Item\[\]](#) property to retrieve a specific object by index. The [Item\[\]](#) property is the [CaptureCollection](#) object's default property (in Visual Basic) or indexer (in C#).

If a quantifier is not applied to a capturing group, the [CaptureCollection](#) object contains a single [Capture](#) object that is of little interest, because it provides information about the same match as its [Group](#) object. If a quantifier is applied to a capturing group, the [CaptureCollection](#) object contains all captures made by the capturing group, and the last member of the collection represents the same capture as the [Group](#) object.

For example, if you use the regular expression pattern `((a(b))c)+` (where the `+` quantifier specifies one or more matches) to capture matches from the string "abcabcabc", the [CaptureCollection](#) object for each [Group](#) object contains three members.

C#

```
using System;  
using System.Text.RegularExpressions;  
  
public class Example  
{  
    public static void Main()  
    {  
        string pattern = "((a(b))c)+";  
        string input = "abcabcabc";
```

```

Match match = Regex.Match(input, pattern);
if (match.Success)
{
    Console.WriteLine("Match: '{0}' at position {1}",
                      match.Value, match.Index);
    GroupCollection groups = match.Groups;
    for (int ctr = 0; ctr < groups.Count; ctr++) {
        Console.WriteLine("    Group {0}: '{1}' at position {2}",
                          ctr, groups[ctr].Value, groups[ctr].Index);
        CaptureCollection captures = groups[ctr].Captures;
        for (int ctr2 = 0; ctr2 < captures.Count; ctr2++) {
            Console.WriteLine("        Capture {0}: '{1}' at position {2}",
                              ctr2, captures[ctr2].Value,
                              captures[ctr2].Index);
        }
    }
}
// The example displays the following output:
//     Match: 'abcababc' at position 0
//         Group 0: 'abcababc' at position 0
//             Capture 0: 'abcababc' at position 0
//             Group 1: 'abc' at position 6
//                 Capture 0: 'abc' at position 0
//                 Capture 1: 'abc' at position 3
//                 Capture 2: 'abc' at position 6
//             Group 2: 'ab' at position 6
//                 Capture 0: 'ab' at position 0
//                 Capture 1: 'ab' at position 3
//                 Capture 2: 'ab' at position 6
//             Group 3: 'b' at position 7
//                 Capture 0: 'b' at position 1
//                 Capture 1: 'b' at position 4
//                 Capture 2: 'b' at position 7

```

The following example uses the regular expression `(Abc)+` to find one or more consecutive runs of the string "Abc" in the string "XYZAbcAbcAbcXYZAbcAb". The example illustrates the use of the `Group.Captures` property to return multiple groups of captured substrings.

C#

```

int counter;
Match m;
CaptureCollection cc;
GroupCollection gc;

// Look for groupings of "Abc".
var r = new Regex("(Abc)+");
// Define the string to search.

```

```

m = r.Match("XYZAbcAbcAbcXYZAbcAb");
gc = m.Groups;

// Display the number of groups.
Console.WriteLine("Captured groups = " + gc.Count.ToString());

// Loop through each group.
for (int i = 0; i < gc.Count; i++)
{
    cc = gc[i].Captures;
    counter = cc.Count;

    // Display the number of captures in this group.
    Console.WriteLine("Captures count = " + counter.ToString());

    // Loop through each capture in the group.
    for (int ii = 0; ii < counter; ii++)
    {
        // Display the capture and its position.
        Console.WriteLine(cc[ii] + " Starts at character " +
            cc[ii].Index);
    }
}

// The example displays the following output:
//     Captured groups = 2
//     Captures count = 1
//     AbcAbcAbc Starts at character 3
//     Captures count = 3
//     Abc Starts at character 3
//     Abc Starts at character 6
//     Abc Starts at character 9

```

[Back to top](#)

The Individual Capture

The [Capture](#) class contains the results from a single subexpression capture. The [Capture.Value](#) property contains the matched text, and the [Capture.Index](#) property indicates the zero-based position in the input string at which the matched substring begins.

The following example parses an input string for the temperature of selected cities. A comma (",") is used to separate a city and its temperature, and a semicolon (";") is used to separate each city's data. The entire input string represents a single match. In the regular expression pattern `((\w+(\s\w+)*),(\d+);)+`, which is used to parse the string, the city name is assigned to the second capturing group, and the temperature is assigned to the fourth capturing group.

C#

```
using System;
using System.Text.RegularExpressions;

public class Example
{
    public static void Main()
    {
        string input = "Miami,78;Chicago,62;New York,67;San
Francisco,59;Seattle,58;";
        string pattern = @"((\w+(\s\w+)*),(\d+);)+";
        Match match = Regex.Match(input, pattern);
        if (match.Success)
        {
            Console.WriteLine("Current temperatures:");
            for (int ctr = 0; ctr < match.Groups[2].Captures.Count; ctr++)
                Console.WriteLine("{0,-20} {1,3}",
match.Groups[2].Captures[ctr].Value,
                                match.Groups[4].Captures[ctr].Value);
        }
    }
}
// The example displays the following output:
//      Current temperatures:
//      Miami          78
//      Chicago        62
//      New York       67
//      San Francisco  59
//      Seattle         58
```

The regular expression is defined as shown in the following table.

| Pattern | Description |
|----------------|---|
| \w+ | Match one or more word characters. |
| (\s\w+)* | Match zero or more occurrences of a white-space character followed by one or more word characters. This pattern matches multi-word city names. This is the third capturing group. |
| (\w+(\s\w+)*) | Match one or more word characters followed by zero or more occurrences of a white-space character and one or more word characters. This is the second capturing group. |
| , | Match a comma. |
| (\d+) | Match one or more digits. This is the fourth capturing group. |
| ; | Match a semicolon. |

| Pattern | Description |
|-----------------------------|--|
| ((\w+(\s\w+)*), (\d+);)+ | Match the pattern of a word followed by any additional words followed by a comma, one or more digits, and a semicolon, one or more times. This is the first capturing group. |

Details of regular expression behavior

Article • 09/15/2021

The .NET regular expression engine is a backtracking regular expression matcher that incorporates a traditional Nondeterministic Finite Automaton (NFA) engine such as that used by Perl, Python, Emacs, and Tcl. This distinguishes it from faster, but more limited, pure regular expression Deterministic Finite Automaton (DFA) engines such as those found in awk, egrep, or lex. This also distinguishes it from standardized, but slower, POSIX NFAs. The following section describes the three types of regular expression engines, and explains why regular expressions in .NET are implemented by using a traditional NFA engine.

Benefits of the NFA engine

When DFA engines perform pattern matching, their processing order is driven by the input string. The engine begins at the beginning of the input string and proceeds sequentially to determine whether the next character matches the regular expression pattern. They can guarantee to match the longest string possible. Because they never test the same character twice, DFA engines do not support backtracking. However, because a DFA engine contains only finite state, it cannot match a pattern with backreferences, and because it does not construct an explicit expansion, it cannot capture subexpressions.

Unlike DFA engines, when traditional NFA engines perform pattern matching, their processing order is driven by the regular expression pattern. As it processes a particular language element, the engine uses greedy matching; that is, it matches as much of the input string as it possibly can. But it also saves its state after successfully matching a subexpression. If a match eventually fails, the engine can return to a saved state so it can try additional matches. This process of abandoning a successful subexpression match so that later language elements in the regular expression can also match is known as *backtracking*. NFA engines use backtracking to test all possible expansions of a regular expression in a specific order and accept the first match. Because a traditional NFA engine constructs a specific expansion of the regular expression for a successful match, it can capture subexpression matches and matching backreferences. However, because a traditional NFA backtracks, it can visit the same state multiple times if it arrives at the state over different paths. As a result, it can run exponentially slowly in the worst case. Because a traditional NFA engine accepts the first match it finds, it can also leave other (possibly longer) matches undiscovered.

POSIX NFA engines are like traditional NFA engines, except that they continue to backtrack until they can guarantee that they have found the longest match possible. As a result, a POSIX NFA engine is slower than a traditional NFA engine, and when you use a POSIX NFA engine, you cannot favor a shorter match over a longer one by changing the order of the backtracking search.

Traditional NFA engines are favored by programmers because they offer greater control over string matching than either DFA or POSIX NFA engines. Although, in the worst case, they can run slowly, you can steer them to find matches in linear or polynomial time by using patterns that reduce ambiguities and limit backtracking. In other words, although NFA engines trade performance for power and flexibility, in most cases they offer good to acceptable performance if a regular expression is well written and avoids cases in which backtracking degrades performance exponentially.

ⓘ Note

For information about the performance penalty caused by excessive backtracking and ways to craft a regular expression to work around them, see [Backtracking](#).

.NET engine capabilities

To take advantage of the benefits of a traditional NFA engine, the .NET regular expression engine includes a complete set of constructs to enable programmers to steer the backtracking engine. These constructs can be used to find matches faster or to favor specific expansions over others.

Other features of the .NET regular expression engine include the following:

- Lazy quantifiers: `??`, `*?`, `+?`, `{n,m}?`. These constructs tell the backtracking engine to search the minimum number of repetitions first. In contrast, ordinary greedy quantifiers try to match the maximum number of repetitions first. The following example illustrates the difference between the two. A regular expression matches a sentence that ends in a number, and a capturing group is intended to extract that number. The regular expression `.+(\d+)\.` includes the greedy quantifier `.+`, which causes the regular expression engine to capture only the last digit of the number. In contrast, the regular expression `.+?(\d+)\.` includes the lazy quantifier `.+?`, which causes the regular expression engine to capture the entire number.

C#

```

using System;
using System.Text.RegularExpressions;

public class Example
{
    public static void Main()
    {
        string greedyPattern = @"^.+(\d+)\.";
        string lazyPattern = @"^.?(\d+)\.";
        string input = "This sentence ends with the number 107325.";
        Match match;

        // Match using greedy quantifier .+.
        match = Regex.Match(input, greedyPattern);
        if (match.Success)
            Console.WriteLine("Number at end of sentence (greedy): {0}",
{0},
                           match.Groups[1].Value);
        else
            Console.WriteLine("{0} finds no match.", greedyPattern);

        // Match using lazy quantifier .+?.
        match = Regex.Match(input, lazyPattern);
        if (match.Success)
            Console.WriteLine("Number at end of sentence (lazy): {0}",
                           match.Groups[1].Value);
        else
            Console.WriteLine("{0} finds no match.", lazyPattern);
    }
}

// The example displays the following output:
//      Number at end of sentence (greedy): 5
//      Number at end of sentence (lazy): 107325

```

The greedy and lazy versions of this regular expression are defined as shown in the following table:

| Pattern | Description |
|------------------------|--|
| .+ (greedy quantifier) | Match at least one occurrence of any character. This causes the regular expression engine to match the entire string, and then to backtrack as needed to match the remainder of the pattern. |
| .+? (lazy quantifier) | Match at least one occurrence of any character, but match as few as possible. |
| (\d+) | Match at least one numeric character, and assign it to the first capturing group. |
| \. | Match a period. |

For more information about lazy quantifiers, see [Quantifiers](#).

- Positive lookahead: `(?=subexpression)`. This feature allows the backtracking engine to return to the same spot in the text after matching a subexpression. It is useful for searching throughout the text by verifying multiple patterns that start from the same position. It also allows the engine to verify that a substring exists at the end of the match without including the substring in the matched text. The following example uses positive lookahead to extract the words in a sentence that are not followed by punctuation symbols.

C#

```
using System;
using System.Text.RegularExpressions;

public class Example
{
    public static void Main()
    {
        string pattern = @"\b[A-Z]+\b(?=\P{P})";
        string input = "If so, what comes next?";
        foreach (Match match in Regex.Matches(input, pattern,
RegexOptions.IgnoreCase))
            Console.WriteLine(match.Value);
    }
}
// The example displays the following output:
//      If
//      what
//      comes
```

The regular expression `\b[A-Z]+\b(?=\P{P})` is defined as shown in the following table.

| Pattern | Description |
|--|---|
| <code>\b</code> | Begin the match at a word boundary. |
| <code>[A-Z]+</code> | Match any alphabetic character one or more times. Because the <code>Regex.Matches</code> method is called with the <code>RegexOptions.IgnoreCase</code> option, the comparison is case-insensitive. |
| <code>\b</code> | End the match at a word boundary. |
| <code>(?=</code> <code>=\P{P})</code> | Look ahead to determine whether the next character is a punctuation symbol. If it is not, the match succeeds. |

For more information about positive lookahead assertions, see [Grouping Constructs](#).

- Negative lookahead: `(?! subexpression)`. This feature adds the ability to match an expression only if a subexpression fails to match. This is powerful for pruning a search, because it is often simpler to provide an expression for a case that should be eliminated than an expression for cases that must be included. For example, it is difficult to write an expression for words that do not begin with "non". The following example uses negative lookahead to exclude them.

C#

```
using System;
using System.Text.RegularExpressions;

public class Example
{
    public static void Main()
    {
        string pattern = @"\b(?!non)\w+\b";
        string input = "Nonsense is not always non-functional.";
        foreach (Match match in Regex.Matches(input, pattern,
RegexOptions.IgnoreCase))
            Console.WriteLine(match.Value);
    }
}
// The example displays the following output:
//      is
//      not
//      always
//      functional
```

The regular expression pattern `\b(?!non)\w+\b` is defined as shown in the following table.

| Pattern | Description |
|----------------------|--|
| <code>\b</code> | Begin the match at a word boundary. |
| <code>(?!non)</code> | Look ahead to ensure that the current string does not begin with "non". If it does, the match fails. |
| <code>(\w+)</code> | Match one or more word characters. |
| <code>\b</code> | End the match at a word boundary. |

For more information about negative lookahead assertions, see [Grouping Constructs](#).

- Conditional evaluation: `(?(expression)yes|no)` and `(?(name)yes|no)`, where *expression* is a subexpression to match, *name* is the name of a capturing group, *yes* is the string to match if *expression* is matched or *name* is a valid, non-empty captured group, and *no* is the subexpression to match if *expression* is not matched or *name* is not a valid, non-empty captured group. This feature allows the engine to search by using more than one alternate pattern, depending on the result of a previous subexpression match or the result of a zero-width assertion. This allows a more powerful form of backreference that permits, for example, matching a subexpression based on whether a previous subexpression was matched. The regular expression in the following example matches paragraphs that are intended for both public and internal use. Paragraphs intended only for internal use begin with a `<PRIVATE>` tag. The regular expression pattern `^(?<Pvt>\<PRIVATE\>)\s)?(?(Pvt)((\w+\p{P})?\s+)|((\w+\p{P})?\s+))\r?$` uses conditional evaluation to assign the contents of paragraphs intended for public and for internal use to separate capturing groups. These paragraphs can then be handled differently.

C#

```

using System;
using System.Text.RegularExpressions;

public class Example
{
    public static void Main()
    {
        string input = "<PRIVATE> This is not for public consumption."
+ Environment.NewLine +
                    "But this is for public consumption." +
Environment.NewLine +
                    "<PRIVATE> Again, this is confidential.\n";
        string pattern = @"^(?<Pvt>\<PRIVATE\>)\s)?(?(Pvt)((\w+\p{P})?\s+)|((\w+\p{P})?\s+))\r?$";
        string publicDocument = null, privateDocument = null;

        foreach (Match match in Regex.Matches(input, pattern,
RegexOptions.Multiline))
        {
            if (match.Groups[1].Success)
            {
                privateDocument += match.Groups[1].Value + "\n";
            }
            else
            {
                publicDocument += match.Groups[3].Value + "\n";
                privateDocument += match.Groups[3].Value + "\n";
            }
        }

        Console.WriteLine("Private Document:");
    }
}

```

```

        Console.WriteLine(privateDocument);
        Console.WriteLine("Public Document:");
        Console.WriteLine(publicDocument);
    }
}

// The example displays the following output:
//  Private Document:
//  This is not for public consumption.
//  But this is for public consumption.
//  Again, this is confidential.
//
//  Public Document:
//  But this is for public consumption.

```

The regular expression pattern is defined as shown in the following table.

| Pattern | Description |
|---|--|
| <code>^</code> | Begin the match at the beginning of a line. |
| <code>(?<Pvt>\<PRIVATE\>\s?)</code> | Match zero or one occurrence of the string <code><PRIVATE></code> followed by a white-space character. Assign the match to a capturing group named <code>Pvt</code> . |
| <code>(?(Pvt)((\w+\p{P})?\s)+)</code> | If the <code>Pvt</code> capturing group exists, match one or more occurrences of one or more word characters followed by zero or one punctuation separator followed by a white-space character. Assign the substring to the first capturing group. |
| <code> ((\w+\p{P})?\s+))</code> | If the <code>Pvt</code> capturing group does not exist, match one or more occurrences of one or more word characters followed by zero or one punctuation separator followed by a white-space character. Assign the substring to the third capturing group. |
| <code>\r?\$</code> | Match the end of a line or the end of the string. |

For more information about conditional evaluation, see [Alternation Constructs](#).

- Balancing group definitions: `(?<name1 - name2> subexpression)`. This feature allows the regular expression engine to keep track of nested constructs such as parentheses or opening and closing brackets. For an example, see [Grouping Constructs](#).
- Atomic groups: `(?> subexpression)`. This feature allows the backtracking engine to guarantee that a subexpression matches only the first match found for that subexpression, as if the expression were running independent of its containing expression. If you do not use this construct, backtracking searches from the larger expression can change the behavior of a subexpression. For example, the regular

expression `(a+)\w` matches one or more "a" characters, along with a word character that follows the sequence of "a" characters, and assigns the sequence of "a" characters to the first capturing group. However, if the final character of the input string is also an "a", it is matched by the `\w` language element and is not included in the captured group.

```
C#  
  
using System;  
using System.Text.RegularExpressions;  
  
public class Example  
{  
    public static void Main()  
    {  
        string[] inputs = { "aaaaa", "aaaaab" };  
        string backtrackingPattern = @"(a+)\w";  
        Match match;  
  
        foreach (string input in inputs)  
        {  
            Console.WriteLine("Input: {0}", input);  
            match = Regex.Match(input, backtrackingPattern);  
            Console.WriteLine("  Pattern: {0}", backtrackingPattern);  
            if (match.Success)  
            {  
                Console.WriteLine("      Match: {0}", match.Value);  
                Console.WriteLine("      Group 1: {0}",  
match.Groups[1].Value);  
            }  
            else  
            {  
                Console.WriteLine("      Match failed.");  
            }  
        }  
        Console.WriteLine();  
    }  
}  
// The example displays the following output:  
//      Input: aaaaa  
//      Pattern: (a+)\w  
//      Match: aaaaa  
//      Group 1: aaaa  
//      Input: aaaaab  
//      Pattern: (a+)\w  
//      Match: aaaaab  
//      Group 1: aaaa
```

The regular expression `((?>a+))\w` prevents this behavior. Because all consecutive "a" characters are matched without backtracking, the first capturing group includes

all consecutive "a" characters. If the "a" characters are not followed by at least one more character other than "a", the match fails.

```
C#  
  
using System;  
using System.Text.RegularExpressions;  
  
public class Example  
{  
    public static void Main()  
    {  
        string[] inputs = { "aaaaa", "aaaaab" };  
        string nonbacktrackingPattern = @"((?>a+))\w";  
        Match match;  
  
        foreach (string input in inputs)  
        {  
            Console.WriteLine("Input: {0}", input);  
            match = Regex.Match(input, nonbacktrackingPattern);  
            Console.WriteLine("    Pattern: {0}",  
nonbacktrackingPattern);  
            if (match.Success)  
            {  
                Console.WriteLine("        Match: {0}", match.Value);  
                Console.WriteLine("        Group 1: {0}",  
match.Groups[1].Value);  
            }  
            else  
            {  
                Console.WriteLine("        Match failed.");  
            }  
        }  
        Console.WriteLine();  
    }  
}  
// The example displays the following output:  
//     Input: aaaaa  
//             Pattern: ((?>a+))\w  
//             Match failed.  
//     Input: aaaaab  
//             Pattern: ((?>a+))\w  
//             Match: aaaaab  
//             Group 1: aaaaa
```

For more information about atomic groups, see [Grouping Constructs](#).

- Right-to-left matching, which is specified by supplying the `RegexOptions.RightToLeft` option to a `Regex` class constructor or static instance matching method. This feature is useful when searching from right to left instead of from left to right, or in cases where it is more efficient to begin a match at the

right part of the pattern instead of the left. As the following example illustrates, using right-to-left matching can change the behavior of greedy quantifiers. The example conducts two searches for a sentence that ends in a number. The left-to-right search that uses the greedy quantifier `+ matches one of the six digits in the sentence, whereas the right-to-left search matches all six digits. For a description of the regular expression pattern, see the example that illustrates lazy quantifiers earlier in this section.`

C#

```
using System;
using System.Text.RegularExpressions;

public class Example
{
    public static void Main()
    {
        string greedyPattern = @"^.+(\d+)\.";
        string input = "This sentence ends with the number 107325.";
        Match match;

        // Match from left-to-right using lazy quantifier .+?.
        match = Regex.Match(input, greedyPattern);
        if (match.Success)
            Console.WriteLine("Number at end of sentence (left-to-right): {0}",
                               match.Groups[1].Value);
        else
            Console.WriteLine("{0} finds no match.", greedyPattern);

        // Match from right-to-left using greedy quantifier .+.
        match = Regex.Match(input, greedyPattern,
                           RegexOptions.RightToLeft);
        if (match.Success)
            Console.WriteLine("Number at end of sentence (right-to-left): {0}",
                               match.Groups[1].Value);
        else
            Console.WriteLine("{0} finds no match.", greedyPattern);
    }
}

// The example displays the following output:
//      Number at end of sentence (left-to-right): 5
//      Number at end of sentence (right-to-left): 107325
```

For more information about right-to-left matching, see [Regular Expression Options](#).

- Positive and negative lookbehind: `(?<= subexpression)` for positive lookbehind, and `(?<! subexpression)` for negative lookbehind. This feature is similar to

lookahead, which is discussed earlier in this topic. Because the regular expression engine allows complete right-to-left matching, regular expressions allow unrestricted lookbehinds. Positive and negative lookbehind can also be used to avoid nesting quantifiers when the nested subexpression is a superset of an outer expression. Regular expressions with such nested quantifiers often offer poor performance. For example, the following example verifies that a string begins and ends with an alphanumeric character, and that any other character in the string is one of a larger subset. It forms a portion of the regular expression used to validate email addresses; for more information, see [How to: Verify that Strings Are in Valid Email Format](#).

C#

```
using System;
using System.Text.RegularExpressions;

public class Example
{
    public static void Main()
    {
        string[] inputs = { "jack.sprat", "dog#", "dog#1", "me.myself",
                           "me.myself!" };
        string pattern = @"^([A-Z0-9]([-!#$%&'.*+/=?^`{}|~\w])*(<=[A-Z0-9])$";
        foreach (string input in inputs)
        {
            if (Regex.IsMatch(input, pattern, RegexOptions.IgnoreCase))
                Console.WriteLine("{0}: Valid", input);
            else
                Console.WriteLine("{0}: Invalid", input);
        }
    }
}
// The example displays the following output:
//      jack.sprat: Valid
//      dog#: Invalid
//      dog#1: Valid
//      me.myself: Valid
//      me.myself!: Invalid
```

The regular expression `^([A-Z0-9]([-!#$%&'.*+/=?^`{}|~\w])*(<=[A-Z0-9])$` is defined as shown in the following table.

| Pattern | Description |
|-----------------------|---|
| <code>^</code> | Begin the match at the beginning of the string. |
| <code>[A-Z0-9]</code> | Match any numeric or alphanumeric character. (The comparison is |

| Pattern | Description |
|---------------------------------|---|
| | case-insensitive.) |
| ([-!#\$%&'.*+/=? ^`{} ~\w])* | Match zero or more occurrences of any word character, or any of the following characters: -, !, #, \$, %, &, ', ., *, +, /, =, ?, ^, ` , {, }, , or ~. |
| (?<=[A-Z0-9]) | Look behind to the previous character, which must be numeric or alphanumeric. (The comparison is case-insensitive.) |
| \$ | End the match at the end of the string. |

For more information about positive and negative lookbehind, see [Grouping Constructs](#).

Backtracking in regular expressions

Article • 08/11/2023

Backtracking occurs when a regular expression pattern contains optional [quantifiers](#) or [alternation constructs](#), and the regular expression engine returns to a previous saved state to continue its search for a match. Backtracking is central to the power of regular expressions; it makes it possible for expressions to be powerful and flexible, and to match very complex patterns. At the same time, this power comes at a cost.

Backtracking is often the single most important factor that affects the performance of the regular expression engine. Fortunately, the developer has control over the behavior of the regular expression engine and how it uses backtracking. This topic explains how backtracking works and how it can be controlled.

⚠ Warning

When using [System.Text.RegularExpressions](#) to process untrusted input, pass a timeout. A malicious user can provide input to `RegularExpression`, causing a [Denial-of-Service attack](#). ASP.NET Core framework APIs that use `RegularExpression` pass a timeout.

Linear comparison without backtracking

If a regular expression pattern has no optional quantifiers or alternation constructs, the regular expression engine executes in linear time. That is, after the regular expression engine matches the first language element in the pattern with text in the input string, it tries to match the next language element in the pattern with the next character or group of characters in the input string. This continues until the match either succeeds or fails. In either case, the regular expression engine advances by one character at a time in the input string.

The following example provides an illustration. The regular expression `e{2}\w\b` looks for two occurrences of the letter "e" followed by any word character followed by a word boundary.

C#

```
using System;
using System.Text.RegularExpressions;

public class Example1
```

```

{
    public static void Run()
    {
        string input = "needing a reed";
        string pattern = @"e{2}\w\b";
        foreach (Match match in Regex.Matches(input, pattern))
            Console.WriteLine("{0} found at position {1}",
                match.Value, match.Index);
    }
}
// The example displays the following output:
//      eed found at position 11

```

Although this regular expression includes the quantifier `{2}`, it is evaluated in a linear manner. The regular expression engine does not backtrack because `{2}` is not an optional quantifier; it specifies an exact number and not a variable number of times that the previous subexpression must match. As a result, the regular expression engine tries to match the regular expression pattern with the input string as shown in the following table.

| Operation | Position in pattern | Position in string | Result |
|------------------|----------------------------|----------------------------|-----------------------|
| 1 | e | "needing a reed" (index 0) | No match. |
| 2 | e | "eeding a reed" (index 1) | Possible match. |
| 3 | e{2} | "eding a reed" (index 2) | Possible match. |
| 4 | \w | "ding a reed" (index 3) | Possible match. |
| 5 | \b | "ing a reed" (index 4) | Possible match fails. |
| 6 | e | "eding a reed" (index 2) | Possible match. |
| 7 | e{2} | "ding a reed" (index 3) | Possible match fails. |
| 8 | e | "ding a reed" (index 3) | Match fails. |
| 9 | e | "ing a reed" (index 4) | No match. |
| 10 | e | "ng a reed" (index 5) | No match. |
| 11 | e | "g a reed" (index 6) | No match. |
| 12 | e | " a reed" (index 7) | No match. |
| 13 | e | "a reed" (index 8) | No match. |
| 14 | e | " reed" (index 9) | No match. |
| 15 | e | "reed" (index 10) | No match |

| Operation | Position in pattern | Position in string | Result |
|------------------|----------------------------|---------------------------|-----------------|
| 16 | e | "eed" (index 11) | Possible match. |
| 17 | e{2} | "ed" (index 12) | Possible match. |
| 18 | \w | "d" (index 13) | Possible match. |
| 19 | \b | "" (index 14) | Match. |

If a regular expression pattern includes no optional quantifiers or alternation constructs, the maximum number of comparisons required to match the regular expression pattern with the input string is roughly equivalent to the number of characters in the input string. In this case, the regular expression engine uses 19 comparisons to identify possible matches in this 13-character string. In other words, the regular expression engine runs in near-linear time if it contains no optional quantifiers or alternation constructs.

Backtracking with optional quantifiers or alternation constructs

When a regular expression includes optional quantifiers or alternation constructs, the evaluation of the input string is no longer linear. Pattern matching with an Nondeterministic Finite Automaton (NFA) engine is driven by the language elements in the regular expression and not by the characters to be matched in the input string. Therefore, the regular expression engine tries to fully match optional or alternative subexpressions. When it advances to the next language element in the subexpression and the match is unsuccessful, the regular expression engine can abandon a portion of its successful match and return to an earlier saved state in the interest of matching the regular expression as a whole with the input string. This process of returning to a previous saved state to find a match is known as backtracking.

For example, consider the regular expression pattern `.*(es)`, which matches the characters "es" and all the characters that precede it. As the following example shows, if the input string is "Essential services are provided by regular expressions.", the pattern matches the whole string up to and including the "es" in "expressions".

C#

```
using System;
using System.Text.RegularExpressions;

public class Example2
{
```

```

public static void Run()
{
    string input = "Essential services are provided by regular
expressions.";
    string pattern = ".*(es)";
    Match m = Regex.Match(input, pattern, RegexOptions.IgnoreCase);
    if (m.Success)
    {
        Console.WriteLine('{0}' found at position {1},
                           m.Value, m.Index);
        Console.WriteLine('es' found at position {0},
                           m.Groups[1].Index);
    }
}
// 'Essential services are provided by regular expressions found at
position 0
// 'es' found at position 47

```

To do this, the regular expression engine uses backtracking as follows:

- It matches the `.*` (which matches zero, one, or more occurrences of any character) with the whole input string.
- It attempts to match "e" in the regular expression pattern. However, the input string has no remaining characters available to match.
- It backtracks to its last successful match, "Essential services are provided by regular expressions", and attempts to match "e" with the period at the end of the sentence. The match fails.
- It continues to backtrack to a previous successful match one character at a time until the tentatively matched substring is "Essential services are provided by regular expr". It then compares the "e" in the pattern to the second "e" in "expressions" and finds a match.
- It compares "s" in the pattern to the "s" that follows the matched "e" character (the first "s" in "expressions"). The match is successful.

When you use backtracking, matching the regular expression pattern with the input string, which is 55 characters long, requires 67 comparison operations. Generally, if a regular expression pattern has a single alternation construct or a single optional quantifier, the number of comparison operations required to match the pattern is more than twice the number of characters in the input string.

Backtracking with nested optional quantifiers

The number of comparison operations required to match a regular expression pattern can increase exponentially if the pattern includes a large number of alternation constructs, if it includes nested alternation constructs, or, most commonly, if it includes nested optional quantifiers. For example, the regular expression pattern `^(a+)+$` is designed to match a complete string that contains one or more "a" characters. The example provides two input strings of identical length, but only the first string matches the pattern. The [System.Diagnostics.Stopwatch](#) class is used to determine how long the match operation takes.

C#

```
using System;
using System.Diagnostics;
using System.Text.RegularExpressions;

public class Example3
{
    public static void Run()
    {
        string pattern = "^(a+)+$";
        string[] inputs = { "aaaaaaaaaaaaaaaaaaaaaaaaaaaaaa",
"aaaaaaaaaaaaaaaaaaaaaaa!" };
        Regex rgx = new Regex(pattern);
        Stopwatch sw;

        foreach (string input in inputs)
        {
            sw = Stopwatch.StartNew();
            Match match = rgx.Match(input);
            sw.Stop();
            if (match.Success)
                Console.WriteLine($"Matched {match.Value} in {sw.Elapsed}");
            else
                Console.WriteLine($"No match found in {sw.Elapsed}");
        }
    }
}

//      Matched aaaaaaaaaaaaaaaaaaaaaaa in 00:00:00.0018281
//      No match found in 00:00:05.1882144
```

As the output from the example shows, the regular expression engine took significantly longer to find that an input string *did not match* the pattern as it did to identify a matching string. This is because an unsuccessful match always represents a worst-case scenario. The regular expression engine must use the regular expression to follow all possible paths through the data before it can conclude that the match is unsuccessful, and the nested parentheses create many additional paths through the data. The regular expression engine concludes that the second string did not match the pattern by doing the following:

- It checks that it was at the beginning of the string, and then matches the first five characters in the string with the pattern `a+`. It then determines that there are no additional groups of "a" characters in the string. Finally, it tests for the end of the string. Because one additional character remains in the string, the match fails. This failed match requires 9 comparisons. The regular expression engine also saves state information from its matches of "a" (which we'll call match 1), "aa" (match 2), "aaa" (match 3), and "aaaa" (match 4).
- It returns to the previously saved match 4. It determines that there is one additional "a" character to assign to an additional captured group. Finally, it tests for the end of the string. Because one additional character remains in the string, the match fails. This failed match requires 4 comparisons. So far, a total of 13 comparisons have been performed.
- It returns to the previously saved match 3. It determines that there are two additional "a" characters to assign to an additional captured group. However, the end-of-string test fails. It then returns to match 3 and tries to match the two additional "a" characters in two additional captured groups. The end-of-string test still fails. These failed matches require 12 comparisons. So far, a total of 25 comparisons have been performed.

Comparison of the input string with the regular expression continues in this way until the regular expression engine has tried all possible combinations of matches, and then concludes that there is no match. Because of the nested quantifiers, this comparison is an $O(2^n)$ or an exponential operation, where n is the number of characters in the input string. This means that in the worst case, an input string of 30 characters requires approximately 1,073,741,824 comparisons, and an input string of 40 characters requires approximately 1,099,511,627,776 comparisons. If you use strings of these or even greater lengths, regular expression methods can take an extremely long time to complete when they process input that does not match the regular expression pattern.

Control backtracking

Backtracking lets you create powerful, flexible regular expressions. However, as the previous section showed, these benefits may be coupled with unacceptably poor performance. To prevent excessive backtracking, you should define a time-out interval when you instantiate a [Regex](#) object or call a static regular expression matching method. This is discussed in the next section. In addition, .NET supports three regular expression language elements that limit or suppress backtracking and that support complex regular expressions with little or no performance penalty: [atomic groups](#), [lookbehind assertions](#),

and lookahead assertions. For more information about each language element, see [Grouping constructs](#).

Non-backtracking regular expression engine

If you don't need to use any constructs that require backtracking (for example, lookarounds, backreferences, or atomic groups), consider using the [RegexOptions.NonBacktracking](#) mode. This mode is designed to execute in time proportional to the length of the input. For more information, see [NonBacktracking mode](#). You can also set a time-out value.

Limit the size of inputs

Some regular expressions have acceptable performance unless the input is exceptionally large. If all reasonable text inputs in your scenario are known to be under a certain length, consider rejecting longer inputs before applying the regular expression to them.

Specify a time-out interval

You can set a time-out value that represents the longest interval the regular expression engine will search for a single match before it abandons the attempt and throws a [RegexMatchTimeoutException](#) exception. You specify the time-out interval by supplying a [TimeSpan](#) value to the [Regex\(String, RegexOptions, TimeSpan\)](#) constructor for instance regular expressions. In addition, each static pattern matching method has an overload with a [TimeSpan](#) parameter that allows you to specify a time-out value.

If you don't set a time-out value explicitly, the default time-out value is determined as follows:

- By using the application-wide time-out value, if one exists. This can be any time-out value that applies to the application domain in which the [Regex](#) object is instantiated or the static method call is made. You can set the application-wide time-out value by calling the [AppDomain.SetData](#) method to assign the string representation of a [TimeSpan](#) value to the "REGEX_DEFAULT_MATCH_TIMEOUT" property.
- By using the value [InfiniteMatchTimeout](#), if no application-wide time-out value has been set.

By default, the time-out interval is set to [Regex.InfiniteMatchTimeout](#) and the regular expression engine does not time out.

Important

When not using [RegexOptions.NonBacktracking](#), we recommend that you always set a time-out interval if your regular expression relies on backtracking or operates on untrusted inputs.

A [RegexMatchTimeoutException](#) exception indicates that the regular expression engine was unable to find a match within the specified time-out interval but does not indicate why the exception was thrown. The reason might be excessive backtracking, but it's also possible that the time-out interval was set too low given the system load at the time the exception was thrown. When you handle the exception, you can choose to abandon further matches with the input string or increase the time-out interval and retry the matching operation.

For example, the following code calls the `Regex(String, RegexOptions, TimeSpan)` constructor to instantiate a `Regex` object with a time-out value of 1 second. The regular expression pattern `(a+)+$`, which matches one or more sequences of one or more "a" characters at the end of a line, is subject to excessive backtracking. If a `RegexMatchTimeoutException` is thrown, the example increases the time-out value up to a maximum interval of 3 seconds. After that, it abandons the attempt to match the pattern.

C#

```

foreach (var inputValue in inputs)
{
    Console.WriteLine("Processing {0}", inputValue);
    bool timedOut = false;
    do
    {
        try
        {
            sw = Stopwatch.StartNew();
            // Display the result.
            if (rgx.IsMatch(inputValue))
            {
                sw.Stop();
                Console.WriteLine(@"Valid: '{0}' ({1:ss\.fffff} seconds)",
                                  inputValue, sw.Elapsed);
            }
            else
            {
                sw.Stop();
                Console.WriteLine(@"'{0}' is not a valid string.
({1:ss\.fffff} seconds)",
                                  inputValue, sw.Elapsed);
            }
        }
        catch (RegexMatchTimeoutException e)
        {
            sw.Stop();
            // Display the elapsed time until the exception.
            Console.WriteLine(@"Timeout with '{0}' after
{1:ss\.fffff}",
                                  inputValue, sw.Elapsed);
            Thread.Sleep(1500);      // Pause for 1.5 seconds.

            // Increase the timeout interval and retry.
            TimeSpan timeout =
e.MatchTimeout.Add(TimeSpan.FromSeconds(1));
            if (timeout.TotalSeconds > MaxTimeoutInSeconds)
            {
                Console.WriteLine("Maximum timeout interval of {0}
seconds exceeded.",
                                  MaxTimeoutInSeconds);
                timedOut = false;
            }
            else
            {
                Console.WriteLine("Changing the timeout interval to
{0}",
                                  timeout);
                rgx = new Regex(pattern, RegexOptions.IgnoreCase,
timeout);
                timedOut = true;
            }
        }
    } while (timedOut);
}

```

```

        Console.WriteLine();
    }
}

// The example displays output like the following :
// Processing aa
// Valid: 'aa' (00.0000779 seconds)
//
// Processing aaaa>
// 'aaaa>' is not a valid string. (00.00005 seconds)
//
// Processingaaaaaaaaaaaaaaaaaaaaaaaaaaaaaaaaaaaaaaaaaaaa
// Valid: 'aaaaaaaaaaaaaaaaaaaaaaaaaaaaaaaaaaaaaaaaaaaa' (00.0000043
seconds)
//
// Processingaaaaaaaaaaaaaaaaaaaa>
// Timeout with 'aaaaaaaaaaaaaaaaaaaa' after 01.00469
// Changing the timeout interval to 00:00:02
// Timeout with 'aaaaaaaaaaaaaaaaaaaa' after 02.01202
// Changing the timeout interval to 00:00:03
// Timeout with 'aaaaaaaaaaaaaaaaaaaa' after 03.01043
// Maximum timeout interval of 3 seconds exceeded.
//
// Processingaaaaaaaaaaaaaaaaaaaaaaaaaaaaaaaaaaaaaaaaaaaa>
// Timeout with 'aaaaaaaaaaaaaaaaaaaaaaaaaaaaaaaaaaaaaaaaaaaa' after
03.01018
// Maximum timeout interval of 3 seconds exceeded.

```

Atomic groups

The `(?>subexpression)` language element is an atomic grouping. It prevents backtracking into the subexpression. Once this language element has successfully matched, it will not give up any part of its match to subsequent backtracking. For example, in the pattern `(?>\w*\d*)1`, if the `1` cannot be matched, the `\d*` will not give up any of its match even if that means it would allow the `1` to successfully match. Atomic groups can help prevent the performance problems associated with failed matches.

The following example illustrates how suppressing backtracking improves performance when using nested quantifiers. It measures the time required for the regular expression engine to determine that an input string does not match two regular expressions. The first regular expression uses backtracking to attempt to match a string that contains one or more occurrences of one or more hexadecimal digits, followed by a colon, followed by one or more hexadecimal digits, followed by two colons. The second regular expression is identical to the first, except that it disables backtracking. As the output from the example shows, the performance improvement from disabling backtracking is significant.

C#

```
using System;
using System.Diagnostics;
using System.Text.RegularExpressions;

public class Example4
{
    public static void Run()
    {
        string input =
"b51:4:1DB:9EE1:5:27d60:f44:D4:cd:E:5:0A5:4a:D24:41Ad:";
        bool matched;
        Stopwatch sw;

        Console.WriteLine("With backtracking:");
        string backPattern = "^(([0-9a-fA-F]{1,4}:)*([0-9a-fA-F]{1,4}))*(:::$";
        sw = Stopwatch.StartNew();
        matched = Regex.IsMatch(input, backPattern);
        sw.Stop();
        Console.WriteLine("Match: {0} in {1}", Regex.IsMatch(input,
backPattern), sw.Elapsed);
        Console.WriteLine();

        Console.WriteLine("Without backtracking:");
        string noBackPattern = "^(?>[0-9a-fA-F]{1,4}:)*(?>[0-9a-fA-F]
{1,4}))*(:::$";
        sw = Stopwatch.StartNew();
        matched = Regex.IsMatch(input, noBackPattern);
        sw.Stop();
        Console.WriteLine("Match: {0} in {1}", Regex.IsMatch(input,
noBackPattern), sw.Elapsed);
    }
}

// The example displays output like the following:
//      With backtracking:
//          Match: False in 00:00:27.4282019
//
//      Without backtracking:
//          Match: False in 00:00:00.0001391
```

Lookbehind assertions

.NET includes two language elements, `(?<=subexpression)` and `(?<!subexpression)`, that match the previous character or characters in the input string. Both language elements are zero-width assertions; that is, they determine whether the character or characters that immediately precede the current character can be matched by *subexpression*, without advancing or backtracking.

`(?<=subexpression)` is a positive lookbehind assertion; that is, the character or characters before the current position must match *subexpression*. `(?<!subexpression)` is a negative lookbehind assertion; that is, the character or characters before the current position must not match *subexpression*. Both positive and negative lookbehind assertions are most useful when *subexpression* is a subset of the previous subexpression.

The following example uses two equivalent regular expression patterns that validate the user name in an email address. The first pattern is subject to poor performance because of excessive backtracking. The second pattern modifies the first regular expression by replacing a nested quantifier with a positive lookbehind assertion. The output from the example displays the execution time of the [Regex.IsMatch](#) method.

C#

```
using System;
using System.Diagnostics;
using System.Text.RegularExpressions;

public class Example5
{
    public static void Run()
    {
        Stopwatch sw;
        string input = "test@contoso.com";
        bool result;

        string pattern = @"^[\w]+@[.\w]*[\w]+@[.\w]+";
        sw = Stopwatch.StartNew();
        result = Regex.IsMatch(input, pattern, RegexOptions.IgnoreCase);
        sw.Stop();
        Console.WriteLine("Match: {0} in {1}", result, sw.Elapsed);

        string behindPattern = @"^[\w]+@[.\w]*(?<=[\w]+)@";
        sw = Stopwatch.StartNew();
        result = Regex.IsMatch(input, behindPattern,
        RegexOptions.IgnoreCase);
        sw.Stop();
        Console.WriteLine("Match with Lookbehind: {0} in {1}", result,
        sw.Elapsed);
    }
}

// The example displays output similar to the following:
//      Match: True in 00:00:00.0017549
//      Match with Lookbehind: True in 00:00:00.0000659
```

The first regular expression pattern, `^[\w]+@[.\w]*[\w]+@[.\w]+`, is defined as shown in the following table.

| Pattern | Description |
|--------------------|---|
| ^ | Start the match at the beginning of the string. |
| [0-9A-Z] | Match an alphanumeric character. This comparison is case-insensitive, because the Regex.IsMatch method is called with the RegexOptions.IgnoreCase option. |
| [-.\w]* | Match zero, one, or more occurrences of a hyphen, period, or word character. |
| [0-9A-Z] | Match an alphanumeric character. |
| ([-.\w]*[0-9A-Z])* | Match zero or more occurrences of the combination of zero or more hyphens, periods, or word characters, followed by an alphanumeric character. This is the first capturing group. |
| @ | Match an at sign ("@"). |

The second regular expression pattern, `^[0-9A-Z][-.\w]*(?=[0-9A-Z])@`, uses a positive lookbehind assertion. It is defined as shown in the following table.

| Pattern | Description |
|--------------|---|
| ^ | Start the match at the beginning of the string. |
| [0-9A-Z] | Match an alphanumeric character. This comparison is case-insensitive, because the Regex.IsMatch method is called with the RegexOptions.IgnoreCase option. |
| [-.\w]* | Match zero or more occurrences of a hyphen, period, or word character. |
| (?=[0-9A-Z]) | Look back at the last matched character and continue the match if it is alphanumeric. Note that alphanumeric characters are a subset of the set that consists of periods, hyphens, and all word characters. |
| @ | Match an at sign ("@"). |

Lookahead assertions

.NET includes two language elements, `(?=subexpression)` and `(?!subexpression)`, that match the next character or characters in the input string. Both language elements are zero-width assertions; that is, they determine whether the character or characters that immediately follow the current character can be matched by *subexpression*, without advancing or backtracking.

`(?=subexpression)` is a positive lookahead assertion; that is, the character or characters after the current position must match *subexpression*. `(?!subexpression)` is a negative lookahead assertion; that is, the character or characters after the current position must

not match *subexpression*. Both positive and negative lookahead assertions are most useful when *subexpression* is a subset of the next subexpression.

The following example uses two equivalent regular expression patterns that validate a fully qualified type name. The first pattern is subject to poor performance because of excessive backtracking. The second modifies the first regular expression by replacing a nested quantifier with a positive lookahead assertion. The output from the example displays the execution time of the `Regex.IsMatch` method.

C#

```
using System;
using System.Diagnostics;
using System.Text.RegularExpressions;

public class Example6
{
    public static void Run()
    {
        string input = "aaaaaaaaaaaaaaaaaaaaaa.";
        bool result;
        Stopwatch sw;

        string pattern = @"^(([A-Z]\w*)+\.)*[A-Z]\w*$/";
        sw = Stopwatch.StartNew();
        result = Regex.IsMatch(input, pattern, RegexOptions.IgnoreCase);
        sw.Stop();
        Console.WriteLine("{0} in {1}", result, sw.Elapsed);

        string aheadPattern = @"^((?=([A-Z])\w+)\.)*[A-Z]\w*$/";
        sw = Stopwatch.StartNew();
        result = Regex.IsMatch(input, aheadPattern,
        RegexOptions.IgnoreCase);
        sw.Stop();
        Console.WriteLine("{0} in {1}", result, sw.Elapsed);
    }
}
// The example displays the following output:
//      False in 00:00:03.8003793
//      False in 00:00:00.0000866
```

The first regular expression pattern, `^(([A-Z]\w*)+\.)*[A-Z]\w*$/`, is defined as shown in the following table.

| Pattern | Description |
|-------------------------------|--|
| <code>^</code> | Start the match at the beginning of the string. |
| <code>(([A-Z]\w*)+\.)*</code> | Match an alphabetical character (A-Z) followed by zero or more word characters one or more times, followed by a period. This comparison is case-insensitive, |

| Pattern | Description |
|---------------------------------|---|
| <code>(([A-Z]\w*)+\.\.)*</code> | Match the previous pattern zero or more times. |
| <code>[A-Z]\w*</code> | Match an alphabetical character followed by zero or more word characters. |
| <code>\$</code> | End the match at the end of the input string. |

The second regular expression pattern, `^((?=([A-Z])\w+\.\.)*[A-Z]\w*)$`, uses a positive lookahead assertion. It is defined as shown in the following table.

| Pattern | Description |
|-----------------------------------|---|
| <code>^</code> | Start the match at the beginning of the string. |
| <code>(?=([A-Z])</code> | Look ahead to the first character and continue the match if it is alphabetical (A-Z). This comparison is case-insensitive, because the Regex.IsMatch method is called with the RegexOptions.IgnoreCase option. |
| <code>\w+\.\.</code> | Match one or more word characters followed by a period. |
| <code>((?=([A-Z])\w+\.\.)*</code> | Match the pattern of one or more word characters followed by a period zero or more times. The initial word character must be alphabetical. |
| <code>[A-Z]\w*</code> | Match an alphabetical character followed by zero or more word characters. |
| <code>\$</code> | End the match at the end of the input string. |

General performance considerations

The following suggestions are not specifically to prevent excessive backtracking, but may help increase the performance of your regular expression:

1. Precompile heavily used patterns. The best way to do this is to use the [regular expression source generator](#) to precompile it. If the source generator is not available for your app, for example you are not targeting .NET 7 or later, or you do not know the pattern at compile time, use the [RegexOptions.Compiled](#) option.
2. Cache heavily used Regex objects. This implicitly occurs when you are using the source generator. Otherwise, create a Regex object and store it for reuse, rather than using the static Regex methods or creating and throwing away a Regex object.
3. Start matching from an offset. If you know that matches will always start beyond a certain offset into the pattern, pass the offset in using an overload like

`Regex.Match(String, Int32)`. This will reduce the amount of the text the engine needs to consider.

4. Gather only the information you need. If you only need to know whether a match occurs but not where the match occurs, prefer `Regex.IsMatch`. If you only need to know how many times something matches, prefer using `Regex.Count`. If you only need to know the bounds of a match but not anything about a match's captures, prefer using `Regex.EnumerateMatches`. The less information the engine needs to provide, the better.
5. Avoid unnecessary captures. Parentheses in your pattern form a capturing group by default. If you don't need captures, either specify `RegexOptions.ExplicitCapture` or use [non-capturing groups](#) instead. This saves the engine keeping track of those captures.

Compilation and Reuse in Regular Expressions

Article • 09/15/2021

You can optimize the performance of applications that make extensive use of regular expressions by understanding how the regular expression engine compiles expressions and by understanding how regular expressions are cached. This topic discusses both compilation and caching.

Compiled Regular Expressions

By default, the regular expression engine compiles a regular expression to a sequence of internal instructions (these are high-level codes that are different from Microsoft intermediate language, or MSIL). When the engine executes a regular expression, it interprets the internal codes.

If a [Regex](#) object is constructed with the [RegexOptions.Compiled](#) option, it compiles the regular expression to explicit MSIL code instead of high-level regular expression internal instructions. This allows .NET's just-in-time (JIT) compiler to convert the expression to native machine code for higher performance. The cost of constructing the [Regex](#) object may be higher, but the cost of performing matches with it is likely to be much smaller.

An alternative is to use precompiled regular expressions. You can compile all of your expressions into a reusable DLL by using the [CompileToAssembly](#) method. This avoids the need to compile at run time while still benefiting from the speed of compiled regular expressions.

The Regular Expressions Cache

To improve performance, the regular expression engine maintains an application-wide cache of compiled regular expressions. The cache stores regular expression patterns that are used only in static method calls. (Regular expression patterns supplied to instance methods are not cached.) This avoids the need to reparse an expression into high-level byte code each time it is used.

The maximum number of cached regular expressions is determined by the value of the [static](#) (Shared in Visual Basic) [Regex.CacheSize](#) property. By default, the regular expression engine caches up to 15 compiled regular expressions. If the number of

compiled regular expressions exceeds the cache size, the least recently used regular expression is discarded and the new regular expression is cached.

Your application can reuse regular expressions in one of the following two ways:

- By using a static method of the [Regex](#) object to define the regular expression. If you're using a regular expression pattern that has already been defined by another static method call, the regular expression engine will try to retrieve it from the cache. If it's not available in the cache, the engine will compile the regular expression and add it to the cache.
- By reusing an existing [Regex](#) object as long as its regular expression pattern is needed.

Because of the overhead of object instantiation and regular expression compilation, creating and rapidly destroying numerous [Regex](#) objects is a very expensive process. For applications that use a large number of different regular expressions, you can optimize performance by using calls to static [Regex](#) methods and possibly by increasing the size of the regular expression cache.

Thread Safety in Regular Expressions

Article • 09/15/2021

The [Regex](#) class itself is thread safe and immutable (read-only). That is, **Regex** objects can be created on any thread and shared between threads; matching methods can be called from any thread and never alter any global state.

However, result objects (**Match** and **MatchCollection**) returned by **Regex** should be used on a single thread. Although many of these objects are logically immutable, their implementations could delay computation of some results to improve performance, and as a result, callers must serialize access to them.

If there is a need to share **Regex** result objects on multiple threads, these objects can be converted to thread-safe instances by calling their synchronized methods. With the exception of enumerators, all regular expression classes are thread safe or can be converted into thread-safe objects by a synchronized method.

Enumerators are the only exception. An application must serialize calls to collection enumerators. The rule is that if a collection can be enumerated on more than one thread simultaneously, you should synchronize enumerator methods on the root object of the collection traversed by the enumerator.

Regular expression example: Scanning for HREFs

Article • 09/15/2021

The following example searches an input string and displays all the href="..." values and their locations in the string.

⚠ Warning

When using `System.Text.RegularExpressions` to process untrusted input, pass a timeout. A malicious user can provide input to `RegularExpressions`, causing a **Denial-of-Service attack** [↗](#). ASP.NET Core framework APIs that use `RegularExpressions` pass a timeout.

The Regex object

Because the `DumpHRefs` method can be called multiple times from user code, it uses the `static` (`Shared` in Visual Basic) `Regex.Match(String, String, RegexOptions)` method. This enables the regular expression engine to cache the regular expression and avoids the overhead of instantiating a new `Regex` object each time the method is called. A `Match` object is then used to iterate through all matches in the string.

C#

```
private static void DumpHRefs(string inputString)
{
    string hrefPattern = @"href\s*=\s*(?:['"](?<1>[^'"]*)['"]|(?<1>
[^>\s]+))";
}

try
{
    Match regexMatch = Regex.Match(inputString, hrefPattern,
                                   RegexOptions.IgnoreCase |
    RegexOptions.Compiled,
                                   TimeSpan.FromSeconds(1));
    while (regexMatch.Success)
    {
        Console.WriteLine($"Found href {regexMatch.Groups[1]} at
{regexMatch.Groups[1].Index}");
        regexMatch = regexMatch.NextMatch();
    }
}
catch (RegexMatchTimeoutException)
```

```

    {
        Console.WriteLine("The matching operation timed out.");
    }
}

```

The following example then illustrates a call to the `DumpHRefs` method.

C#

```

public static void Main()
{
    string inputString = "My favorite web sites include:</P>" +
        "<A HREF=\"https://learn.microsoft.com/en-
us/dotnet/\">>" +
        ".NET Documentation</A></P>" +
        "<A HREF=\"http://www.microsoft.com\>" +
        "Microsoft Corporation Home Page</A></P>" +
        "<A
HREF=\"https://devblogs.microsoft.com/dotnet/\>" +
        ".NET Blog</A></P>";
    DumpHRefs(inputString);
}

// The example displays the following output:
//      Found href https://learn.microsoft.com/dotnet/ at 43
//      Found href http://www.microsoft.com at 114
//      Found href https://devblogs.microsoft.com/dotnet/ at 188

```

The regular expression pattern `href\s*=\s*(?:['"](?<1>[^'"]*)['"]|(?<1>[^>\s]+))` is interpreted as shown in the following table.

| Pattern | Description |
|--|---|
| <code>href</code> | Match the literal string "href". The match is case-insensitive. |
| <code>\s*</code> | Match zero or more white-space characters. |
| <code>=</code> | Match the equals sign. |
| <code>\s*</code> | Match zero or more white-space characters. |
| <code>(?:</code> | Start a non-capturing group. |
| <code>['"](?<1>[^'"]*)['"] (?<1>[^>\s]+)</code> | Match a quotation mark or apostrophe, followed by a capturing group that matches any character other than a quotation mark or apostrophe, followed by a quotation mark or apostrophe. The group named <code>1</code> is included in this pattern. |
| <code> </code> | Boolean OR that matches either the previous expression or the next expression. |
| <code>(?<1>[^>\s]+)</code> | A capturing group that uses a negated set to match any character other than a greater-than sign or a whitespace character. The group named <code>1</code> is included in |

| Pattern | Description |
|---------|------------------------------|
| | this pattern. |
|) | End the non-capturing group. |

Match result class

The results of a search are stored in the [Match](#) class, which provides access to all the substrings extracted by the search. It also remembers the string being searched and the regular expression being used, so it can call the [Match.NextMatch](#) method to perform another search starting where the last one ended.

Explicitly named captures

In traditional regular expressions, capturing parentheses are automatically numbered sequentially. This leads to two problems. First, if a regular expression is modified by inserting or removing a set of parentheses, all code that refers to the numbered captures must be rewritten to reflect the new numbering. Second, because different sets of parentheses often are used to provide two alternative expressions for an acceptable match, it might be difficult to determine which of the two expressions actually returned a result.

To address these problems, the [Regex](#) class supports the syntax `(?<name>...)` for capturing a match into a specified slot (the slot can be named using a string or an integer; integers can be recalled more quickly). Thus, alternative matches for the same string all can be directed to the same place. In case of a conflict, the last match dropped into a slot is the successful match. (However, a complete list of multiple matches for a single slot is available. See the [Group.Captures](#) collection for details.)

Regular Expression Example: Changing Date Formats

Article • 09/15/2021

The following code example uses the `Regex.Replace` method to replace dates that have the form *mm/dd/yy* with dates that have the form *dd-mm-yy*.

⚠ Warning

When using `System.Text.RegularExpressions` to process untrusted input, pass a timeout. A malicious user can provide input to `RegularExpressions`, causing a [Denial-of-Service attack](#). ASP.NET Core framework APIs that use `RegularExpressions` pass a timeout.

Example

C#

```
static string MDYToDMY(string input)
{
    try {
        return Regex.Replace(input,
            @"\b(?:month)\d{1,2})/(?:day)\d{1,2})/(?:year)\d{2,4})\b",
            "${day}-${month}-${year}", RegexOptions.None,
            TimeSpan.FromMilliseconds(150));
    }
    catch (RegexMatchTimeoutException) {
        return input;
    }
}
```

The following code shows how the `MDYToDMY` method can be called in an application.

C#

```
using System;
using System.Globalization;
using System.Text.RegularExpressions;

public class Class1
{
    public static void Main()
    {
```

```

        string dateString = DateTime.Today.ToString("d",
                                                DateTimeFormatInfo.InvariantInfo);
        string resultString = MDYToDMY(dateString);
        Console.WriteLine("Converted {0} to {1}.", dateString, resultString);
    }

    static string MDYToDMY(string input)
    {
        try {
            return Regex.Replace(input,
                @"\b(?<month>\d{1,2})/(\?<day>\d{1,2})/(\?<year>\d{2,4})\b",
                "${day}-${month}-${year}", RegexOptions.None,
                TimeSpan.FromMilliseconds(150));
        }
        catch (RegexMatchTimeoutException) {
            return input;
        }
    }
}

// The example displays the following output to the console if run on
// 8/21/2007:
//      Converted 08/21/2007 to 21-08-2007.

```

Comments

The regular expression pattern `\b(?<month>\d{1,2})/(\?<day>\d{1,2})/(\?<year>\d{2,4})\b` is interpreted as shown in the following table.

| Pattern | Description |
|--------------------------------------|--|
| <code>\b</code> | Begin the match at a word boundary. |
| <code>(?<month>\d{1,2})</code> | Match one or two decimal digits. This is the <code>month</code> captured group. |
| <code>/</code> | Match the slash mark. |
| <code>(?<day>\d{1,2})</code> | Match one or two decimal digits. This is the <code>day</code> captured group. |
| <code>/</code> | Match the slash mark. |
| <code>(?<year>\d{2,4})</code> | Match from two to four decimal digits. This is the <code>year</code> captured group. |
| <code>\b</code> | End the match at a word boundary. |

The pattern `${day}-${month}-${year}` defines the replacement string as shown in the following table.

| Pattern | Description |
|------------------------|--|
| <code>\$(day)</code> | Add the string captured by the <code>day</code> capturing group. |
| <code>-</code> | Add a hyphen. |
| <code>\$(month)</code> | Add the string captured by the <code>month</code> capturing group. |
| <code>-</code> | Add a hyphen. |
| <code>\$(year)</code> | Add the string captured by the <code>year</code> capturing group. |

How to: Extract a Protocol and Port Number from a URL

Article • 09/15/2021

The following example extracts a protocol and port number from a URL.

⚠ Warning

When using `System.Text.RegularExpressions` to process untrusted input, pass a timeout. A malicious user can provide input to `RegularExpressions`, causing a [Denial-of-Service attack](#). ASP.NET Core framework APIs that use `RegularExpressions` pass a timeout.

Example

The example uses the `Match.Result` method to return the protocol followed by a colon followed by the port number.

C#

```
using System;
using System.Text.RegularExpressions;

public class Example
{
    public static void Main()
    {
        string url = "http://www.contoso.com:8080/letters/readme.html";

        Regex r = new Regex(@"^(?<proto>\w+://[^/]+?(?<port>:\d+)?/");
        RegexOptions.None,
        TimeSpan.FromMilliseconds(150));
        Match m = r.Match(url);
        if (m.Success)
            Console.WriteLine(m.Result("${proto}${port}"));
    }
}
// The example displays the following output:
//      http:8080
```

The regular expression pattern `^(?<proto>\w+://[^/]+?(?<port>:\d+)?/` can be interpreted as shown in the following table.

| Pattern | Description |
|--|---|
| <code>^</code> | Begin the match at the start of the string. |
| <code>(?<proto>\w+)</code> | Match one or more word characters. Name this group <code>proto</code> . |
| <code>::/</code> | Match a colon followed by two slash marks. |
| <code>[^/]+?</code> | Match one or more occurrences (but as few as possible) of any character other than a slash mark. |
| <code>(?<port>:\d+)?< code=""></port>:\d+)?<></code> | Match zero or one occurrence of a colon followed by one or more digit characters. Name this group <code>port</code> . |
| <code>/</code> | Match a slash mark. |

The [Match.Result](#) method expands the `${proto}${port}` replacement sequence, which concatenates the value of the two named groups captured in the regular expression pattern. It is a convenient alternative to explicitly concatenating the strings retrieved from the collection object returned by the [Match.Groups](#) property.

The example uses the [Match.Result](#) method with two substitutions, `${proto}` and `${port}`, to include the captured groups in the output string. You can retrieve the captured groups from the match's [GroupCollection](#) object instead, as the following code shows.

C#

```
Console.WriteLine(m.Groups["proto"].Value + m.Groups["port"].Value);
```

How to: Strip Invalid Characters from a String

Article • 09/15/2021

The following example uses the static `Regex.Replace` method to strip invalid characters from a string.

⚠ Warning

When using `System.Text.RegularExpressions` to process untrusted input, pass a timeout. A malicious user can provide input to `RegularExpressions`, causing a **Denial-of-Service attack**. ASP.NET Core framework APIs that use `RegularExpressions` pass a timeout.

Example

You can use the `CleanInput` method defined in this example to strip potentially harmful characters that have been entered into a text field that accepts user input. In this case, `CleanInput` strips out all nonalphanumeric characters except periods (.), at symbols (@), and hyphens (-), and returns the remaining string. However, you can modify the regular expression pattern so that it strips out any characters that should not be included in an input string.

C#

```
using System;
using System.Text.RegularExpressions;

public class Example
{
    static string CleanInput(string strIn)
    {
        // Replace invalid characters with empty strings.
        try {
            return Regex.Replace(strIn, @"[^\\w\\.@-]", "", RegexOptions.None,
TimeSpan.FromSeconds(1.5));
        }
        // If we timeout when replacing invalid characters,
        // we should return Empty.
        catch (RegexMatchTimeoutException) {
            return String.Empty;
        }
    }
}
```

```
    }  
}
```

The regular expression pattern `[^\w\.\@-]` matches any character that is not a word character, a period, an @ symbol, or a hyphen. A word character is any letter, decimal digit, or punctuation connector such as an underscore. Any character that matches this pattern is replaced by `String.Empty`, which is the string defined by the replacement pattern. To allow additional characters in user input, add those characters to the character class in the regular expression pattern. For example, the regular expression pattern `[^\w\.\@-\%\]` also allows a percentage symbol and a backslash in an input string.

How to verify that strings are in valid email format

Article • 10/04/2022

The example in this article uses a regular expression to verify that a string is in valid email format.

This regular expression is comparatively simple to what can actually be used as an email. Using a regular expression to validate an email is useful to ensure that the structure of an email is correct. However, it isn't a substitution for verifying the email actually exists.

- ✓ DO use a small regular expression to check for the valid structure of an email.
- ✓ DO send a test email to the address provided by a user of your app.
- ✗ DON'T use a regular expression as the only way you validate an email.

If you try to create the *perfect* regular expression to validate that the structure of an email is correct, the expression becomes so complex that it's incredibly difficult to debug or improve. Regular expressions can't validate an email exists, even if it's structured correctly. The best way to validate an email is to send a test email to the address.

⚠ Warning

When using `System.Text.RegularExpressions` to process untrusted input, pass a timeout. A malicious user can provide input to `RegularExpressions`, causing a [Denial-of-Service attack](#). ASP.NET Core framework APIs that use `RegularExpressions` pass a timeout.

Example

The example defines an `IsValidEmail` method, which returns `true` if the string contains a valid email address and `false` if it doesn't but takes no other action.

To verify that the email address is valid, the `IsValidEmail` method calls the `Regex.Replace(String, String, MatchEvaluator)` method with the `(@)(.+)$` regular expression pattern to separate the domain name from the email address. The third parameter is a `MatchEvaluator` delegate that represents the method that processes and replaces the matched text. The regular expression pattern is interpreted as follows:

| Pattern | Description |
|---------|--|
| (@) | Match the @ character. This part is the first capturing group. |
| (.+) | Match one or more occurrences of any character. This part is the second capturing group. |
| \$ | End the match at the end of the string. |

The domain name, along with the @ character, is passed to the `DomainMapper` method. The method uses the `IdnMapping` class to translate Unicode characters that are outside the US-ASCII character range to Punycode. The method also sets the `invalid` flag to `True` if the `IdnMapping.GetAscii` method detects any invalid characters in the domain name. The method returns the Punycode domain name preceded by the @ symbol to the `IsValidEmail` method.

💡 Tip

It's recommended that you use the simple `(@)(.+)$` regular expression pattern to normalize the domain and then return a value indicating that it passed or failed. However, the example in this article describes how to use a regular expression further to validate the email. Regardless of how you validate an email, you should always send a test email to the address to ensure it exists.

The `IsValidEmail` method then calls the `Regex.IsMatch(String, String)` method to verify that the address conforms to a regular expression pattern.

The `IsValidEmail` method merely determines whether the email format is valid for an email address; it doesn't validate that the email exists. Also, the `IsValidEmail` method doesn't verify that the top-level domain name is a valid domain name listed in the [IANA Root Zone Database](#), which would require a look-up operation.

C#

```
using System;
using System.Globalization;
using System.Text.RegularExpressions;

namespace RegexExamples
{
    class RegexUtilities
    {
        public static bool IsValidEmail(string email)
        {
            if (string.IsNullOrWhiteSpace(email))
                return false;
            else
                return Regex.IsMatch(email, "(@)(.+)$");
        }
    }
}
```

```

        return false;

    try
    {
        // Normalize the domain
        email = Regex.Replace(email, @"(@)(.+)$", DomainMapper,
            RegexOptions.None,
        TimeSpan.FromMilliseconds(200));

        // Examines the domain part of the email and normalizes it.
        string DomainMapper(Match match)
        {
            // Use IdnMapping class to convert Unicode domain names.
            var idn = new IdnMapping();

            // Pull out and process domain name (throws
            ArgumentException on invalid)
            string domainName = idn.GetAscii(match.Groups[2].Value);

            return match.Groups[1].Value + domainName;
        }
    }
    catch (RegexMatchTimeoutException e)
    {
        return false;
    }
    catch (ArgumentException e)
    {
        return false;
    }

    try
    {
        return Regex.IsMatch(email,
            @"^[@\s]+@[^\s]+\.[^\s]+$",
            RegexOptions.IgnoreCase,
        TimeSpan.FromMilliseconds(250));
    }
    catch (RegexMatchTimeoutException)
    {
        return false;
    }
}
}

```

In this example, the regular expression pattern `^[@\s]+@[^\s]+\.[^\s]+$` is interpreted as shown in the following table. The regular expression is compiled using the `RegexOptions.IgnoreCase` flag.

| Pattern | Description |
|----------------------|--|
| <code>^</code> | Begin the match at the start of the string. |
| <code>[^@\s]+</code> | Match one or more occurrences of any character other than the @ character or whitespace. |
| <code>@</code> | Match the @ character. |
| <code>[^@\s]+</code> | Match one or more occurrences of any character other than the @ character or whitespace. |
| <code>\.</code> | Match a single period character. |
| <code>[^@\s]+</code> | Match one or more occurrences of any character other than the @ character or whitespace. |
| <code>\$</code> | End the match at the end of the string. |

ⓘ Important

This regular expression isn't intended to cover every aspect of a valid email address. It's provided as an example for you to extend as needed.

Serialization in .NET

Article • 10/25/2023

Serialization is the process of converting the state of an object into a form that can be persisted or transported. The complement of serialization is deserialization, which converts a stream into an object. Together, these processes allow data to be stored and transferred.

.NET features the following serialization technologies:

- [JSON serialization](#) maps .NET objects to and from JavaScript Object Notation (JSON). JSON is an open standard that's commonly used to share data across the web. The JSON serializer serializes public properties by default, and can be configured to serialize private and internal members as well.
- [XML and SOAP serialization](#) serializes only `public` properties and fields and does not preserve type fidelity. This is useful when you want to provide or consume data without restricting the application that uses the data. Because XML is an open standard, it is an attractive choice for sharing data across the Web. SOAP is likewise an open standard, which makes it an attractive choice.
- [Binary serialization](#) preserves *type fidelity*, which means that the complete state of the object is recorded and when you deserialize, an exact copy is created. This type of serialization is useful for preserving the state of an object between different invocations of an application. For example, you can share an object between different applications by serializing it to the Clipboard. You can serialize an object to a stream, to a disk, to memory, over the network, and so forth. Remoting uses serialization to pass objects "by value" from one computer or application domain to another.

⚠ Warning

Binary serialization can be dangerous. For more information, see [BinaryFormatter security guide](#).

Reference

[System.Text.Json](#)

Contains classes that can be used to serialize objects into JSON format documents or streams.

[System.Runtime.Serialization](#)

Contains classes that can be used for serializing and deserializing objects.

[System.Xml.Serialization](#)

Contains classes that can be used to serialize objects into XML format documents or streams.

JSON serialization and deserialization (marshalling and unmarshalling) in .NET - overview

Article • 10/25/2023

The [System.Text.Json](#) namespace provides functionality for serializing to and deserializing from JavaScript Object Notation (JSON). *Serialization* is the process of converting the state of an object, that is, the values of its properties, into a form that can be stored or transmitted. The serialized form doesn't include any information about an object's associated methods. *Deserialization* reconstructs an object from the serialized form.

The `System.Text.Json` library design emphasizes high performance and low memory allocation over an extensive feature set. Built-in UTF-8 support optimizes the process of reading and writing JSON text encoded as UTF-8, which is the most prevalent encoding for data on the web and files on disk.

The library also provides classes for working with an in-memory [document object model \(DOM\)](#). This feature enables random access to the elements in a JSON file or string.

For Visual Basic, there are some limitations on what parts of the library you can use. For more information, see [Visual Basic support](#).

How to get the library

The library is built-in as part of the shared framework for .NET Core 3.0 and later versions. The [source generation feature](#) is built-in as part of the shared framework for .NET 6 and later versions.

For framework versions earlier than .NET Core 3.0, install the [System.Text.Json](#) NuGet package. The package supports:

- .NET Standard 2.0 and later
- .NET Framework 4.6.2 and later
- .NET Core 2.1 and later
- .NET 5 and later

Namespaces and APIs

- The [System.Text.Json](#) namespace contains all the entry points and the main types.
- The [System.Text.Json.Serialization](#) namespace contains attributes and APIs for advanced scenarios and customization specific to serialization and deserialization.

The code examples shown in this article require `using` directives for one or both of these namespaces.

Important

`System.Text.Json` doesn't support the following serialization APIs that you might have used previously:

- Attributes from the [System.Runtime.Serialization](#) namespace.
 - The [System.SerializableAttribute](#) attribute and the [ISerializable](#) interface.
- These types are used only for [Binary](#) and [XML](#) serialization.

HttpClient and HttpContent extension methods

Serializing and deserializing JSON payloads from the network are common operations. Extension methods on [HttpClient](#) and [HttpContent](#) let you do these operations in a single line of code. These extension methods use [web defaults for JsonSerializerOptions](#).

The following example illustrates use of [HttpClientJsonExtensions.GetFromJsonAsync](#) and [HttpClientJsonExtensions.PostAsJsonAsync](#):

C#

```
using System.Net.Http.Json;

namespace HttpClientExtensionMethods
{
    public class User
    {
        public int Id { get; set; }
        public string? Name { get; set; }
        public string? Username { get; set; }
        public string? Email { get; set; }
    }

    public class Program
    {
        public static async Task Main()
        {
            using HttpClient client = new()
            {
                BaseAddress = new
            }
        }
    }
}
```

```

Uri("https://jsonplaceholder.typicode.com")
};

// Get the user information.
User? user = await client.GetFromJsonAsync<User>("users/1");
Console.WriteLine($"Id: {user?.Id}");
Console.WriteLine($"Name: {user?.Name}");
Console.WriteLine($"Username: {user?.Username}");
Console.WriteLine($"Email: {user?.Email}");

// Post a new user.
HttpResponseMessage response = await
client.PostAsJsonAsync("users", user);
Console.WriteLine(
 $"{(response.IsSuccessStatusCode ? "Success" : "Error")} - 
{response.StatusCode}");
}
}

// Produces output like the following example but with different names:
// 
//Id: 1
//Name: Tyler King
//Username: Tyler
//Email: Tyler @contoso.com
//Success - Created

```

There are also extension methods for `System.Text.Json` on `HttpContent`.

Reflection vs. source generation

By default, `System.Text.Json` gathers the metadata it needs to access properties of objects for serialization and deserialization *at run time* using [reflection](#). As an alternative, `System.Text.Json` can use the C# [source generation](#) feature to improve performance, reduce private memory usage, and facilitate [assembly trimming](#), which reduces app size.

For more information, see [Reflection versus source generation](#).

Security information

For information about security threats that were considered when designing `JsonSerializer`, and how they can be mitigated, see [System.Text.Json Threat Model](#).

Thread safety

The `System.Text.Json` serializer was designed with thread safety in mind. Practically, this means that once locked, `JsonSerializerOptions` instances can be safely shared across multiple threads. `JsonDocument` provides an immutable, and in .NET 8 and later versions, thread-safe, DOM representation for JSON values.

How to write .NET objects as JSON (serialize)

Article • 10/25/2023

This article shows how to use the [System.Text.Json](#) namespace to serialize to JavaScript Object Notation (JSON). If you're porting existing code from [Newtonsoft.Json](#), see [How to migrate to System.Text.Json](#).

To write JSON to a string or to a file, call the [JsonSerializer.Serialize](#) method.

The following example creates JSON as a string:

C#

```
using System.Text.Json;

namespace SerializeBasic
{
    public class WeatherForecast
    {
        public DateTimeOffset Date { get; set; }
        public int TemperatureCelsius { get; set; }
        public string? Summary { get; set; }
    }

    public class Program
    {
        public static void Main()
        {
            var weatherForecast = new WeatherForecast
            {
                Date = DateTime.Parse("2019-08-01"),
                TemperatureCelsius = 25,
                Summary = "Hot"
            };

            string jsonString = JsonSerializer.Serialize(weatherForecast);

            Console.WriteLine(jsonString);
        }
    }
}

// output:
//{"Date":"2019-08-01T00:00:00-07:00","TemperatureCelsius":25,"Summary":"Hot"}
```

The JSON output is minified (whitespace, indentation, and new-line characters are removed) by default.

The following example uses synchronous code to create a JSON file:

```
C#  
  
using System.Text.Json;  
  
namespace SerializeToFile  
{  
    public class WeatherForecast  
    {  
        public DateTimeOffset Date { get; set; }  
        public int TemperatureCelsius { get; set; }  
        public string? Summary { get; set; }  
    }  
  
    public class Program  
    {  
        public static void Main()  
        {  
            var weatherForecast = new WeatherForecast  
            {  
                Date = DateTime.Parse("2019-08-01"),  
                TemperatureCelsius = 25,  
                Summary = "Hot"  
            };  
  
            string fileName = "WeatherForecast.json";  
            string jsonString = JsonSerializer.Serialize(weatherForecast);  
            File.WriteAllText(fileName, jsonString);  
  
            Console.WriteLine(File.ReadAllText(fileName));  
        }  
    }  
}  
// output:  
//{"Date":"2019-08-01T00:00:00-  
//07:00","TemperatureCelsius":25,"Summary":"Hot"}
```

The following example uses asynchronous code to create a JSON file:

```
C#  
  
using System.Text.Json;  
  
namespace SerializeToFileAsync  
{  
    public class WeatherForecast  
    {  
        public DateTimeOffset Date { get; set; }  
        public int TemperatureCelsius { get; set; }  
        public string? Summary { get; set; }  
    }  
}
```

```

public class Program
{
    public static async Task Main()
    {
        var weatherForecast = new WeatherForecast
        {
            Date = DateTime.Parse("2019-08-01"),
            TemperatureCelsius = 25,
            Summary = "Hot"
        };

        string fileName = "WeatherForecast.json";
        using FileStream createStream = File.Create(fileName);
        await JsonSerializer.SerializeAsync(createStream,
weatherForecast);
        await createStream.DisposeAsync();

        Console.WriteLine(File.ReadAllText(fileName));
    }
}
// output:
//{"Date":"2019-08-01T00:00:00-
07:00","TemperatureCelsius":25,"Summary":"Hot"}

```

The preceding examples use type inference for the type being serialized. An overload of `Serialize()` takes a generic type parameter:

C#

```

using System.Text.Json;

namespace SerializeWithGenericParameter
{
    public class WeatherForecast
    {
        public DateTimeOffset Date { get; set; }
        public int TemperatureCelsius { get; set; }
        public string? Summary { get; set; }
    }

    public class Program
    {
        public static void Main()
        {
            var weatherForecast = new WeatherForecast
            {
                Date = DateTime.Parse("2019-08-01"),
                TemperatureCelsius = 25,
                Summary = "Hot"
            };
        }
    }
}

```

```
        string jsonString = JsonSerializer.Serialize<WeatherForecast>(weatherForecast);

        Console.WriteLine(jsonString);
    }
}
// output:
//{"Date":"2019-08-01T00:00:00-
07:00","TemperatureCelsius":25,"Summary":"Hot"}
```

Serialization behavior

- By default, all public properties are serialized. You can [specify properties to ignore](#). You can also include [private members](#).
- The [default encoder](#) escapes non-ASCII characters, HTML-sensitive characters within the ASCII-range, and characters that must be escaped according to [the RFC 8259 JSON spec ↗](#).
- By default, JSON is minified. You can [pretty-print the JSON](#).
- By default, casing of JSON names matches the .NET names. You can [customize JSON name casing](#).
- By default, circular references are detected and exceptions thrown. You can [preserve references and handle circular references](#).
- By default, [fields](#) are ignored. You can [include fields](#).

When you use `System.Text.Json` indirectly in an ASP.NET Core app, some default behaviors are different. For more information, see [Web defaults for `JsonSerializerOptions`](#).

Supported types include:

- .NET primitives that map to JavaScript primitives, such as numeric types, strings, and Boolean.
- User-defined [plain old CLR objects \(POCOs\)](#).
- One-dimensional and jagged arrays (`T[][]`).
- Collections and dictionaries from the following namespaces:
 - `System.Collections`
 - `System.Collections.Generic`
 - `System.Collections.Immutable`
 - `System.Collections.Concurrent`
 - `System.Collections.Specialized`

- o [System.Collections.ObjectModel](#)

For more information, see [Supported collection types in System.Text.Json](#).

You can [implement custom converters](#) to handle additional types or to provide functionality that isn't supported by the built-in converters.

Here's an example showing how a class that contains collection properties and a user-defined type is serialized:

C#

```
using System.Text.Json;

namespace SerializeExtra
{
    public class WeatherForecast
    {
        public DateTimeOffset Date { get; set; }
        public int TemperatureCelsius { get; set; }
        public string? Summary { get; set; }
        public string? SummaryField;
        public IList<DateTimeOffset>? DatesAvailable { get; set; }
        public Dictionary<string, HighLowTemps>? TemperatureRanges { get;
set; }
        public string[]? SummaryWords { get; set; }
    }

    public class HighLowTemps
    {
        public int High { get; set; }
        public int Low { get; set; }
    }

    public class Program
    {
        public static void Main()
        {
            var weatherForecast = new WeatherForecast
            {
                Date = DateTime.Parse("2019-08-01"),
                TemperatureCelsius = 25,
                Summary = "Hot",
                SummaryField = "Hot",
                DatesAvailable = new List<DateTimeOffset>()
                    { DateTime.Parse("2019-08-01"), DateTime.Parse("2019-08-
02") },
                TemperatureRanges = new Dictionary<string, HighLowTemps>
                {
                    ["Cold"] = new HighLowTemps { High = 20, Low = -10
},
                    ["Hot"] = new HighLowTemps { High = 60 , Low = 20 }
                },
            };
        }
    }
}
```

```

        SummaryWords = new[] { "Cool", "Windy", "Humid" }
    };

        var options = new JsonSerializerOptions { WriteIndented = true
    };
        string jsonString = JsonSerializer.Serialize(weatherForecast,
options);

        Console.WriteLine(jsonString);
    }
}
// output:
//{
//  "Date": "2019-08-01T00:00:00-07:00",
//  "TemperatureCelsius": 25,
//  "Summary": "Hot",
//  "DatesAvailable": [
//    "2019-08-01T00:00:00-07:00",
//    "2019-08-02T00:00:00-07:00"
//  ],
//  "TemperatureRanges": {
//    "Cold": {
//      "High": 20,
//      "Low": -10
//    },
//    "Hot": {
//      "High": 60,
//      "Low": 20
//    }
//  },
//  "SummaryWords": [
//    "Cool",
//    "Windy",
//    "Humid"
//  ]
//}

```

Serialize to UTF-8

It's 5-10% faster to serialize to a UTF-8 byte array than to use the string-based methods. That's because the bytes (as UTF-8) don't need to be converted to strings (UTF-16).

To serialize to a UTF-8 byte array, call the [JsonSerializer.SerializeToUtf8Bytes](#) method:

C#

```
byte[] jsonUtf8Bytes = JsonSerializer.SerializeToUtf8Bytes(weatherForecast);
```

A [Serialize](#) overload that takes a [Utf8JsonWriter](#) is also available.

Serialize to formatted JSON

To pretty-print the JSON output, set `JsonSerializerOptions.WriteIndented` to `true`:

C#

```
using System.Text.Json;

namespace SerializeWriteIndented
{
    public class WeatherForecast
    {
        public DateTimeOffset Date { get; set; }
        public int TemperatureCelsius { get; set; }
        public string? Summary { get; set; }
    }

    public class Program
    {
        public static void Main()
        {
            var weatherForecast = new WeatherForecast
            {
                Date = DateTime.Parse("2019-08-01"),
                TemperatureCelsius = 25,
                Summary = "Hot"
            };

            var options = new JsonSerializerOptions { WriteIndented = true };
            string jsonString = JsonSerializer.Serialize(weatherForecast,
options);

            Console.WriteLine(jsonString);
        }
    }
}

// output:
//{
//    "Date": "2019-08-01T00:00:00-07:00",
//    "TemperatureCelsius": 25,
//    "Summary": "Hot"
//}
```

💡 Tip

If you use `JsonSerializerOptions` repeatedly with the same options, don't create a new `JsonSerializerOptions` instance each time you use it. Reuse the same instance for every call. For more information, see [Reuse JsonSerializerOptions instances](#).

How to customize property names and values with System.Text.Json

Article • 10/18/2023

By default, property names and dictionary keys are unchanged in the JSON output, including case. Enum values are represented as numbers. And properties are serialized in the order they're defined. However, you can customize these behaviors by:

- Specifying specific serialized property names.
- Using a built-in [naming policy](#), such as camelCase, snake_case, or kebab-case, for property names and dictionary keys.
- Using a custom naming policy for property names and dictionary keys.
- Serializing enum values as strings, with or without a naming policy.
- Configuring the order of serialized properties.

ⓘ Note

The [web default](#) naming policy is camel case.

For other scenarios that require special handling of JSON property names and values, you can [implement custom converters](#).

Customize individual property names

To set the name of individual properties, use the [\[JsonPropertyName\]](#) attribute.

Here's an example type to serialize and resulting JSON:

C#

```
public class WeatherForecastWithPropertyNameAttribute
{
    public DateTimeOffset Date { get; set; }
    public int TemperatureCelsius { get; set; }
    public string? Summary { get; set; }
    [JsonPropertyName("Wind")]
    public int WindSpeed { get; set; }
}
```

JSON

```
{
    "Date": "2019-08-01T00:00:00-07:00",
    "TemperatureCelsius": 25,
    "Summary": "Hot",
    "Wind": 35
}
```

The property name set by this attribute:

- Applies in both directions, for serialization and deserialization.
- Takes precedence over property naming policies.
- Doesn't affect parameter name matching for parameterized constructors.

Use a built-in naming policy

The following table shows the built-in naming policies and how they affect property names.

| Naming policy | Description | Original property name | Converted property name |
|-----------------|---|------------------------|-------------------------|
| CamelCase | First word starts with a lower case character. Successive words start with an uppercase character. | TempCelsius | tempCelsius |
| KebabCaseLower* | Words are separated by hyphens. All characters are lowercase. | TempCelsius | temp-celsius |
| KebabCaseUpper* | Words are separated by hyphens. All characters are uppercase. | TempCelsius | TEMP-CELSIUS |
| SnakeCaseLower* | Words are separated by underscores. All characters are lowercase. | TempCelsius | temp_celsius |
| SnakeCaseUpper* | Words are separated by underscores. All characters are uppercase. | TempCelsius | TEMP_CELSIUS |

* Available in .NET 8 and later versions.

The following example shows how to use camel case for all JSON property names by setting `JsonSerializerOptions.PropertyNamingPolicy` to `JsonNamingPolicy.CamelCase`:

C#

```
var serializeOptions = new JsonSerializerOptions
{
    PropertyNamingPolicy = JsonNamingPolicy.CamelCase,
    WriteIndented = true
};
jsonString = JsonSerializer.Serialize(weatherForecast, serializeOptions);
```

Here's an example class to serialize and JSON output:

C#

```
public class WeatherForecastWithPropertyNameAttribute
{
    public DateTimeOffset Date { get; set; }
    public int TemperatureCelsius { get; set; }
    public string? Summary { get; set; }
    [JsonPropertyName("Wind")]
    public int WindSpeed { get; set; }
}
```

JSON

```
{
    "date": "2019-08-01T00:00:00-07:00",
    "temperatureCelsius": 25,
    "summary": "Hot",
    "Wind": 35
}
```

The naming policy:

- Applies to serialization and deserialization.
- Is overridden by `[JsonPropertyName]` attributes. This is why the JSON property name `Wind` in the example is not camel case.

ⓘ Note

None of the built-in naming policies support letters that are surrogate pairs. For more information, see [dotnet/runtime issue 90352](#).

Use a custom JSON property naming policy

To use a custom JSON property naming policy, create a class that derives from [JsonNamingPolicy](#) and override the [ConvertName](#) method, as shown in the following example:

C#

```
using System.Text.Json;

namespace SystemTextJsonSamples
{
    public class UpperCaseNamingPolicy : JsonNamingPolicy
    {
        public override string ConvertName(string name) =>
            name.ToUpper();
    }
}
```

Then set the [JsonSerializerOptions.PropertyNamingPolicy](#) property to an instance of your naming policy class:

C#

```
var options = new JsonSerializerOptions
{
    PropertyNamingPolicy = new UpperCaseNamingPolicy(),
    WriteIndented = true
};
jsonString = JsonSerializer.Serialize(weatherForecast, options);
```

Here's an example class to serialize and JSON output:

C#

```
public class WeatherForecastWithPropertyNameAttribute
{
    public DateTimeOffset Date { get; set; }
    public int TemperatureCelsius { get; set; }
    public string? Summary { get; set; }
    [JsonPropertyName("Wind")]
    public int WindSpeed { get; set; }
}
```

JSON

```
{
    "DATE": "2019-08-01T00:00:00-07:00",
    "TEMPERATURECELSIUS": 25,
    "SUMMARY": "Hot",
```

```
    "Wind": 35  
}
```

The JSON property naming policy:

- Applies to serialization and deserialization.
- Is overridden by `[JsonPropertyName]` attributes. This is why the JSON property name `Wind` in the example is not upper case.

Use a naming policy for dictionary keys

If a property of an object to be serialized is of type `Dictionary<string, TValue>`, the `string` keys can be converted using a naming policy, such as camel case. To do that, set `JsonSerializerOptions.DictionaryKeyPolicy` to your desired naming policy. The following example uses the `CamelCase` naming policy:

C#

```
var options = new JsonSerializerOptions  
{  
    DictionaryKeyPolicy = JsonNamingPolicy.CamelCase,  
    WriteIndented = true  
};  
jsonString = JsonSerializer.Serialize(weatherForecast, options);
```

Serializing an object with a dictionary named `TemperatureRanges` that has key-value pairs `"ColdMinTemp", 20` and `"HotMinTemp", 40` would result in JSON output like the following example:

JSON

```
{  
    "Date": "2019-08-01T00:00:00-07:00",  
    "TemperatureCelsius": 25,  
    "Summary": "Hot",  
    "TemperatureRanges": {  
        "coldMinTemp": 20,  
        "hotMinTemp": 40  
    }  
}
```

Naming policies for dictionary keys apply to serialization only. If you deserialize a dictionary, the keys will match the JSON file even if you set `JsonSerializerOptions.DictionaryKeyPolicy` to a non-default naming policy.

Enums as strings

By default, enums are serialized as numbers. To serialize enum names as strings, use the [JsonStringEnumConverter](#) or [JsonStringEnumConverter<TEnum>](#) converter. Only [JsonStringEnumConverter<TEnum>](#) is supported by the Native AOT runtime.

For example, suppose you need to serialize the following class that has an enum:

C#

```
public class WeatherForecastWithEnum
{
    public DateTimeOffset Date { get; set; }
    public int TemperatureCelsius { get; set; }
    public Summary? Summary { get; set; }
}

public enum Summary
{
    Cold, Cool, Warm, Hot
}
```

If the Summary is `Hot`, by default the serialized JSON has the numeric value 3:

JSON

```
{
    "Date": "2019-08-01T00:00:00-07:00",
    "TemperatureCelsius": 25,
    "Summary": 3
}
```

The following sample code serializes the enum names instead of the numeric values, and converts the names to camel case:

C#

```
options = new JsonSerializerOptions
{
    WriteIndented = true,
    Converters =
    {
        new JsonStringEnumConverter(JsonNamingPolicy.CamelCase)
    }
};
jsonString = JsonSerializer.Serialize(weatherForecast, options);
```

The resulting JSON looks like the following example:

JSON

```
{  
    "Date": "2019-08-01T00:00:00-07:00",  
    "TemperatureCelsius": 25,  
    "Summary": "hot"  
}
```

The built-in [JsonStringEnumConverter](#) can deserialize string values as well. It works with or without a specified naming policy. The following example shows deserialization using [CamelCase](#):

C#

```
options = new JsonSerializerOptions  
{  
    Converters =  
    {  
        new JsonStringEnumConverter(JsonNamingPolicy.CamelCase)  
    }  
};  
weatherForecast = JsonSerializer.Deserialize<WeatherForecastWithEnum>  
(jsonString, options);
```

You can also specify the converter to use by annotating your enum with [JsonConverterAttribute](#). The following example shows how to specify the [JsonStringEnumConverter<TEnum>](#) (available in .NET 8 and later versions) by using the [JsonConverterAttribute](#) attribute. For example, suppose you need to serialize the following class that has an enum:

C#

```
public class WeatherForecastWithPrecipEnum  
{  
    public DateTimeOffset Date { get; set; }  
    public int TemperatureCelsius { get; set; }  
    public Precipitation? Precipitation { get; set; }  
  
    [JsonConverter(typeof(JsonStringEnumConverter<Precipitation>))]  
    public enum Precipitation  
    {  
        Drizzle, Rain, Sleet, Hail, Snow  
    }  
}
```

The following sample code serializes the enum names instead of the numeric values:

C#

```
var options = new JsonSerializerOptions
{
    WriteIndented = true,
};
jsonString = JsonSerializer.Serialize(weatherForecast, options);
```

The resulting JSON looks like the following example:

JSON

```
{
    "Date": "2019-08-01T00:00:00-07:00",
    "TemperatureCelsius": 25,
    "Precipitation": "Sleet"
}
```

To use the converter with source generation, see [Serialize enum fields as strings](#).

Configure the order of serialized properties

By default, properties are serialized in the order in which they're defined in their class. The [\[JsonPropertyOrder\]](#) attribute lets you specify the order of properties in the JSON output from serialization. The default value of the `Order` property is zero. Set `Order` to a positive number to position a property after those that have the default value. A negative `Order` positions a property before those that have the default value. Properties are written in order from the lowest `Order` value to the highest. Here's an example:

C#

```
using System.Text.Json;
using System.Text.Json.Serialization;

namespace PropertyOrder
{
    public class WeatherForecast
    {
        [JsonPropertyOrder(-5)]
        public DateTime Date { get; set; }
        public int TemperatureC { get; set; }
        [JsonPropertyOrder(-2)]
        public int TemperatureF { get; set; }
        [JsonPropertyOrder(5)]
        public string? Summary { get; set; }
        [JsonPropertyOrder(2)]
        public int WindSpeed { get; set; }
    }
}
```

```
}

public class Program
{
    public static void Main()
    {
        var weatherForecast = new WeatherForecast
        {
            Date = DateTime.Parse("2019-08-01"),
            TemperatureC = 25,
            TemperatureF = 25,
            Summary = "Hot",
            WindSpeed = 10
        };

        var options = new JsonSerializerOptions { WriteIndented = true };
        string jsonString = JsonSerializer.Serialize(weatherForecast,
options);
        Console.WriteLine(jsonString);
    }
}
// output:
//{
//    "Date": "2019-08-01T00:00:00",
//    "TemperatureF": 25,
//    "TemperatureC": 25,
//    "WindSpeed": 10,
//    "Summary": "Hot"
//}
```

How to ignore properties with System.Text.Json

Article • 05/26/2023

When serializing C# objects to JavaScript Object Notation (JSON), by default, all public properties are serialized. If you don't want some of them to appear in the resulting JSON, you have several options. In this article, you learn how to ignore properties based on various criteria:

- Individual properties
- All read-only properties
- All null-value properties
- All default-value properties

Ignore individual properties

To ignore individual properties, use the `[JsonIgnore]` attribute.

The following example shows a type to serialize. It also shows the JSON output:

C#

```
public class WeatherForecastWithIgnoreAttribute
{
    public DateTimeOffset Date { get; set; }
    public int TemperatureCelsius { get; set; }
    [JsonIgnore]
    public string? Summary { get; set; }
}
```

JSON

```
{
    "Date": "2019-08-01T00:00:00-07:00",
    "TemperatureCelsius": 25,
}
```

You can specify conditional exclusion by setting the `[JsonIgnore]` attribute's `Condition` property. The `JsonIgnoreCondition` enum provides the following options:

- `Always` - The property is always ignored. If no `Condition` is specified, this option is assumed.

- `Never` - The property is always serialized and deserialized, regardless of the `DefaultIgnoreCondition`, `IgnoreReadOnlyProperties`, and `IgnoreReadOnlyFields` global settings.
- `WhenWritingDefault` - The property is ignored on serialization if it's a reference type `null`, a nullable value type `null`, or a value type `default`.
- `WhenWritingNull` - The property is ignored on serialization if it's a reference type `null`, or a nullable value type `null`.

The following example illustrates the use of the `[JsonIgnore]` attribute's `Condition` property:

C#

```
using System.Text.Json;
using System.Text.Json.Serialization;

namespace JsonIgnoreAttributeExample
{
    public class Forecast
    {
        [JsonIgnore(Condition = JsonIgnoreCondition.WhenWritingDefault)]
        public DateTime Date { get; set; }

        [JsonIgnore(Condition = JsonIgnoreCondition.Never)]
        public int TemperatureC { get; set; }

        [JsonIgnore(Condition = JsonIgnoreCondition.WhenWritingNull)]
        public string? Summary { get; set; }
    };

    public class Program
    {
        public static void Main()
        {
            Forecast forecast = new()
            {
                Date = default,
                Summary = null,
                TemperatureC = default
            };

            JsonSerializerOptions options = new()
            {
                DefaultIgnoreCondition =
JsonIgnoreCondition.WhenWritingDefault
            };

            string forecastJson =
JsonSerializer.Serialize<Forecast>(forecast,options);

            Console.WriteLine(forecastJson);
        }
    }
}
```

```
        }
    }

// Produces output like the following example:
//
//>{"TemperatureC":0}
```

Ignore all read-only properties

A property is read-only if it contains a public getter but not a public setter. To ignore all read-only properties when serializing, set the [JsonSerializerOptions.IgnoreReadOnlyProperties](#) to `true`, as shown in the following example:

C#

```
var options = new JsonSerializerOptions
{
    IgnoreReadOnlyProperties = true,
    WriteIndented = true
};
jsonString = JsonSerializer.Serialize(weatherForecast, options);
```

The following example shows a type to serialize. It also shows the JSON output:

C#

```
public class WeatherForecastWithR0Property
{
    public DateTimeOffset Date { get; set; }
    public int TemperatureCelsius { get; set; }
    public string? Summary { get; set; }
    public int WindSpeedReadOnly { get; private set; } = 35;
}
```

JSON

```
{
    "Date": "2019-08-01T00:00:00-07:00",
    "TemperatureCelsius": 25,
    "Summary": "Hot",
}
```

This option applies only to properties. To ignore read-only fields when [serializing fields](#), use the [JsonSerializerOptions.IgnoreReadOnlyFields](#) global setting.

Ignore all null-value properties

To ignore all null-value properties, set the [DefaultIgnoreCondition](#) property to [WhenWritingNull](#), as shown in the following example:

C#

```
using System.Text.Json;
using System.Text.Json.Serialization;

namespace IgnoreNullOnSerialize
{
    public class Forecast
    {
        public DateTime Date { get; set; }
        public int TemperatureC { get; set; }
        public string? Summary { get; set; }
    };

    public class Program
    {
        public static void Main()
        {
            Forecast forecast = new()
            {
                Date = DateTime.Now,
                Summary = null,
                TemperatureC = default
            };

            JsonSerializerOptions options = new()
            {
                DefaultIgnoreCondition = JsonIgnoreCondition.WhenWritingNull
            };

            string forecastJson =
                JsonSerializer.Serialize<Forecast>(forecast, options);

            Console.WriteLine(forecastJson);
        }
    }
}

// Produces output like the following example:
// [{"Date": "2020-10-30T10:11:40.2359135-07:00", "TemperatureC": 0}
```

Ignore all default-value properties

To prevent serialization of default values in value type properties, set the [DefaultIgnoreCondition](#) property to [WhenWritingDefault](#), as shown in the following example:

C#

```
using System.Text.Json;
using System.Text.Json.Serialization;

namespace IgnoreValueDefaultOnSerialize
{
    public class Forecast
    {
        public DateTime Date { get; set; }
        public int TemperatureC { get; set; }
        public string? Summary { get; set; }
    };

    public class Program
    {
        public static void Main()
        {
            Forecast forecast = new()
            {
                Date = DateTime.Now,
                Summary = null,
                TemperatureC = default
            };

            JsonSerializerOptions options = new()
            {
                DefaultIgnoreCondition =
JsonIgnoreCondition.WhenWritingDefault
            };

            string forecastJson =
                JsonSerializer.Serialize<Forecast>(forecast, options);

            Console.WriteLine(forecastJson);
        }
    }
}

// Produces output like the following example:
// 
// {"Date":"2020-10-21T15:40:06.8920138-07:00"}  

```

The [WhenWritingDefault](#) setting also prevents serialization of null-value reference type and nullable value type properties.

Include fields

Article • 10/25/2023

By default, fields aren't serialized. Use the `JsonSerializerOptions.IncludeFields` global setting or the `[JsonInclude]` attribute to include fields when serializing or deserializing, as shown in the following example:

C#

```
using System.Text.Json;
using System.Text.Json.Serialization;

namespace Fields
{
    public class Forecast
    {
        public DateTime Date;
        public int TemperatureC;
        public string? Summary;
    }

    public class Forecast2
    {
        [JsonInclude]
        public DateTime Date;
        [JsonInclude]
        public int TemperatureC;
        [JsonInclude]
        public string? Summary;
    }

    public class Program
    {
        public static void Main()
        {
            var json =
                @"{""Date"":""2020-09-
06T11:31:01.923395"",""TemperatureC"":-1,""Summary"":""Cold""} ";
            Console.WriteLine($"Input JSON: {json}");

            var options = new JsonSerializerOptions
            {
                IncludeFields = true,
            };
            var forecast = JsonSerializer.Deserialize<Forecast>(json,
options)!;

            Console.WriteLine($"forecast.Date: {forecast.Date}");
            Console.WriteLine($"forecast.TemperatureC:
{forecast.TemperatureC}");
            Console.WriteLine($"forecast.Summary: {forecast.Summary}");
        }
    }
}
```

```

        var roundTrippedJson =
            JsonSerializer.Serialize<Forecast>(forecast, options);

        Console.WriteLine($"Output JSON: {roundTrippedJson}");

        var forecast2 = JsonSerializer.Deserialize<Forecast2>(json)!;

        Console.WriteLine($"forecast2.Date: {forecast2.Date}");
        Console.WriteLine($"forecast2.TemperatureC:
{forecast2.TemperatureC}");
        Console.WriteLine($"forecast2.Summary: {forecast2.Summary}");

        roundTrippedJson = JsonSerializer.Serialize<Forecast2>
(forecast2);

        Console.WriteLine($"Output JSON: {roundTrippedJson}");
    }
}
}

// Produces output like the following example:
//
//Input JSON: { "Date":"2020-09-
06T11:31:01.923395", "TemperatureC": -1, "Summary": "Cold" }
//forecast.Date: 9/6/2020 11:31:01 AM
//forecast.TemperatureC: -1
//forecast.Summary: Cold
//Output JSON: { "Date": "2020-09-
06T11:31:01.923395", "TemperatureC": -1, "Summary": "Cold" }
//forecast2.Date: 9/6/2020 11:31:01 AM
//forecast2.TemperatureC: -1
//forecast2.Summary: Cold
//Output JSON: { "Date": "2020-09-
06T11:31:01.923395", "TemperatureC": -1, "Summary": "Cold" }

```

To ignore read-only fields, use the [JsonSerializerOptions.IgnoreReadOnlyFields](#) global setting.

How to read JSON as .NET objects (deserialize)

Article • 10/25/2023

This article shows how to use the [System.Text.Json](#) namespace to serialize to and deserialize from JavaScript Object Notation (JSON). If you're porting existing code from [Newtonsoft.Json](#), see [How to migrate to System.Text.Json](#).

A common way to deserialize JSON is to have (or create) a .NET class with properties and fields that represent one or more of the JSON properties. Then, to deserialize from a string or a file, call the [JsonSerializer.Deserialize](#) method. For the generic overloads, the generic type parameter is the .NET class. For the non-generic overloads, you pass the type of the class as a method parameter. You can deserialize either synchronously or asynchronously.

Any JSON properties that aren't represented in your class are ignored [by default](#). Also, if any properties on the type are [required](#) but not present in the JSON payload, deserialization will fail.

The following example shows how to deserialize a JSON string:

C#

```
using System.Text.Json;

namespace DeserializeExtra
{
    public class WeatherForecast
    {
        public DateTimeOffset Date { get; set; }
        public int TemperatureCelsius { get; set; }
        public string? Summary { get; set; }
        public string? SummaryField;
        public IList<DateTimeOffset>? DatesAvailable { get; set; }
        public Dictionary<string, HighLowTemps>? TemperatureRanges { get;
set; }
        public string[]? SummaryWords { get; set; }
    }

    public class HighLowTemps
    {
        public int High { get; set; }
        public int Low { get; set; }
    }

    public class Program
```

```

{
    public static void Main()
    {
        string jsonString =
@"{
    ""Date"": ""2019-08-01T00:00:00-07:00"",
    ""TemperatureCelsius"": 25,
    ""Summary"": ""Hot"",
    ""DatesAvailable"": [
        ""2019-08-01T00:00:00-07:00"",
        ""2019-08-02T00:00:00-07:00""
    ],
    ""TemperatureRanges"": {
        ""Cold"": {
            ""High"": 20,
            ""Low"": -10
        },
        ""Hot"": {
            ""High"": 60,
            ""Low"": 20
        }
    },
    ""SummaryWords"": [
        ""Cool"",
        ""Windy"",
        ""Humid""
    ]
}
";

```

```

        WeatherForecast? weatherForecast =
            JsonSerializer.Deserialize<WeatherForecast>(jsonString);

        Console.WriteLine($"Date: {weatherForecast?.Date}");
        Console.WriteLine($"TemperatureCelsius:
{weatherForecast?.TemperatureCelsius}");
        Console.WriteLine($"Summary: {weatherForecast?.Summary}");
    }
}
// output:
//Date: 8/1/2019 12:00:00 AM -07:00
//TemperatureCelsius: 25
//Summary: Hot

```

To deserialize from a file by using synchronous code, read the file into a string, as shown in the following example:

```
C#
using System.Text.Json;
namespace DeserializeFromFile
```

```

{
    public class WeatherForecast
    {
        public DateTimeOffset Date { get; set; }
        public int TemperatureCelsius { get; set; }
        public string? Summary { get; set; }
    }

    public class Program
    {
        public static void Main()
        {
            string fileName = "WeatherForecast.json";
            string jsonString = File.ReadAllText(fileName);
            WeatherForecast weatherForecast =
JsonSerializer.Deserialize<WeatherForecast>(jsonString)!

            Console.WriteLine($"Date: {weatherForecast.Date}");
            Console.WriteLine($"TemperatureCelsius:
{weatherForecast.TemperatureCelsius}");
            Console.WriteLine($"Summary: {weatherForecast.Summary}");
        }
    }
}

// output:
//Date: 8/1/2019 12:00:00 AM -07:00
//TemperatureCelsius: 25
//Summary: Hot

```

To deserialize from a file by using asynchronous code, call the [DeserializeAsync](#) method:

```

C#

using System.Text.Json;

namespace DeserializeFromFileAsync
{
    public class WeatherForecast
    {
        public DateTimeOffset Date { get; set; }
        public int TemperatureCelsius { get; set; }
        public string? Summary { get; set; }
    }

    public class Program
    {
        public static async Task Main()
        {
            string fileName = "WeatherForecast.json";
            using FileStream openStream = File.OpenRead(fileName);
            WeatherForecast? weatherForecast =
                await JsonSerializer.DeserializeAsync<WeatherForecast>
(openStream);

```

```
        Console.WriteLine($"Date: {weatherForecast?.Date}");
        Console.WriteLine($"TemperatureCelsius:
{weatherForecast?.TemperatureCelsius}");
        Console.WriteLine($"Summary: {weatherForecast?.Summary}");
    }
}
// output:
//Date: 8/1/2019 12:00:00 AM -07:00
//TemperatureCelsius: 25
//Summary: Hot
```

Deserialization behavior

The following behaviors apply when deserializing JSON:

- By default, property name matching is case-sensitive. You can [specify case-insensitivity](#).
- Non-public constructors are ignored by the serializer.
- Deserialization to immutable objects or properties that don't have public `set` accessors is supported but not enabled by default. See [Immutable types and records](#).
- By default, enums are supported as numbers. You can [deserialize string enum fields](#).
- By default, fields are ignored. You can [include fields](#).
- By default, comments or trailing commas in the JSON throw exceptions. You can [allow comments and trailing commas](#).
- The [default maximum depth](#) is 64.

When you use `System.Text.Json` indirectly in an ASP.NET Core app, some default behaviors are different. For more information, see [Web defaults for `JsonSerializerOptions`](#).

You can [implement custom converters](#) to provide functionality that isn't supported by the built-in converters.

Deserialize without a .NET class

If you have JSON that you want to deserialize, and you don't have the class to deserialize it into, you have options other than manually creating the class that you need:

- Use the [Utf8JsonReader](#) directly.

- Deserialize into a [JSON DOM \(document object model\)](#) and extract what you need from the DOM.

The DOM lets you navigate to a subsection of a JSON payload and deserialize a single value, a custom type, or an array. For information about the [JsonNode](#) DOM, see [Deserialize subsections of a JSON payload](#). For information about the [JsonDocument](#) DOM, see [How to search a JsonDocument and JsonElement for sub-elements](#).

- Use Visual Studio 2022 to automatically generate the class you need:
 - Copy the JSON that you need to deserialize.
 - Create a class file and delete the template code.
 - Choose **Edit > Paste Special > Paste JSON as Classes**.

The result is a class that you can use for your deserialization target.

Deserialize from UTF-8

To deserialize from UTF-8, call a [JsonSerializer.Deserialize](#) overload that takes a `ReadOnlySpan<byte>` or a `Utf8JsonReader`, as shown in the following examples. The examples assume the JSON is in a byte array named `jsonUtf8Bytes`.

C#

```
var readOnlySpan = new ReadOnlySpan<byte>(jsonUtf8Bytes);
WeatherForecast serializedWeatherForecast =
    JsonSerializer.Deserialize<WeatherForecast>(readOnlySpan);
```

C#

```
var utf8Reader = new Utf8JsonReader(jsonUtf8Bytes);
WeatherForecast serializedWeatherForecast =
    JsonSerializer.Deserialize<WeatherForecast>(ref utf8Reader);
```

Required properties

Article • 10/04/2022

Starting in .NET 7, you can mark certain properties to signify that they must be present in the JSON payload for deserialization to succeed. If one or more of these required properties is not present, the [JsonSerializer.Deserialize](#) methods throw a [JsonException](#).

There are three ways to mark a property or field as required for JSON deserialization:

- By adding the [required modifier](#), which is new in C# 11.
- By annotating it with [JsonRequiredAttribute](#), which is new in .NET 7.
- By modifying the [JsonPropertyInfo.IsRequired](#) property of the contract model, which is new in .NET 7.

From the serializer's perspective, these two demarcations are equivalent and both map to the same piece of metadata, which is [JsonPropertyInfo.IsRequired](#). In most cases, you'd simply use the built-in C# keyword. However, in the following cases, you should use [JsonRequiredAttribute](#) instead:

- If you're using a programming language other than C# or a down-level version of C#.
- If you only want the requirement to apply to JSON deserialization.
- If you're using `System.Text.Json` serialization in [source generation](#) mode. In this case, your code won't compile if you use the `required` modifier, as source generation occurs at compile time.

The following code snippet shows an example of a property modified with the `required` keyword. This property must be present in the JSON payload for deserialization to succeed.

C#

```
using System.Text.Json;

// The following line throws a JsonException at run time.
Console.WriteLine(JsonSerializer.Deserialize<Person>("""{"Age": 42}"""));

public class Person
{
    public required string Name { get; set; }
    public int Age { get; set; }
}
```

Alternatively, you can use [JsonRequiredAttribute](#):

C#

```
using System.Text.Json;

// The following line throws a JsonException at run time.
Console.WriteLine(JsonSerializer.Deserialize<Person>("""{"Age": 42}"""));

public class Person
{
    [JsonPropertyRequired]
    public string Name { get; set; }
    public int Age { get; set; }
}
```

It's also possible to control whether a property is required via the contract model using the `JsonPropertyInfo.isRequired` property:

C#

```
var options = new JsonSerializerOptions
{
    TypeInfoResolver = new DefaultJsonTypeInfoResolver
    {
        Modifiers =
        {
            static TypeInfo =>
            {
                if (typeInfo.Kind != JsonTypeInfoKind.Object)
                    return;

                foreach (JsonPropertyInfo propertyInfo in
typeInfo.Properties)
                {
                    // Strip IsRequired constraint from every property.
                    propertyInfo.isRequired = false;
                }
            }
        }
    };
};

// Deserialization now succeeds even though the Name property isn't in the
// JSON payload.
JsonSerializer.Deserialize<Person>("""{"Age": 42}""", options);
```

The source for this content can be found on GitHub, where you can also create and review issues and pull requests. For more information, see [our contributor guide](#).

The .NET documentation is open source. Provide feedback here.

 [Provide product feedback](#)

How to allow some kinds of invalid JSON with System.Text.Json

Article • 05/26/2023

In this article, you will learn how to allow comments, trailing commas, and quoted numbers in JSON, and how to write numbers as strings.

Allow comments and trailing commas

By default, comments and trailing commas are not allowed in JSON. To allow comments in the JSON, set the `JsonSerializerOptions.ReadCommentHandling` property to `JsonCommentHandling.Skip`. And to allow trailing commas, set the `JsonSerializerOptions.AllowTrailingCommas` property to `true`. The following example shows how to allow both:

C#

```
var options = new JsonSerializerOptions
{
    ReadCommentHandling = JsonCommentHandling.Skip,
    AllowTrailingCommas = true,
};
var weatherForecast = JsonSerializer.Deserialize<WeatherForecast>
(jsonString, options);
```

Here's example JSON with comments and a trailing comma:

JSON

```
{
    "Date": "2019-08-01T00:00:00-07:00",
    "TemperatureCelsius": 25, // Fahrenheit 77
    "Summary": "Hot", /* Zharko */
    // Comments on
    /* separate lines */
}
```

Allow or write numbers in quotes

Some serializers encode numbers as JSON strings (surrounded by quotes).

For example:

JSON

```
{  
    "DegreesCelsius": "23"  
}
```

Instead of:

JSON

```
{  
    "DegreesCelsius": 23  
}
```

To serialize numbers in quotes or accept numbers in quotes across the entire input object graph, set [JsonSerializerOptions.NumberHandling](#) as shown in the following example:

C#

```
using System.Text.Json;  
using System.Text.Json.Serialization;  
  
namespace QuotedNumbers  
{  
    public class Forecast  
    {  
        public DateTime Date { get; init; }  
        public int TemperatureC { get; set; }  
        public string? Summary { get; set; }  
    };  
  
    public class Program  
    {  
        public static void Main()  
        {  
            Forecast forecast = new()  
            {  
                Date = DateTime.Now,  
                TemperatureC = 40,  
                Summary = "Hot"  
            };  
  
            JsonSerializerOptions options = new()  
            {  
                NumberHandling =  
                    JsonNumberHandling.AllowReadingFromString |  
                    JsonNumberHandling.WriteString,  
                WriteIndented = true  
            };
```

```

        string forecastJson =
            JsonSerializer.Serialize<Forecast>(forecast, options);

        Console.WriteLine($"Output JSON:\n{forecastJson}");

        Forecast forecastDeserialized =
            JsonSerializer.Deserialize<Forecast>(forecastJson,
options)!;

        Console.WriteLine($"Date: {forecastDeserialized.Date}");
        Console.WriteLine($"TemperatureC:
{forecastDeserialized.TemperatureC}");
        Console.WriteLine($"Summary: {forecastDeserialized.Summary}");
    }
}

// Produces output like the following example:
//
//Output JSON:
//{
//  "Date": "2020-10-23T12:27:06.4017385-07:00",
//  "TemperatureC": "40",
//  "Summary": "Hot"
//}
//Date: 10/23/2020 12:27:06 PM
//TemperatureC: 40
//Summary: Hot

```

When you use `System.Text.Json` indirectly through ASP.NET Core, quoted numbers are allowed when deserializing because ASP.NET Core specifies [web default options](#).

To allow or write quoted numbers for specific properties, fields, or types, use the [\[JsonNumberHandling\]](#) attribute.

Handle missing members during deserialization

Article • 03/03/2023

By default, if the JSON payload you're deserializing contains properties that don't exist in the deserialized plain old CLR object (POCO) type, they're simply ignored. Starting in .NET 8, you can specify that all members must be present in the payload. If they're not, a [JsonException](#) exception is thrown. You can configure this behavior in one of three ways:

- Annotate your POCO type with the

```
[<xref:System.Text.Json.Serialization.JsonUnmappedMemberHandlingAttribute>]  
attribute, specifying either to Skip or Disallow missing members.
```

C#

```
[JsonUnmappedMemberHandling(JsonUnmappedMemberHandling.Disallow)]  
public class MyPoco  
{  
    public int Id { get; set; }  
}  
  
JsonSerializer.Deserialize<MyPoco>(""""{"Id" : 42, "AnotherId" : -1  
}""");  
// JsonException : The JSON property 'AnotherId' could not be mapped to  
any .NET member contained in type 'MyPoco'.
```

- Set [JsonSerializerOptions.UnmappedMemberHandling](#) to either [Skip](#) or [Disallow](#).
- Customize the [JsonTypeInfo](#) contract for the relevant type. (For information about customizing a contract, see [Customize a JSON contract](#).)

How to handle overflow JSON or use JsonElement or JsonNode in System.Text.Json

Article • 05/26/2023

This article shows how to handle overflow JSON with the `System.Text.Json` namespace. It also shows how to deserialize into `JsonElement` or `JsonNode`, as an alternative for other scenarios where the target type might not perfectly match all of the JSON being deserialized.

Handle overflow JSON

While deserializing, you might receive data in the JSON that is not represented by properties of the target type. For example, suppose your target type is this:

```
C#  
  
public class WeatherForecast  
{  
    public DateTimeOffset Date { get; set; }  
    public int TemperatureCelsius { get; set; }  
    public string? Summary { get; set; }  
}
```

And the JSON to be deserialized is this:

```
JSON  
  
{  
    "Date": "2019-08-01T00:00:00-07:00",  
    "temperatureCelsius": 25,  
    "Summary": "Hot",  
    "DatesAvailable": [  
        "2019-08-01T00:00:00-07:00",  
        "2019-08-02T00:00:00-07:00"  
    ],  
    "SummaryWords": [  
        "Cool",  
        "Windy",  
        "Humid"  
    ]  
}
```

If you deserialize the JSON shown into the type shown, the `DatesAvailable` and `SummaryWords` properties have nowhere to go and are lost. To capture extra data such as these properties, apply the `[JsonExtensionData]` attribute to a property of type `Dictionary<string,object>` or `Dictionary<string,JsonElement>`:

C#

```
public class WeatherForecastWithExtensionData
{
    public DateTimeOffset Date { get; set; }
    public int TemperatureCelsius { get; set; }
    public string? Summary { get; set; }
    [JsonExtensionData]
    public Dictionary<string, JsonElement>? ExtensionData { get; set; }
}
```

The following table shows the result of deserializing the JSON shown earlier into this sample type. The extra data becomes key-value pairs of the `ExtensionData` property:

[+] Expand table

| Property | Value | Notes |
|--------------------|--|---|
| Date | "8/1/2019 12:00:00 AM -07:00" | |
| TemperatureCelsius | 0 | Case-sensitive mismatch (<code>temperatureCelsius</code> in the JSON), so the property isn't set. |
| Summary | "Hot" | |
| ExtensionData | {"temperatureCelsius": 25, "DatesAvailable": ["2019-08-01T00:00:00-07:00", "2019-08-02T00:00:00-07:00"], "SummaryWords": ["Cool", "Windy", "Humid"]} | Since the case didn't match, <code>temperatureCelsius</code> is an extra and becomes a key-value pair in the dictionary. Each extra array from the JSON becomes a key-value pair, with an array as the value object. |

When the target object is serialized, the extension data key value pairs become JSON properties just as they were in the incoming JSON:

JSON

```
{
    "Date": "2019-08-01T00:00:00-07:00",
    "TemperatureCelsius": 0,
    "Summary": "Hot",
```

```

    "temperatureCelsius": 25,
    "DatesAvailable": [
        "2019-08-01T00:00:00-07:00",
        "2019-08-02T00:00:00-07:00"
    ],
    "SummaryWords": [
        "Cool",
        "Windy",
        "Humid"
    ]
}

```

Notice that the `ExtensionData` property name doesn't appear in the JSON. This behavior lets the JSON make a round trip without losing any extra data that otherwise wouldn't be serialized.

The following example shows a round trip from JSON to a deserialized object and back to JSON:

C#

```

using System.Text.Json;
using System.Text.Json.Serialization;

namespace RoundtripExtensionData
{
    public class WeatherForecast
    {
        public DateTimeOffset Date { get; set; }
        public int TemperatureCelsius { get; set; }
        public string? Summary { get; set; }
        [JsonExtensionData]
        public Dictionary<string, JsonElement>? ExtensionData { get; set; }
    }
    public class Program
    {
        public static void Main()
        {
            string jsonString =
@"
{
    ""Date"": ""2019-08-01T00:00:00-07:00"",
    ""temperatureCelsius"": 25,
    ""Summary"": """",
    ""SummaryField"": """",
    ""DatesAvailable"": [
        ""2019-08-01T00:00:00-07:00"",
        ""2019-08-02T00:00:00-07:00"""
    ],
    ""SummaryWords"": [
        """Cool""",
        """Windy""",
        """Humid"""
    ]
}

```

```
        ]
    }";
    WeatherForecast weatherForecast =
        JsonSerializer.Deserialize<WeatherForecast>(jsonString)!;

    var serializeOptions = new JsonSerializerOptions { WriteIndented
= true };
    jsonString = JsonSerializer.Serialize(weatherForecast,
serializeOptions);
    Console.WriteLine($"JSON output:\n{jsonString}\n");
}
}

// output:
//JSON output:
//{
//  "Date": "2019-08-01T00:00:00-07:00",
//  "TemperatureCelsius": 0,
//  "Summary": "Hot",
//  "temperatureCelsius": 25,
//  "SummaryField": "Hot",
//  "DatesAvailable": [
//    "2019-08-01T00:00:00-07:00",
//    "2019-08-02T00:00:00-07:00"
//  ],
//  "SummaryWords": [
//    "Cool",
//    "Windy",
//    "Humid"
//  ]
//}
```

Deserialize into JsonElement or JsonNode

If you just want to be flexible about what JSON is acceptable for a particular property, an alternative is to deserialize into [JsonElement](#) or [JsonNode](#). Any valid JSON property can be deserialized into [JsonElement](#) or [JsonNode](#). Choose [JsonElement](#) to create an immutable object or [JsonNode](#) to create a mutable object.

The following example shows a round trip from JSON and back to JSON for a class that includes properties of type [JsonElement](#) and [JsonNode](#).

C#

```
using System.Text.Json;
using System.Text.Json.Nodes;

namespace RoundtripJsonElementAndNode
{
    public class WeatherForecast
```

```

    {
        public DateTimeOffset Date { get; set; }
        public int TemperatureCelsius { get; set; }
        public string? Summary { get; set; }
        public JsonElement DatesAvailable { get; set; }
        public JsonNode? SummaryWords { get; set; }
    }
    public class Program
    {
        public static void Main()
        {
            string jsonString =
@"{  

    ""Date"": ""2019-08-01T00:00:00-07:00"",
    ""TemperatureCelsius"": 25,
    ""Summary"": ""Hot"",
    ""DatesAvailable"": [
        ""2019-08-01T00:00:00-07:00"",
        ""2019-08-02T00:00:00-07:00""
    ],
    ""SummaryWords"": [
        ""Cool"",
        ""Windy"",
        ""Humid""
    ]
}";
            WeatherForecast? weatherForecast =
                JsonSerializer.Deserialize<WeatherForecast>(jsonString);

            var serializeOptions = new JsonSerializerOptions { WriteIndented
= true };
            jsonString = JsonSerializer.Serialize(weatherForecast,
serializeOptions);
            Console.WriteLine(jsonString);
        }
    }
// output:
//{
//    "Date": "2019-08-01T00:00:00-07:00",
//    "TemperatureCelsius": 25,
//    "Summary": "Hot",
//    "DatesAvailable": [
//        "2019-08-01T00:00:00-07:00",
//        "2019-08-02T00:00:00-07:00"
//    ],
//    "SummaryWords": [
//        "Cool",
//        "Windy",
//        "Humid"
//    ]
//}

```

Use immutable types and properties

Article • 10/25/2023

An immutable *type* is one that prevents you from changing any property or field values of an object after it's instantiated. The type might be a record, have no public properties or fields, have read-only properties, or have properties with private or init-only setters. [System.String](#) is an example of an immutable type. [System.Text.Json](#) provides different ways that you can deserialize JSON to immutable types.

Parameterized constructors

By default, [System.Text.Json](#) uses the default public parameterless constructor.

However, you can tell it to use a parameterized constructor, which makes it possible to deserialize an immutable class or struct.

- For a class, if the only constructor is a parameterized one, that constructor will be used.
- For a struct, or a class with multiple constructors, specify the one to use by applying the [\[JsonConstructor\]](#) attribute. When the attribute is not used, a public parameterless constructor is always used if present.

The following example uses the [\[JsonConstructor\]](#) attribute:

C#

```
using System.Text.Json;
using System.Text.Json.Serialization;

namespace ImmutableTypes
{
    public struct Forecast
    {
        public DateTime Date { get; }
        public int TemperatureC { get; }
        public string Summary { get; }

        [JsonConstructor]
        public Forecast(DateTime date, int temperatureC, string
summary) =>
            (Date, TemperatureC, Summary) = (date, temperatureC,
summary);
    }

    public class Program
    {
```

```

        public static void Main()
    {
        var json = @"{""date"":""2020-09-06T11:31:01.923395-
07:00"",""temperatureC"":-1,""summary"":""Cold""} ";
        Console.WriteLine($"Input JSON: {json}");

        var options = new
JsonSerializerOptions(JsonSerializerDefaults.Web);

        var forecast = JsonSerializer.Deserialize<Forecast>(json,
options);

        Console.WriteLine($"forecast.Date: {forecast.Date}");
        Console.WriteLine($"forecast.TemperatureC:
{forecast.TemperatureC}");
        Console.WriteLine($"forecast.Summary: {forecast.Summary}");

        var roundTrippedJson =
JsonSerializer.Serialize<Forecast>(forecast, options);

        Console.WriteLine($"Output JSON: {roundTrippedJson}");

    }
}

// Produces output like the following example:
//
//Input JSON: { "date":"2020-09-06T11:31:01.923395-
07:00","temperatureC":-1,"summary":"Cold"}
//forecast.Date: 9 / 6 / 2020 11:31:01 AM
//forecast.TemperatureC: -1
//forecast.Summary: Cold
//Output JSON: { "date":"2020-09-06T11:31:01.923395-
07:00","temperatureC":-1,"summary":"Cold"}
```

In .NET 7 and earlier versions, the `[JsonConstructor]` attribute can only be used with public constructors.

The parameter names of a parameterized constructor must match the property names and types. Matching is case-insensitive, and the constructor parameter must match the actual property name even if you use `[JsonPropertyName]` to rename a property. In the following example, the name for the `TemperatureC` property is changed to `celsius` in the JSON, but the constructor parameter is still named `temperaturec`:

C#

```

using System.Text.Json;
using System.Text.Json.Serialization;

namespace ImmutableTypesCtorParams
```

```

{
    public struct Forecast
    {
        public DateTime Date { get; }
        [JsonPropertyName("celsius")]
        public int TemperatureC { get; }
        public string Summary { get; }

        [JsonConstructor]
        public Forecast(DateTime date, int temperatureC, string summary) =>
            (Date, TemperatureC, Summary) = (date, temperatureC, summary);
    }
}

public class Program
{
    public static void Main()
    {
        var json = @"{""date"":""2020-09-06T11:31:01.923395-
07:00"",""celsius"":-1,""summary"":""Cold""} ";
        Console.WriteLine($"Input JSON: {json}");

        var options = new
JsonSerializerOptions(JsonSerializerDefaults.Web);

        var forecast = JsonSerializer.Deserialize<Forecast>(json,
options);

        Console.WriteLine($"forecast.Date: {forecast.Date}");
        Console.WriteLine($"forecast.TemperatureC:
{forecast.TemperatureC}");
        Console.WriteLine($"forecast.Summary: {forecast.Summary}");

        var roundTrippedJson =
            JsonSerializer.Serialize<Forecast>(forecast, options);

        Console.WriteLine($"Output JSON: {roundTrippedJson}");

    }
}
}

// Produces output like the following example:
//
//Input JSON: { "date":"2020-09-06T11:31:01.923395-
07:00","celsius":-1,"summary":"Cold"}
//forecast.Date: 9 / 6 / 2020 11:31:01 AM
//forecast.TemperatureC: -1
//forecast.Summary: Cold
//Output JSON: { "date":"2020-09-06T11:31:01.923395-
07:00","celsius":-1,"summary":"Cold"}
```

Besides `[JsonPropertyName]`, the following attributes support deserialization with parameterized constructors:

- [\[JsonConverter\]](#)
- [\[JsonIgnore\]](#)
- [\[JsonInclude\]](#)
- [\[JsonNumberHandling\]](#)

Records

Records are also supported for both serialization and deserialization, as shown in the following example:

C#

```
using System.Text.Json;

namespace Records
{
    public record Forecast(DateTime Date, int TemperatureC)
    {
        public string? Summary { get; init; }
    };

    public class Program
    {
        public static void Main()
        {
            Forecast forecast = new(DateTime.Now, 40)
            {
                Summary = "Hot!"
            };

            string forecastJson = JsonSerializer.Serialize<Forecast>
(forecast);
            Console.WriteLine(forecastJson);
            Forecast? forecastObj = JsonSerializer.Deserialize<Forecast>
(forecastJson);
            Console.WriteLine(forecastObj);
        }
    }
}

// Produces output like the following example:
// 
//{"Date":"2020-10-21T15:26:10.5044594-
07:00","TemperatureC":40,"Summary":"Hot!"}
//Forecast { Date = 10 / 21 / 2020 3:26:10 PM, TemperatureC = 40, Summary =
Hot! }
```

You can apply any of the attributes to the property names, using the `property:` target on the attribute. For more information on positional records, see the article on [records](#)

in the C# language reference.

Non-public members and property accessors

You can enable use of a non-public *accessor* on a property by using the [\[JsonInclude\]](#) attribute, as shown in the following example:

C#

```
using System.Text.Json;
using System.Text.Json.Serialization;

namespace NonPublicAccessors
{
    public class Forecast
    {
        public DateTime Date { get; init; }

        [JsonInclude]
        public int TemperatureC { get; private set; }

        [JsonInclude]
        public string? Summary { private get; set; }
    };

    public class Program
    {
        public static void Main()
        {
            string json = @"{""Date"":""2020-10-23T09:51:03.8702889-07:00"",""TemperatureC"":40,""Summary"":""Hot""}";
            Console.WriteLine($"Input JSON: {json}");

            Forecast forecastDeserialized =
JsonSerializer.Deserialize<Forecast>(json)!;
            Console.WriteLine($"Date: {forecastDeserialized.Date}");
            Console.WriteLine($"TemperatureC: {forecastDeserialized.TemperatureC}");

            json = JsonSerializer.Serialize<Forecast>(forecastDeserialized);
            Console.WriteLine($"Output JSON: {json}");
        }
    }
}

// Produces output like the following example:
//
//Input JSON: { "Date":"2020-10-23T09:51:03.8702889-07:00","TemperatureC":40,"Summary":"Hot"}
//Date: 10 / 23 / 2020 9:51:03 AM
//TemperatureC: 40
```

```
//Output JSON: { "Date":"2020-10-23T09:51:03.8702889-07:00", "TemperatureC":40, "Summary":"Hot"}
```

By including a property with a private setter, you can still deserialize that property.

In .NET 8 and later versions, you can also use the [\[JsonInclude\]](#) attribute to opt non-public *members* into the serialization contract for a given type.

ⓘ Note

In source-generation mode, you can't serialize `private` members or use `private` accessors by annotating them with the [\[JsonInclude\]](#) attribute. And you can only serialize `internal` members or use `internal` accessors if they're in the same assembly as the generated [JsonSerializerContext](#).

Read-only properties

In .NET 8 and later versions, read-only properties, or those that have no setter either private or public, can also be deserialized. While you can't change the instance that the property references, if the type of the property is mutable, you can modify it. For example, you can add an element to a list. To deserialize a read-only property, you need to set its object creation handling behavior to *populate* instead of *replace*. For example, you can annotate the property with the [JsonObjectCreationHandlingAttribute](#) attribute.

C#

```
class A
{
    [JsonObjectCreationHandling(JsonObjectCreationHandling.Populate)]
    public List<int> Numbers1 { get; } = new List<int>() { 1, 2, 3 };
}
```

For more information, see [Populate initialized properties](#).

Populate initialized properties

Article • 10/25/2023

Starting in .NET 8, you can specify a preference to either [replace](#) or [populate](#) .NET properties when JSON is deserialized. The [JsonObjectCreationHandling](#) enum provides the object creation handling choices:

- [JsonObjectCreationHandling.Replace](#)
- [JsonObjectCreationHandling.Populate](#)

Default (replace) behavior

The `System.Text.Json` deserializer always creates a new instance of the target type. However, even though a new instance is created, some properties and fields might already be initialized as part of the object's construction. Consider the following type:

C#

```
class A
{
    public List<int> Numbers1 { get; } = [1, 2, 3];
    public List<int> Numbers2 { get; set; } = [1, 2, 3];
}
```

When you create an instance of this class, the `Numbers1` (and `Numbers2`) property's value is a list with three elements (1, 2, and 3). If you deserialize JSON to this type, the *default* behavior is that property values are *replaced*:

- For `Numbers1`, since it's read-only (no setter), it still has the values 1, 2, and 3 in its list.
- For `Numbers2`, which is read-write, a new list is allocated and the values from the JSON are added.

For example, if you execute the following deserialization code, `Numbers1` contains the values 1, 2, and 3 and `Numbers2` contains the values 4, 5, and 6.

C#

```
A? a = JsonSerializer.Deserialize<A>("""" {"Numbers1": [4,5,6], "Numbers2": [4,5,6]} """");
```

Populate behavior

Starting in .NET 8, you can change the deserialization behavior to modify (*populate*) properties and fields instead of replace them:

- For a collection type property, the object is reused without clearing. If the collection is prepopulated with elements, they'll show in the final deserialized result along with the values from the JSON. For an example, see [Collection property example](#).
- For a property that's an object with properties, its mutable properties are updated to the JSON values but the object reference itself doesn't change.
- For a struct type property, the effective behavior is that for its mutable properties, any existing values are kept and new values from the JSON are added. However, unlike a reference property, the object itself isn't reused since it's a value type. Instead, a copy of the struct is modified and then reassigned to the property. For an example, see [Struct property example](#).

A struct property must have a setter; otherwise, an [InvalidOperationException](#) is thrown at run time.

ⓘ Note

The populate behavior currently doesn't work for types that have a parameterized constructor. For more information, see [dotnet/runtime issue 92877](#).

Read-only properties

For populating reference properties that are mutable, since the instance that the property references isn't *replaced*, the property doesn't need to have a setter. This behavior means that deserialization can also populate *read-only* properties.

ⓘ Note

Struct properties still require setters because the instance is replaced with a modified copy.

Collection property example

Consider the same class `A` from the [replace behavior](#) example, but this time annotated with a preference for *populating* properties instead of replacing them:

```
C#  
  
[JsonObjectCreationHandling(JsonObjectCreationHandling.Populate)]  
class A  
{  
    public List<int> Numbers1 { get; } = [1, 2, 3];  
    public List<int> Numbers2 { get; set; } = [1, 2, 3];  
}
```

If you execute the following deserialization code, both `Numbers1` and `Numbers2` contain the values 1, 2, 3, 4, 5, and 6:

```
C#  
  
A? a = JsonSerializer.Deserialize<A>( """{ "Numbers1": [4,5,6], "Numbers2": [4,5,6] } """ );
```

Struct property example

The following class contains a struct property, `s1`, whose deserialization behavior is set to [Populate](#). After executing this code, `c.s1.Value1` has a value of 10 (from the constructor) and `c.s1.Value2` has a value of 5 (from the JSON).

```
C#  
  
C? c = JsonSerializer.Deserialize<C>( """{ "S1": { "Value2": 5 } } """ );  
  
class C  
{  
    public C()  
    {  
        _s1 = new S  
        {  
            Value1 = 10  
        };  
    }  
  
    private S _s1;  
  
    [JsonObjectCreationHandling(JsonObjectCreationHandling.Populate)]  
    public S S1  
    {  
        get { return _s1; }  
        set { _s1 = value; }  
    }
```

```
}
```

```
struct S
```

```
{
```

```
    public int Value1 { get; set; }
```

```
    public int Value2 { get; set; }
```

```
}
```

If the default [Replace](#) behavior was used instead, `c.S1.Value1` would have its default value of 0 after deserialization. That's because the constructor `c()` would be called, setting `c.S1.Value1` to 10, but then the value of S1 would be replaced with a new instance. (`c.S1.Value2` would still be 5, since the JSON replaces the default value.)

How to specify

There are multiple ways to specify a preference for *replace* or *populate*:

- Use the [JsonObjectCreationHandlingAttribute](#) attribute to annotate at the type or property level. If you set the attribute at the type level and set its [Handling](#) property to [Populate](#), the behavior will only apply to those properties where population is possible (for example, value types must have a setter).

If you want the type-wide preference to be [Populate](#), but want to exclude one or more properties from that behavior, you can add the attribute at the type level and again at the property level to override the inherited behavior. That pattern is shown in the following code.

C#

```
// Type-level preference is Populate.  
[JsonObjectCreationHandling(JsonObjectCreationHandling.Populate)]  
class B  
{  
    // For this property only, use Replace behavior.  
    [JsonObjectCreationHandling(JsonObjectCreationHandling.Replace)]  
    public List<int> Numbers1 { get; } = [1, 2, 3];  
    public List<int> Numbers2 { get; set; } = [1, 2, 3];  
}
```

- Set [JsonSerializerOptions.PreferredObjectCreationHandling](#) (or, for source generation, [JsonSourceGenerationOptionsAttribute.PreferredObjectCreationHandling](#)) to specify a global preference.

C#

```
var options = new JsonSerializerOptions
{
    PreferredObjectCreationHandling =
    JsonObjectCreationHandling.Populate
};
```

Migrate from Newtonsoft.Json to System.Text.Json

Article • 10/20/2023

This article shows how to migrate from [Newtonsoft.Json](#) to [System.Text.Json](#).

The `System.Text.Json` namespace provides functionality for serializing to and deserializing from JavaScript Object Notation (JSON). The `System.Text.Json` library is included in the runtime for [.NET Core 3.1](#) and later versions. For other target frameworks, install the [System.Text.Json](#) NuGet package. The package supports:

- .NET Standard 2.0 and later versions
- .NET Framework 4.7.2 and later versions
- .NET Core 2.0, 2.1, and 2.2

`System.Text.Json` focuses primarily on performance, security, and standards compliance. It has some key differences in default behavior and doesn't aim to have feature parity with `Newtonsoft.Json`. For some scenarios, `System.Text.Json` currently has no built-in functionality, but there are recommended workarounds. For other scenarios, workarounds are impractical.

We're investing in adding the features that are most often requested. If your application depends on a missing feature, consider [filing an issue](#) in the dotnet/runtime GitHub repository to find out if support for your scenario can be added.

Most of this article is about how to use the `JsonSerializer` API, but it also includes guidance on how to use the `JsonDocument` (which represents the Document Object Model or DOM), `Utf8JsonReader`, and `Utf8JsonWriter` types.

In Visual Basic, you can't use `Utf8JsonReader`, which also means you can't write custom converters. Most of the workarounds presented here require that you write custom converters. You can write a custom converter in C# and register it in a Visual Basic project. For more information, see [Visual Basic support](#).

Table of differences

The following table lists `Newtonsoft.Json` features and `System.Text.Json` equivalents.

The equivalents fall into the following categories:

- Supported by built-in functionality. Getting similar behavior from `System.Text.Json` may require the use of an attribute or global option.

- ⚠ Not supported, but workaround is possible. The workarounds are [custom converters](#), which may not provide complete parity with `Newtonsoft.Json` functionality. For some of these, sample code is provided as examples. If you rely on these `Newtonsoft.Json` features, migration will require modifications to your .NET object models or other code changes.
- ✗ Not supported, and workaround is not practical or possible. If you rely on these `Newtonsoft.Json` features, migration will not be possible without significant changes.

| Newtonsoft.Json feature | System.Text.Json equivalent |
|--|---|
| Case-insensitive deserialization by default | ✓ PropertyNameCaseInsensitive global setting |
| Camel-case property names | ✓ PropertyNamingPolicy global setting |
| Snake-case property names | ✓ Snake case naming policy |
| Minimal character escaping | ✓ Strict character escaping, configurable |

| TypeNameHandling.All global setting | ✖ Not supported by design |
| Support for <code>JsonPath</code> queries | ✖ Not supported |
| Configurable limits | ✖ Not supported |

This is not an exhaustive list of `Newtonsoft.Json` features. The list includes many of the scenarios that have been requested in [GitHub issues](#) or [StackOverflow](#) posts. If you implement a workaround for one of the scenarios listed here that doesn't currently have sample code, and if you want to share your solution, select [This page](#) in the [Feedback](#) section at the bottom of this page. That creates an issue in this documentation's GitHub repo and lists it in the [Feedback](#) section on this page too.

Differences in default behavior

`System.Text.Json` is strict by default and avoids any guessing or interpretation on the caller's behalf, emphasizing deterministic behavior. The library is intentionally designed this way for performance and security. `Newtonsoft.Json` is flexible by default. This fundamental difference in design is behind many of the following specific differences in default behavior.

Case-insensitive deserialization

During deserialization, `Newtonsoft.Json` does case-insensitive property name matching by default. The `System.Text.Json` default is case-sensitive, which gives better performance since it's doing an exact match. For information about how to do case-insensitive matching, see [Case-insensitive property matching](#).

If you're using `System.Text.Json` indirectly by using ASP.NET Core, you don't need to do anything to get behavior like `Newtonsoft.Json`. ASP.NET Core specifies the settings for camel-casing property names and case-insensitive matching when it uses `System.Text.Json`.

ASP.NET Core also enables deserializing [quoted numbers](#) by default.

Minimal character escaping

During serialization, `Newtonsoft.Json` is relatively permissive about letting characters through without escaping them. That is, it doesn't replace them with `\uxxxx` where `xxxx` is the character's code point. Where it does escape them, it does so by emitting a `\` before the character (for example, `"` becomes `\"`). `System.Text.Json` escapes more characters by default to provide defense-in-depth protections against cross-site scripting (XSS) or information-disclosure attacks and does so by using the six-character sequence. `System.Text.Json` escapes all non-ASCII characters by default, so you don't need to do anything if you're using `StringEscapeHandling.EscapeNonAscii` in `Newtonsoft.Json`. `System.Text.Json` also escapes HTML-sensitive characters, by default. For information about how to override the default `System.Text.Json` behavior, see [Customize character encoding](#).

Comments

During deserialization, `Newtonsoft.Json` ignores comments in the JSON by default. The `System.Text.Json` default is to throw exceptions for comments because the [RFC 8259](#) specification doesn't include them. For information about how to allow comments, see [Allow comments and trailing commas](#).

Trailing commas

During deserialization, `Newtonsoft.Json` ignores trailing commas by default. It also ignores multiple trailing commas (for example, `[{"Color":"Red"}, {"Color":"Green"}, ,]`). The `System.Text.Json` default is to throw exceptions for trailing commas because the [RFC 8259](#) specification doesn't allow them. For information about how to make `System.Text.Json` accept them, see [Allow comments and trailing commas](#). There's no way to allow multiple trailing commas.

Converter registration precedence

The `Newtonsoft.Json` registration precedence for custom converters is as follows:

- Attribute on property
- Attribute on type
- [Converters](#) collection

This order means that a custom converter in the `Converters` collection is overridden by a converter that is registered by applying an attribute at the type level. Both of those registrations are overridden by an attribute at the property level.

The `System.Text.Json` registration precedence for custom converters is different:

- Attribute on property
- `Converters` collection
- Attribute on type

The difference here is that a custom converter in the `Converters` collection overrides an attribute at the type level. The intention behind this order of precedence is to make runtime changes override design-time choices. There's no way to change the precedence.

For more information about custom converter registration, see [Register a custom converter](#).

Maximum depth

The latest version of `Newtonsoft.Json` has a maximum depth limit of 64 by default.

`System.Text.Json` also has a default limit of 64, and it's configurable by setting `JsonSerializerOptions.MaxDepth`.

If you're using `System.Text.Json` indirectly by using ASP.NET Core, the default maximum depth limit is 32. The default value is the same as for model binding and is set in the `JsonOptions class` ↗.

JSON strings (property names and string values)

During deserialization, `Newtonsoft.Json` accepts property names surrounded by double quotes, single quotes, or without quotes. It accepts string values surrounded by double quotes or single quotes. For example, `Newtonsoft.Json` accepts the following JSON:

```
JSON
{
  "name1": "value",
  'name2': "value",
  name3: 'value'
}
```

`System.Text.Json` only accepts property names and string values in double quotes because that format is required by the [RFC 8259](#) ↗ specification and is the only format considered valid JSON.

A value enclosed in single quotes results in a `JsonException` with the following message:

Output

```
''' is an invalid start of a value.
```

Non-string values for string properties

`Newtonsoft.Json` accepts non-string values, such as a number or the literals `true` and `false`, for deserialization to properties of type `string`. Here's an example of JSON that `Newtonsoft.Json` successfully deserializes to the following class:

JSON

```
{
    "String1": 1,
    "String2": true,
    "String3": false
}
```

C#

```
public class ExampleClass
{
    public string String1 { get; set; }
    public string String2 { get; set; }
    public string String3 { get; set; }
}
```

`System.Text.Json` doesn't deserialize non-string values into `string` properties. A non-string value received for a `string` field results in a `JsonException` with the following message:

Output

```
The JSON value could not be converted to System.String.
```

Scenarios using `JsonSerializer`

Some of the following scenarios aren't supported by built-in functionality, but workarounds are possible. The workarounds are [custom converters](#), which may not provide complete parity with `Newtonsoft.Json` functionality. For some of these, sample code is provided as examples. If you rely on these `Newtonsoft.Json` features, migration will require modifications to your .NET object models or other code changes.

For some of the following scenarios, workarounds are not practical or possible. If you rely on these `Newtonsoft.Json` features, migration will not be possible without significant changes.

Allow or write numbers in quotes

`Newtonsoft.Json` can serialize or deserialize numbers represented by JSON strings (surrounded by quotes). For example, it can accept: `{"DegreesCelsius": "23"}` instead of `{"DegreesCelsius": 23}`. To enable that behavior in `System.Text.Json`, set `JsonSerializerOptions.NumberHandling` to `WriteAsString` or `AllowReadingFromString`, or use the `[JsonNumberHandling]` attribute.

If you're using `System.Text.Json` indirectly by using ASP.NET Core, you don't need to do anything to get behavior like `Newtonsoft.Json`. ASP.NET Core specifies [web defaults](#) when it uses `System.Text.Json`, and web defaults allow quoted numbers.

For more information, see [Allow or write numbers in quotes](#).

Specify constructor to use when deserializing

The `Newtonsoft.Json [JsonConstructor]` attribute lets you specify which constructor to call when deserializing to a POCO.

`System.Text.Json` also has a `[JsonConstructor]` attribute. For more information, see [Immutable types and Records](#).

Conditionally ignore a property

`Newtonsoft.Json` has several ways to conditionally ignore a property on serialization or deserialization:

- `DefaultContractResolver` lets you select properties to include or ignore, based on arbitrary criteria.
- The `NullValueHandling` and `DefaultValueHandling` settings on `JsonSerializerSettings` let you specify that all null-value or default-value properties should be ignored.
- The `NullValueHandling` and `DefaultValueHandling` settings on the `[JsonProperty]` attribute let you specify individual properties that should be ignored when set to null or the default value.

`System.Text.Json` provides the following ways to ignore properties or fields while serializing:

- The `[JsonIgnore]` attribute on a property causes the property to be omitted from the JSON during serialization.
- The `IgnoreReadOnlyProperties` global option lets you ignore all read-only properties.
- If you're [including fields](#), the `JsonSerializerOptions.IgnoreReadOnlyFields` global option lets you ignore all read-only fields.
- The `DefaultIgnoreCondition` global option lets you [ignore all value type properties that have default values](#), or [ignore all reference type properties that have null values](#).

In addition, in .NET 7 and later versions, you can customize the JSON contract to ignore properties based on arbitrary criteria. For more information, see [Custom contracts](#).

Public and non-public fields

`Newtonsoft.Json` can serialize and deserialize fields as well as properties.

In `System.Text.Json`, use the `JsonSerializerOptions.IncludeFields` global setting or the `[JsonInclude]` attribute to include public fields when serializing or deserializing. For an example, see [Include fields](#).

Preserve object references and handle loops

By default, `Newtonsoft.Json` serializes by value. For example, if an object contains two properties that contain a reference to the same `Person` object, the values of that `Person` object's properties are duplicated in the JSON.

`Newtonsoft.Json` has a `PreserveReferencesHandling` setting on `JsonSerializerSettings` that lets you serialize by reference:

- An identifier metadata is added to the JSON created for the first `Person` object.
- The JSON that is created for the second `Person` object contains a reference to that identifier instead of property values.

`Newtonsoft.Json` also has a `ReferenceLoopHandling` setting that lets you ignore circular references rather than throw an exception.

To preserve references and handle circular references in `System.Text.Json`, set `JsonSerializerOptions.ReferenceHandler` to `Preserve`. The `ReferenceHandler.Preserve`

setting is equivalent to `PreserveReferencesHandling = PreserveReferencesHandling.All` in `Newtonsoft.Json`.

The `ReferenceHandler.IgnoreCycles` option has behavior similar to `Newtonsoft.Json ReferenceLoopHandling.Ignore`. One difference is that the `System.Text.Json` implementation replaces reference loops with the `null` JSON token instead of ignoring the object reference. For more information, see [Ignore circular references](#).

Like the `Newtonsoft.Json ReferenceResolver`, the `System.Text.Json.Serialization.ReferenceResolver` class defines the behavior of preserving references on serialization and deserialization. Create a derived class to specify custom behavior. For an example, see [GuidReferenceResolver](#).

Some related `Newtonsoft.Json` features aren't supported:

- [JsonPropertyAttribute.IsReference](#)
- [JsonPropertyAttribute.ReferenceLoopHandling](#)

For more information, see [Preserve references and handle circular references](#).

Dictionary with non-string key

Both `Newtonsoft.Json` and `System.Text.Json` support collections of type `Dictionary<TKey, TValue>`. However, in `System.Text.Json`, `TKey` must be a primitive type, not a custom type. For more information, see [Supported key types](#).

⊗ Caution

Deserializing to a `Dictionary<TKey, TValue>` where `TKey` is typed as anything other than `string` could introduce a security vulnerability in the consuming application. For more information, see [dotnet/runtime#4761](#).

Types without built-in support

`System.Text.Json` doesn't provide built-in support for the following types:

- `DataTable` and related types (for more information, see [Supported collection types](#))
- `ExpandoObject`
- `TimeZoneInfo`
- `BigInteger`
- `DBNull`

- [Type](#)
- [ValueTuple](#) and its associated generic types

Custom converters can be implemented for types that don't have built-in support.

Polymorphic serialization

[Newtonsoft.Json](#) automatically does polymorphic serialization. Starting in .NET 7, [System.Text.Json](#) supports polymorphic serialization through the [JsonDerivedTypeAttribute](#) attribute. For more information, see [Serialize properties of derived classes](#).

Polymorphic deserialization

[Newtonsoft.Json](#) has a [TypeNameHandling](#) setting that adds type-name metadata to the JSON while serializing. It uses the metadata while deserializing to do polymorphic deserialization. Starting in .NET 7, [System.Text.Json](#) relies on type discriminator information to perform polymorphic deserialization. This metadata is emitted in the JSON and then used during deserialization to determine whether to deserialize to the base type or a derived type. For more information, see [Serialize properties of derived classes](#).

To support polymorphic deserialization in older .NET versions, create a converter like the example in [How to write custom converters](#).

Deserialize string enum values

By default, [System.Text.Json](#) doesn't support deserializing string enum values, whereas [Newtonsoft.Json](#) does. For example, the following code throws a [JsonException](#):

C#

```
string json = "{ \"Text\": \"Hello\", \"Enum\": \"Two\" }";
var _ = JsonSerializer.Deserialize<MyObj>(json); // Throws exception.

class MyObj
{
    public string Text { get; set; } = "";
    public MyEnum Enum { get; set; }
}

enum MyEnum
{
    One,
    Two,
```

```
    Three  
}
```

However, you can enable deserialization of string enum values by using the [JsonStringEnumConverter](#) converter. For more information, see [Enums as strings](#).

Deserialization of object properties

When `Newtonsoft.Json` deserializes to [Object](#), it:

- Infers the type of primitive values in the JSON payload (other than `null`) and returns the stored `string`, `long`, `double`, `boolean`, or `DateTime` as a boxed object. *Primitive values* are single JSON values such as a JSON number, string, `true`, `false`, or `null`.
- Returns a `JObject` or `JArray` for complex values in the JSON payload. *Complex values* are collections of JSON key-value pairs within braces (`{}`) or lists of values within brackets (`[]`). The properties and values within the braces or brackets can have additional properties or values.
- Returns a null reference when the payload has the `null` JSON literal.

`System.Text.Json` stores a boxed `JsonElement` for both primitive and complex values whenever deserializing to [Object](#), for example:

- An `object` property.
- An `object` dictionary value.
- An `object` array value.
- A root `object`.

However, `System.Text.Json` treats `null` the same as `Newtonsoft.Json` and returns a null reference when the payload has the `null` JSON literal in it.

To implement type inference for `object` properties, create a converter like the example in [How to write custom converters](#).

Deserialize null to non-nullable type

`Newtonsoft.Json` doesn't throw an exception in the following scenario:

- `NullValueHandling` is set to `Ignore`, and
- During deserialization, the JSON contains a null value for a non-nullable value type.

In the same scenario, `System.Text.Json` does throw an exception. (The corresponding null-handling setting in `System.Text.Json` is `JsonSerializerOptions.IgnoreNullValues = true`.)

If you own the target type, the best workaround is to make the property in question nullable (for example, change `int` to `int?`).

Another workaround is to make a converter for the type, such as the following example that handles null values for `DateTimeOffset` types:

C#

```
using System.Text.Json;
using System.Text.Json.Serialization;

namespace SystemTextJsonSamples
{
    public class DateTimeOffsetNullHandlingConverter : 
JsonConverter<DateTimeOffset>
    {
        public override DateTimeOffset Read(
            ref Utf8JsonReader reader,
            Type typeToConvert,
            JsonSerializerOptions options) =>
        reader.TokenType == JsonTokenType.Null
            ? default
            : reader.GetDateTimeOffset();

        public override void Write(
            Utf8JsonWriter writer,
            DateTimeOffset dateTimeValue,
            JsonSerializerOptions options) =>
        writer.WriteStringValue(dateTimeValue);
    }
}
```

Register this custom converter by [using an attribute on the property](#) or by [adding the converter](#) to the `Converters` collection.

Note: The preceding converter **handles null values differently** than `Newtonsoft.Json` does for POCOs that specify default values. For example, suppose the following code represents your target object:

C#

```
public class WeatherForecastWithDefault
{
    public WeatherForecastWithDefault()
    {
```

```
        Date = DateTimeOffset.Parse("2001-01-01");
        Summary = "No summary";
    }
    public DateTimeOffset Date { get; set; }
    public int TemperatureCelsius { get; set; }
    public string Summary { get; set; }
}
```

And suppose the following JSON is deserialized by using the preceding converter:

JSON

```
{
    "Date": null,
    "TemperatureCelsius": 25,
    "Summary": null
}
```

After deserialization, the `Date` property has 1/1/0001 (`default(DateTimeOffset)`), that is, the value set in the constructor is overwritten. Given the same POCO and JSON, `Newtonsoft.Json` deserialization would leave 1/1/2001 in the `Date` property.

Deserialize to immutable classes and structs

`Newtonsoft.Json` can deserialize to immutable classes and structs because it can use constructors that have parameters.

In `System.Text.Json`, use the `[JsonConstructor]` attribute to specify use of a parameterized constructor. Records in C# 9 are also immutable and are supported as deserialization targets. For more information, see [Immutable types and Records](#).

Required properties

In `Newtonsoft.Json`, you specify that a property is required by setting `Required` on the `[JsonProperty]` attribute. `Newtonsoft.Json` throws an exception if no value is received in the JSON for a property marked as required.

Specify date format

`Newtonsoft.Json` provides several ways to control how properties of `DateTime` and `DateTimeOffset` types are serialized and deserialized:

- The `DateTimeZoneHandling` setting can be used to serialize all `DateTime` values as UTC dates.
- The `DateFormatString` setting and `DateTime` converters can be used to customize the format of date strings.

`System.Text.Json` supports ISO 8601-1:2019, including the RFC 3339 profile. This format is widely adopted, unambiguous, and makes round trips precisely. To use any other format, create a custom converter. For example, the following converters serialize and deserialize JSON that uses Unix epoch format with or without a time zone offset (values such as `/Date(1590863400000-0700)/` or `/Date(1590863400000)/`):

C#

```
sealed class UnixEpochDateTimeOffsetConverter :  
JsonConverter<DateTimeOffset>  
{  
    static readonly DateTimeOffset s_epoch = new DateTimeOffset(1970, 1, 1,  
0, 0, 0, TimeSpan.Zero);  
    static readonly Regex s_regex = new Regex("^/Date\\\"(([+-]*)((\\d{2})\\(\\d{2}\\))\\)\\/$", RegexOptions.CultureInvariant);  
  
    public override DateTimeOffset Read(ref Utf8JsonReader reader, Type  
typeToConvert, JsonSerializerOptions options)  
    {  
        string formatted = reader.GetString()!;  
        Match match = s_regex.Match(formatted);  
  
        if (  
            !match.Success  
            || !long.TryParse(match.Groups[1].Value,  
System.Globalization.NumberStyles.Integer, CultureInfo.InvariantCulture, out  
long unixTime)  
            || !int.TryParse(match.Groups[3].Value,  
System.Globalization.NumberStyles.Integer, CultureInfo.InvariantCulture, out  
int hours)  
            || !int.TryParse(match.Groups[4].Value,  
System.Globalization.NumberStyles.Integer, CultureInfo.InvariantCulture, out  
int minutes))  
        {  
            throw new JsonException();  
        }  
  
        int sign = match.Groups[2].Value[0] == '+' ? 1 : -1;  
        TimeSpan utcOffset = new TimeSpan(hours * sign, minutes * sign, 0);  
  
        return s_epoch.AddMilliseconds(unixTime).ToOffset(utcOffset);  
    }  
  
    public override void Write(Utf8JsonWriter writer, DateTimeOffset value,  
JsonSerializerOptions options)  
    {
```

```
        long unixTime = Convert.ToInt64((value -  
s_epoch).TotalMilliseconds);  
        TimeSpan utcOffset = value.Offset;  
  
        string formatted = string.Create(CultureInfo.InvariantCulture,  
$/Date({unixTime}{(utcOffset >= TimeSpan.Zero ? "+" : "-")}  
{utcOffset:hhmm})/");  
  
        writer.WriteStringValue(formatted);  
    }  
}
```

C#

```
sealed class UnixEpochDateTimeConverter : JsonConverter<DateTime>
{
    static readonly DateTime s_epoch = new DateTime(1970, 1, 1, 0, 0, 0);
    static readonly Regex s_regex = new Regex("^/Date\\\"(([+-]*/\\d+)\\\")/$",
RegexOptions.CultureInvariant);

    public override DateTime Read(ref Utf8JsonReader reader, Type typeToConvert, JsonSerializerOptions options)
    {
        string formatted = reader.GetString()!;
        Match match = s_regex.Match(formatted);

        if (
            !match.Success
            || !long.TryParse(match.Groups[1].Value,
System.Globalization.NumberStyles.Integer, CultureInfo.InvariantCulture, out
long unixTime))
        {
            throw new JsonException();
        }

        return s_epoch.AddMilliseconds(unixTime);
    }

    public override void Write(Utf8JsonWriter writer, DateTime value,
JsonSerializerOptions options)
    {
        long unixTime = Convert.ToInt64((value -
s_epoch).TotalMilliseconds);

        string formatted = string.Create(CultureInfo.InvariantCulture,
$"/Date({unixTime})/");
        writer.WriteStringValue(formatted);
    }
}
```

For more information, see [DateTime and DateTimeOffset support in System.Text.Json](#).

Callbacks

`Newtonsoft.Json` lets you execute custom code at several points in the serialization or deserialization process:

- `OnDeserializing` (when beginning to deserialize an object)
- `OnDeserialized` (when finished deserializing an object)
- `OnSerializing` (when beginning to serialize an object)
- `OnSerialized` (when finished serializing an object)

`System.Text.Json` exposes the same notifications during serialization and deserialization. To use them, implement one or more of the following interfaces from the [System.Text.Json.Serialization](#) namespace:

- [IJsonOnDeserializing](#)
- [IJsonOnDeserialized](#)
- [IJsonOnSerializing](#)
- [IJsonOnSerialized](#)

Here's an example that checks for a null property and writes messages at start and end of serialization and deserialization:

C#

```
using System.Text.Json;
using System.Text.Json.Serialization;

namespace Callbacks
{
    public class WeatherForecast :
        IJsonOnDeserializing, IJsonOnDeserialized,
        IJsonOnSerializing, IJsonOnSerialized
    {
        public DateTime Date { get; set; }
        public int TemperatureCelsius { get; set; }
        public string? Summary { get; set; }

        void IJsonOnDeserializing.OnDeserializing() =>
Console.WriteLine("\nBegin deserializing");
        void IJsonOnDeserialized.OnDeserialized()
        {
            Validate();
            Console.WriteLine("Finished deserializing");
        }
        void IJsonOnSerializing.OnSerializing()
        {
            Console.WriteLine("Begin serializing");
            Validate();
        }
    }
}
```

```

        void IJsonOnSerialized.OnSerialized() => Console.WriteLine("Finished
serializing");

        private void Validate()
        {
            if (Summary is null)
            {
                Console.WriteLine("The 'Summary' property is 'null'.");
            }
        }
    }

    public class Program
    {
        public static void Main()
        {
            var weatherForecast = new WeatherForecast
            {
                Date = DateTime.Parse("2019-08-01"),
                TemperatureCelsius = 25,
            };

            string jsonString = JsonSerializer.Serialize(weatherForecast);
            Console.WriteLine(jsonString);

            weatherForecast = JsonSerializer.Deserialize<WeatherForecast>
(jjsonString);
            Console.WriteLine($"Date={weatherForecast?.Date}");
            Console.WriteLine($"TemperatureCelsius=
{weatherForecast?.TemperatureCelsius}");
            Console.WriteLine($"Summary={weatherForecast?.Summary}");
        }
    }
}

// output:
//Begin serializing
//The 'Summary' property is 'null'.
//Finished serializing
//{"Date":"2019-08-01T00:00:00","TemperatureCelsius":25,"Summary":null}

//Begin deserializing
//The 'Summary' property is 'null'.
//Finished deserializing
//Date=8/1/2019 12:00:00 AM
//TemperatureCelsius = 25
//Summary=

```

The `OnDeserializing` code doesn't have access to the new POCO instance. To manipulate the new POCO instance at the start of deserialization, put that code in the POCO constructor.

Non-public property setters and getters

`Newtonsoft.Json` can use private and internal property setters and getters via the `JsonProperty` attribute.

`System.Text.Json` supports private and internal property setters and getters via the `[JsonInclude]` attribute. For sample code, see [Non-public property accessors](#).

Populate existing objects

The `JsonConvert.PopulateObject` method in `Newtonsoft.Json` deserializes a JSON document to an existing instance of a class, instead of creating a new instance. `System.Text.Json` always creates a new instance of the target type by using the default public parameterless constructor. Custom converters can deserialize to an existing instance.

Reuse rather than replace properties

Starting in .NET 8, `System.Text.Json` supports reusing initialized properties rather than replacing them. There are some differences in behavior, which you can read about in the [API proposal ↗](#).

For more information, see [Populate initialized properties](#).

Populate properties without setters

Starting in .NET 8, `System.Text.Json` supports populating properties, including those that don't have a setter. For more information, see [Populate initialized properties](#).

Snake case naming policy

`System.Text.Json` includes a built-in naming policy for snake case. However, there are some behavior differences with `Newtonsoft.Json` for some inputs. The following table shows some of these differences when converting input using the `JsonNamingPolicy.SnakeCaseLower` policy.

| Input | Newtonsoft.Json result | System.Text.Json result |
|-----------------|-------------------------------|--------------------------------|
| "AB1" | "a_b1" | "ab1" |
| "SHA512Managed" | "sh_a512_managed" | "sha512_managed" |
| "abc123DEF456" | "abc123_de_f456" | "abc123_def456" |
| "KEBAB-CASE" | "keba_b-_case" | "kebab-case" |

System.Runtime.Serialization attributes

`System.Runtime.Serialization` attributes such as `DataContractAttribute`, `DataMemberAttribute`, and `IgnoreDataMemberAttribute` let you define a *data contract*. A data contract is a formal agreement between a service and a client that abstractly describes the data to be exchanged. The data contract precisely defines which properties are serialized for exchange.

`System.Text.Json` doesn't have built-in support for these attributes. However, starting in .NET 7, you can use a [custom type resolver](#) to add support. For a sample, see [ZCS.DataContractResolver](#).

Octal numbers

`Newtonsoft.Json` treats numbers with a leading zero as octal numbers. `System.Text.Json` doesn't allow leading zeroes because the [RFC 8259](#) specification doesn't allow them.

Handle missing members

If the JSON that's being deserialized includes properties that are missing in the target type, `Newtonsoft.Json` can be configured to throw exceptions. By default, `System.Text.Json` ignores extra properties in the JSON, except when you use the [\[JsonExtensionData\] attribute](#).

In .NET 8 and later versions, you can set your preference for whether to skip or disallow unmapped JSON properties using one of the following means:

- Apply the `JsonUnmappedMemberHandlingAttribute` attribute to the type you're deserializing to.
- To set your preference globally, set the `JsonSerializerOptions.UnmappedMemberHandling` property. Or, for source generation, set the `JsonSourceGenerationOptionsAttribute.UnmappedMemberHandling` property and apply the attribute to your `JsonSerializerContext` class.
- Customize the `JsonTypeInfo.UnmappedMemberHandling` property.

JsonObjectAttribute

`Newtonsoft.Json` has an attribute, `JsonObjectAttribute`, that can be applied at the *type level* to control which members are serialized, how `null` values are handled, and whether all members are required. `System.Text.Json` has no equivalent attribute that can

be applied on a type. For some behaviors, such as `null` value handling, you can either configure the same behavior on the global `JsonSerializerOptions` or individually on each property.

Consider the following example that uses `Newtonsoft.Json.JsonObjectAttribute` to specify that all `null` properties should be ignored:

```
C#
```

```
[JsonObject(ItemNullValueHandling = NullValueHandling.Ignore)]
public class Person { ... }
```

In `System.Text.Json`, you can set the behavior [for all types and properties](#):

```
C#
```

```
JsonSerializerOptions options = new()
{
    DefaultIgnoreCondition = JsonIgnoreCondition.WhenWritingNull
};

string json = JsonSerializer.Serialize<Person>(person, options);
```

Or you can set the behavior [on each property separately](#):

```
C#
```

```
public class Person
{
    [JsonIgnore(Condition = JsonIgnoreCondition.WhenWritingNull)]
    public string? Name { get; set; }

    [JsonIgnore(Condition = JsonIgnoreCondition.WhenWritingNull)]
    public int? Age { get; set; }
}
```

Next, consider the following example that uses `Newtonsoft.Json.JsonObjectAttribute` to specify that all member properties must be present in the JSON:

```
C#
```

```
[JsonObject(ItemRequired = Required.Always)]
public class Person { ... }
```

You can achieve the same behavior in `System.Text.Json` by adding the C# `required` modifier or the `JsonPropertyAttribute` to *each property*. For more information, see

Required properties.

C#

```
public class Person
{
    [JsonRequired]
    public string? Name { get; set; }

    public required int? Age { get; set; }
}
```

TraceWriter

`Newtonsoft.Json` lets you debug by using a `TraceWriter` to view logs that are generated by serialization or deserialization. `System.Text.Json` doesn't do logging.

JsonDocument and JsonElement compared to JToken (like JObject, JArray)

`System.Text.Json.JsonDocument` provides the ability to parse and build a **read-only** Document Object Model (DOM) from existing JSON payloads. The DOM provides random access to data in a JSON payload. The JSON elements that compose the payload can be accessed via the `JsonElement` type. The `JsonElement` type provides APIs to convert JSON text to common .NET types. `JsonDocument` exposes a `RootElement` property.

Starting in .NET 6, you can parse and build a **mutable** DOM from existing JSON payloads by using the `JsonNode` type and other types in the `System.Text.Json.Nodes` namespace. For more information, see [Use JsonNode](#).

JsonDocument is IDisposable

`JsonDocument` builds an in-memory view of the data into a pooled buffer. Therefore, unlike `JObject` or `JArray` from `Newtonsoft.Json`, the `JsonDocument` type implements `IDisposable` and needs to be used inside a using block. For more information, see [JsonDocument is IDisposable](#).

JsonDocument is read-only

The `System.Text.Json` DOM can't add, remove, or modify JSON elements. It's designed this way for performance and to reduce allocations for parsing common JSON payload sizes (that is, < 1 MB).

JsonElement is a union struct

`JsonDocument` exposes the `RootElement` as a property of type `JsonElement`, which is a union struct type that encompasses any JSON element. `Newtonsoft.Json` uses dedicated hierarchical types like `JObject`, `JArray`, `JToken`, and so forth. `JsonElement` is what you can search and enumerate over, and you can use `JsonElement` to materialize JSON elements into .NET types.

Starting in .NET 6, you can use `JsonNode` type and types in the `System.Text.Json.Nodes` namespace that correspond to `JObject`, `JArray`, and `JToken`. For more information, see [Use JsonNode](#).

How to search a JsonDocument and JsonElement for sub-elements

Searches for JSON tokens using `JObject` or `JArray` from `Newtonsoft.Json` tend to be relatively fast because they're lookups in some dictionary. By comparison, searches on `JsonElement` require a sequential search of the properties and hence are relatively slow (for example when using `TryGetProperty`). `System.Text.Json` is designed to minimize initial parse time rather than lookup time. For more information, see [How to search a JsonDocument and JsonElement for sub-elements](#).

Utf8JsonReader compared to JsonTextReader

`System.Text.Json.Utf8JsonReader` is a high-performance, low allocation, forward-only reader for UTF-8 encoded JSON text, read from a `ReadOnlySpan<byte>` or `ReadOnlySequence<byte>`. The `Utf8JsonReader` is a low-level type that can be used to build custom parsers and deserializers.

Utf8JsonReader is a ref struct

The `JsonTextReader` in `Newtonsoft.Json` is a class. The `Utf8JsonReader` type differs in that it's a *ref struct*. For more information, see [ref struct limitations for Utf8JsonReader](#).

Read null values into nullable value types

`Newtonsoft.Json` provides APIs that return `Nullable<T>`, such as `ReadAsBoolean`, which handles a `Null TokenType` for you by returning a `bool?`. The built-in `System.Text.Json` APIs return only non-nullable value types. For more information, see [Read null values into nullable value types](#).

Multi-targeting

If you need to continue to use `Newtonsoft.Json` for certain target frameworks, you can multi-target and have two implementations. However, this is not trivial and would require some `#ifdefs` and source duplication. One way to share as much code as possible is to create a `ref struct` wrapper around `Utf8JsonReader` and `Newtonsoft.Json.JsonTextReader`. This wrapper would unify the public surface area while isolating the behavioral differences. This lets you isolate the changes mainly to the construction of the type, along with passing the new type around by reference. This is the pattern that the [Microsoft.Extensions.DependencyModel](#) library follows:

- [UnifiedJsonReader.JsonTextReader.cs](#)
- [UnifiedJsonReader.Utf8JsonReader.cs](#)

Utf8JsonWriter compared to JsonTextWriter

`System.Text.Json.Utf8JsonWriter` is a high-performance way to write UTF-8 encoded JSON text from common .NET types like `String`, `Int32`, and `DateTime`. The writer is a low-level type that can be used to build custom serializers.

Write raw values

The `Newtonsoft.Json` `WriteRawValue` method writes raw JSON where a value is expected. `System.Text.Json` has a direct equivalent: `Utf8JsonWriter.WriteRawValue`. For more information, see [Write raw JSON](#).

Customize JSON format

`JsonTextWriter` includes the following settings, for which `Utf8JsonWriter` has no equivalent:

- `Indentation` - Specifies how many characters to indent. `Utf8JsonWriter` always indents by 2 characters.
- `IndentChar` - Specifies the character to use for indentation. `Utf8JsonWriter` always uses whitespace.

- `QuoteChar` ↴ - Specifies the character to use to surround string values.
`Utf8JsonWriter` always uses double quotes.
- `QuoteName` ↴ - Specifies whether or not to surround property names with quotes.
`Utf8JsonWriter` always surrounds them with quotes.

There are no workarounds that would let you customize the JSON produced by `Utf8JsonWriter` in these ways.

Write Timespan, Uri, or char values

`JsonTextWriter` provides `WriteValue` methods for `TimeSpan` ↴, `Uri` ↴, and `char` ↴ values. `Utf8JsonWriter` doesn't have equivalent methods. Instead, format these values as strings (by calling `ToString()`, for example) and call `WriteStringValue`.

Multi-targeting

If you need to continue to use `Newtonsoft.Json` for certain target frameworks, you can multi-target and have two implementations. However, this is not trivial and would require some `#ifdefs` and source duplication. One way to share as much code as possible is to create a wrapper around `Utf8JsonWriter` and `Newtonsoft.JsonTextWriter`. This wrapper would unify the public surface area while isolating the behavioral differences. This lets you isolate the changes mainly to the construction of the type. `Microsoft.Extensions.DependencyModel` ↴ library follows:

- `UnifiedJsonWriter.JsonTextWriter.cs` ↴
- `UnifiedJsonWriter.Utf8JsonWriter.cs` ↴

TypeNameHandling.All not supported

The decision to exclude `TypeNameHandling.All`-equivalent functionality from `System.Text.Json` was intentional. Allowing a JSON payload to specify its own type information is a common source of vulnerabilities in web applications. In particular, configuring `Newtonsoft.Json` with `TypeNameHandling.All` allows the remote client to embed an entire executable application within the JSON payload itself, so that during deserialization the web application extracts and runs the embedded code. For more information, see [Friday the 13th JSON attacks PowerPoint](#) ↴ and [Friday the 13th JSON attacks details](#) ↴.

JSON Path queries not supported

The `JsonDocument` DOM doesn't support querying by using JSON Path[↗].

In a `JsonNode` DOM, each `JsonNode` instance has a `GetPath` method that returns a path to that node. But there is no built-in API to handle queries based on JSON Path query strings.

For more information, see the [dotnet/runtime #31068 GitHub issue[↗]](#).

Some limits not configurable

`System.Text.Json` sets limits that can't be changed for some values, such as the maximum token size in characters (166 MB) and in base 64 (125 MB). For more information, see [JsonConstants in the source code[↗]](#) and GitHub issue [dotnet/runtime #39953[↗]](#).

NaN, Infinity, -Infinity

Newtonsoft parses `NaN`, `Infinity`, and `-Infinity` JSON string tokens. With `System.Text.Json`, use `JsonNumberHandling.AllowNamedFloatingPointLiterals`. For information about how to use this setting, see [Allow or write numbers in quotes](#).

How to instantiate JsonSerializerOptions instances with System.Text.Json

Article • 05/23/2023

This article explains how to avoid performance problems when you use [JsonSerializerOptions](#). It also shows how to use the parameterized constructors that are available.

Reuse JsonSerializerOptions instances

If you use `JsonSerializerOptions` repeatedly with the same options, don't create a new `JsonSerializerOptions` instance each time you use it. Reuse the same instance for every call. This guidance applies to code you write for custom converters and when you call `JsonSerializer.Serialize` or `JsonSerializer.Deserialize`. It's safe to use the same instance across multiple threads. The metadata caches on the options instance are thread-safe, and the instance is immutable after the first serialization or deserialization.

The `JsonSerializerOptions.Default` property

If the instance of `JsonSerializerOptions` that you need to use is the default instance (has all of the default settings and the default converters), use the `JsonSerializerOptions.Default` property rather than creating an options instance. For more information, see [Use default system converter](#).

Copy JsonSerializerOptions

There is a [JsonSerializerOptions constructor](#) that lets you create a new instance with the same options as an existing instance, as shown in the following example:

```
C#  
  
using System.Text.Json;  
  
namespace CopyOptions  
{  
    public class Forecast  
    {  
        public DateTime Date { get; init; }  
        public int TemperatureC { get; set; }  
        public string? Summary { get; set; }  
    };  
}
```

```

public class Program
{
    public static void Main()
    {
        Forecast forecast = new()
        {
            Date = DateTime.Now,
            TemperatureC = 40,
            Summary = "Hot"
        };

        JsonSerializerOptions options = new()
        {
            WriteIndented = true
        };

        JsonSerializerOptions optionsCopy = new(options);
        string forecastJson =
            JsonSerializer.Serialize<Forecast>(forecast, optionsCopy);

        Console.WriteLine($"Output JSON:\n{forecastJson}");
    }
}

// Produces output like the following example:
// 
//Output JSON:
//{
//    "Date": "2020-10-21T15:40:06.8998502-07:00",
//    "TemperatureC": 40,
//    "Summary": "Hot"
//}

```

The metadata cache of the existing `JsonSerializerOptions` instance isn't copied to the new instance. So using this constructor is not the same as reusing an existing instance of `JsonSerializerOptions`.

Web defaults for JsonSerializerOptions

The following options have different defaults for web apps:

- `PropertyNameCaseInsensitive` = `true`
- `JsonNamingPolicy` = `CamelCase`
- `NumberHandling` = `AllowReadingFromString`

The [JsonSerializerOptions constructor](#) lets you create a new instance with the default options that ASP.NET Core uses for web apps, as shown in the following example:

C#

```
using System.Text.Json;

namespace OptionsDefaults
{
    public class Forecast
    {
        public DateTime? Date { get; init; }
        public int TemperatureC { get; set; }
        public string? Summary { get; set; }
    };

    public class Program
    {
        public static void Main()
        {
            Forecast forecast = new()
            {
                Date = DateTime.Now,
                TemperatureC = 40,
                Summary = "Hot"
            };

            JsonSerializerOptions options = new(JsonSerializerDefaults.Web)
            {
                WriteIndented = true
            };

            Console.WriteLine(
                $"PropertyNameCaseInsensitive:
{options.PropertyNameCaseInsensitive}");
            Console.WriteLine(
                $"JsonNamingPolicy: {options.JsonNamingPolicy}");
            Console.WriteLine(
                $"NumberHandling: {options.NumberHandling}");

            string forecastJson = JsonSerializer.Serialize<Forecast>
(forecast, options);
            Console.WriteLine($"Output JSON:\n{forecastJson}");

            Forecast? forecastDeserialized =
                JsonSerializer.Deserialize<Forecast>(forecastJson, options);

            Console.WriteLine($"Date: {forecastDeserialized?.Date}");
            Console.WriteLine($"TemperatureC:
{forecastDeserialized?.TemperatureC}");
            Console.WriteLine($"Summary: {forecastDeserialized?.Summary}");
        }
    }

    // Produces output like the following example:
    //
}
```

```
//PropertyNameCaseInsensitive: True
//JsonNamingPolicy: System.Text.Json.JsonCamelCaseNamingPolicy
//NumberHandling: AllowReadingFromString
//Output JSON:
//{
//  "date": "2020-10-21T15:40:06.9040831-07:00",
//  "temperatureC": 40,
//  "summary": "Hot"
//}
//Date: 10 / 21 / 2020 3:40:06 PM
//TemperatureC: 40
//Summary: Hot
```

How to enable case-insensitive property name matching with System.Text.Json

Article • 05/26/2023

In this article, you will learn how to enable case-insensitive property name matching with the `System.Text.Json` namespace.

Case-insensitive property matching

By default, deserialization looks for case-sensitive property name matches between JSON and the target object properties. To change that behavior, set `JsonSerializerOptions.PropertyNameCaseInsensitive` to `true`:

ⓘ Note

The web default is case-insensitive.

C#

```
var options = new JsonSerializerOptions
{
    PropertyNameCaseInsensitive = true
};
var weatherForecast = JsonSerializer.Deserialize<WeatherForecast>
(jsonString, options);
```

Here's example JSON with camel case property names. It can be deserialized into the following type that has Pascal case property names.

JSON

```
{  
    "date": "2019-08-01T00:00:00-07:00",  
    "temperatureCelsius": 25,  
    "summary": "Hot",  
}
```

C#

```
public class WeatherForecast  
{  
    public DateTimeOffset Date { get; set; }
```

```
public int TemperatureCelsius { get; set; }
public string? Summary { get; set; }
}
```

How to preserve references and handle or ignore circular references in System.Text.Json

Article • 05/26/2023

This article shows how to preserve references and handle or ignore circular references while using System.Text.Json to serialize and deserialize JSON in .NET

Preserve references and handle circular references

To preserve references and handle circular references, set [ReferenceHandler](#) to `Preserve`. This setting causes the following behavior:

- On serialize:

When writing complex types, the serializer also writes metadata properties (`$id`, `$values`, and `$ref`).

- On deserialize:

Metadata is expected (although not mandatory), and the deserializer tries to understand it.

The following code illustrates use of the `Preserve` setting.

C#

```
using System.Text.Json;
using System.Text.Json.Serialization;

namespace PreserveReferences
{
    public class Employee
    {
        public string? Name { get; set; }
        public Employee? Manager { get; set; }
        public List<Employee>? DirectReports { get; set; }
    }

    public class Program
    {
        public static void Main()
```

```
    {
        Employee tyler = new()
        {
            Name = "Tyler Stein"
        };

        Employee adrian = new()
        {
            Name = "Adrian King"
        };

        tyler.DirectReports = new List<Employee> { adrian };
        adrian.Manager = tyler;

        JsonSerializerOptions options = new()
        {
            ReferenceHandler = ReferenceHandler.Preserve,
            WriteIndented = true
        };

        string tylerJson = JsonSerializer.Serialize(tyler, options);
        Console.WriteLine($"Tyler serialized:\n{tylerJson}");

        Employee? tylerDeserialized =
            JsonSerializer.Deserialize<Employee>(tylerJson, options);

        Console.WriteLine(
            "Tyler is manager of Tyler's first direct report: ");
        Console.WriteLine(
            tylerDeserialized?.DirectReports?[0].Manager ==
tylerDeserialized);
    }
}

// Produces output like the following example:
// 
//Tyler serialized:
//{
//  "$id": "1",
//  "Name": "Tyler Stein",
//  "Manager": null,
//  "DirectReports": [
//    {
//      "$id": "2",
//      "$values": [
//        {
//          "$id": "3",
//          "Name": "Adrian King",
//          "Manager": {
//            "$ref": "1"
//          },
//          "DirectReports": null
//        }
//      ]
//    }
//  ]
//}
```

```
//}  
//Tyler is manager of Tyler's first direct report:  
//True
```

This feature can't be used to preserve value types or immutable types. On deserialization, the instance of an immutable type is created after the entire payload is read. So it would be impossible to deserialize the same instance if a reference to it appears within the JSON payload.

For value types, immutable types, and arrays, no reference metadata is serialized. On deserialization, an exception is thrown if `$ref` or `$id` is found. However, value types ignore `$id` (and `$values` in the case of collections) to make it possible to deserialize payloads that were serialized by using Newtonsoft.Json. Newtonsoft.Json does serialize metadata for such types.

To determine if objects are equal, `System.Text.Json` uses [ReferenceEqualityComparer.Instance](#), which uses reference equality (`Object.ReferenceEquals(Object, Object)`) instead of value equality (`Object.Equals(Object)`) when comparing two object instances.

For more information about how references are serialized and deserialized, see [ReferenceHandler.Preserve](#).

The [ReferenceResolver](#) class defines the behavior of preserving references on serialization and deserialization. Create a derived class to specify custom behavior. For an example, see [GuidReferenceResolver](#).

Persist reference metadata across multiple serialization and deserialization calls

By default, reference data is only cached for each call to `Serialize` or `Deserialize`. To persist references from one `Serialize/Deserialize` call to another one, root the `ReferenceResolver` instance in the call site of `Serialize/Deserialize`. The following code shows an example for this scenario:

- You have a list of `Employee` objects and you have to serialize each one individually.
- You want to take advantage of the references saved in the resolver for the `ReferenceHandler`.

Here is the `Employee` class:

C#

```
public class Employee
{
    public string? Name { get; set; }
    public Employee? Manager { get; set; }
    public List<Employee>? DirectReports { get; set; }
}
```

A class that derives from [ReferenceResolver](#) stores the references in a dictionary:

C#

```
class MyReferenceResolver : ReferenceResolver
{
    private uint _referenceCount;
    private readonly Dictionary<string, object> _referenceIdToObjectMap =
    new ();
    private readonly Dictionary<object, string> _objectToReferenceIdMap =
    new (ReferenceEqualityComparer.Instance);

    public override void AddReference(string referenceId, object value)
    {
        if (!_referenceIdToObjectMap.TryAdd(referenceId, value))
        {
            throw new JsonException();
        }
    }

    public override string GetReference(object value, out bool
alreadyExists)
    {
        if (_objectToReferenceIdMap.TryGetValue(value, out string?
referenceId))
        {
            alreadyExists = true;
        }
        else
        {
            _referenceCount++;
            referenceId = _referenceCount.ToString();
            _objectToReferenceIdMap.Add(value, referenceId);
            alreadyExists = false;
        }
    }

    return referenceId;
}

public override object ResolveReference(string referenceId)
{
    if (!_referenceIdToObjectMap.TryGetValue(referenceId, out object?
value))
    {
        throw new JsonException();
    }
}
```

```
        }

        return value;
    }
}
```

A class that derives from [ReferenceHandler](#) holds an instance of [MyReferenceResolver](#) and creates a new instance only when needed (in a method named `Reset` in this example):

C#

```
class MyReferenceHandler : ReferenceHandler
{
    public MyReferenceHandler() => Reset();
    private ReferenceResolver? _rootedResolver;
    public override ReferenceResolver CreateResolver() => _rootedResolver!;
    public void Reset() => _rootedResolver = new MyReferenceResolver();
}
```

When the sample code calls the serializer, it uses a [JsonSerializerOptions](#) instance in which the [ReferenceHandler](#) property is set to an instance of [MyReferenceHandler](#). When you follow this pattern, be sure to reset the [ReferenceResolver](#) dictionary when you're finished serializing, to keep it from growing forever.

C#

```
var options = new JsonSerializerOptions();
options.WriteIndented = true;
var myReferenceHandler = new MyReferenceHandler();
options.ReferenceHandler = myReferenceHandler;

string json;
foreach (Employee emp in employees)
{
    json = JsonSerializer.Serialize(emp, options);
    DoSomething(json);
}

// Reset after serializing to avoid out of bounds memory growth in the
// resolver.
myReferenceHandler.Reset();
```

Ignore circular references

Instead of handling circular references, you can ignore them. To ignore circular references, set [ReferenceHandler](#) to [IgnoreCycles](#). The serializer sets circular reference properties to `null`, as shown in the following example:

C#

```
using System.Text.Json;
using System.Text.Json.Serialization;

namespace SerializeIgnoreCycles
{
    public class Employee
    {
        public string? Name { get; set; }
        public Employee? Manager { get; set; }
        public List<Employee>? DirectReports { get; set; }
    }

    public class Program
    {
        public static void Main()
        {
            Employee tyler = new()
            {
                Name = "Tyler Stein"
            };

            Employee adrian = new()
            {
                Name = "Adrian King"
            };

            tyler.DirectReports = new List<Employee> { adrian };
            adrian.Manager = tyler;

            JsonSerializerOptions options = new()
            {
                ReferenceHandler = ReferenceHandler.IgnoreCycles,
                WriteIndented = true
            };

            string tylerJson = JsonSerializer.Serialize(tyler, options);
            Console.WriteLine($"Tyler serialized:\n{tylerJson}");

            Employee? tylerDeserialized =
                JsonSerializer.Deserialize<Employee>(tylerJson, options);

            Console.WriteLine(
                "Tyler is manager of Tyler's first direct report: ");
            Console.WriteLine(
                tylerDeserialized?.DirectReports?[0]?.Manager ==
            tylerDeserialized);
        }
    }
}
```

```
        }

    // Produces output like the following example:
    //
    //Tyler serialized:
    //{
    //  "Name": "Tyler Stein",
    //  "Manager": null,
    //  "DirectReports": [
    //    {
    //      "Name": "Adrian King",
    //      "Manager": null,
    //      "DirectReports": null
    //    }
    //  ]
    //}
    //Tyler is manager of Tyler's first direct report:
    //False
```

In the preceding example, `Manager` under `Adrian King` is serialized as `null` to avoid the circular reference. This behavior has the following advantages over `ReferenceHandler.Preserve`:

- It decreases payload size.
- It creates JSON that is comprehensible for serializers other than `System.Text.Json` and `Newtonsoft.Json`.

This behavior has the following disadvantages:

- Silent loss of data.
- Data can't make a round trip from JSON back to the source object.

How to serialize properties of derived classes with System.Text.Json

Article • 05/26/2023

In this article, you will learn how to serialize properties of derived classes with the `System.Text.Json` namespace.

Serialize properties of derived classes

Beginning with .NET 7, `System.Text.Json` supports polymorphic type hierarchy serialization and deserialization with attribute annotations.

| Attribute | Description |
|---------------------------------------|--|
| <code>JsonDerivedTypeAttribute</code> | When placed on a type declaration, indicates that the specified subtype should be opted into polymorphic serialization. It also exposes the ability to specify a type discriminator. |
| <code>JsonPolymorphicAttribute</code> | When placed on a type declaration, indicates that the type should be serialized polymorphically. It also exposes various options to configure polymorphic serialization and deserialization for that type. |

For example, suppose you have a `WeatherForecastBase` class and a derived class `WeatherForecastWithCity`:

```
C#  
  
[JsonDerivedType(typeof(WeatherForecastWithCity))]  
public class WeatherForecastBase  
{  
    public DateTimeOffset Date { get; set; }  
    public int TemperatureCelsius { get; set; }  
    public string? Summary { get; set; }  
}
```

```
C#  
  
public class WeatherForecastWithCity : WeatherForecastBase  
{  
    public string? City { get; set; }  
}
```

And suppose the type argument of the `Serialize< TValue >` method at compile time is

`WeatherForecastBase`:

C#

```
options = new JsonSerializerOptions
{
    WriteIndented = true
};
jsonString = JsonSerializer.Serialize<WeatherForecastBase>
(weatherForecastBase, options);
```

In this scenario, the `City` property is serialized because the `weatherForecastBase` object is actually a `WeatherForecastWithCity` object. This configuration enables polymorphic serialization for `WeatherForecastBase`, specifically when the runtime type is

`WeatherForecastWithCity`:

JSON

```
{
    "City": "Milwaukee",
    "Date": "2022-09-26T00:00:00-05:00",
    "TemperatureCelsius": 15,
    "Summary": "Cool"
}
```

While round-tripping of the payload as `WeatherForecastBase` is supported, it won't materialize as a run-time type of `WeatherForecastWithCity`. Instead, it will materialize as a run-time type of `WeatherForecastBase`:

C#

```
WeatherForecastBase value = JsonSerializer.Deserialize<WeatherForecastBase>
(""""
{
    "City": "Milwaukee",
    "Date": "2022-09-26T00:00:00-05:00",
    "TemperatureCelsius": 15,
    "Summary": "Cool"
}
""");
Console.WriteLine(value is WeatherForecastWithCity); // False
```

The following section describes how to add metadata to enable round-tripping of the derived type.

Polymorphic type discriminators

To enable polymorphic deserialization, you must specify a type discriminator for the derived class:

C#

```
[JsonDerivedType(typeof(WeatherForecastBase), typeDiscriminator: "base")]
[JsonDerivedType(typeof(WeatherForecastWithCity), typeDiscriminator:
"withCity")]
public class WeatherForecastBase
{
    public DateTimeOffset Date { get; set; }
    public int TemperatureCelsius { get; set; }
    public string? Summary { get; set; }
}

public class WeatherForecastWithCity : WeatherForecastBase
{
    public string? City { get; set; }
}
```

With the added metadata, specifically, the type discriminator, the serializer can serialize and deserialize the payload as the `WeatherForecastWithCity` type from its base type `WeatherForecastBase`. Serialization will emit JSON along with the type discriminator metadata:

C#

```
WeatherForecastBase weather = new WeatherForecastWithCity
{
    City = "Milwaukee",
    Date = new DateTimeOffset(2022, 9, 26, 0, 0, 0, TimeSpan.FromHours(-5)),
    TemperatureCelsius = 15,
    Summary = "Cool"
}
var json = JsonSerializer.Serialize<WeatherForecastBase>(weather, options);
Console.WriteLine(json);
// Sample output:
// {
//     "$type" : "withCity",
//     "City": "Milwaukee",
//     "Date": "2022-09-26T00:00:00-05:00",
//     "TemperatureCelsius": 15,
//     "Summary": "Cool"
// }
```

With the type discriminator, the serializer can deserialize the payload polymorphically as `WeatherForecastWithCity`:

C#

```
WeatherForecastBase value = JsonSerializer.Deserialize<WeatherForecastBase>(json);
Console.WriteLine(value is WeatherForecastWithCity); // True
```

ⓘ Note

The type discriminator must be placed at the start of the JSON object, grouped together with other metadata properties like `$id` and `$ref`.

VB

```
Dim value As WeatherForecastBase = JsonSerializer.Deserialize(json)
Console.WriteLine(value is WeatherForecastWithCity) // True
```

Mix and match type discriminator formats

Type discriminator identifiers are valid in either `string` or `int` forms, so the following is valid:

C#

```
[JsonDerivedType(typeof(WeatherForecastWithCity), 0)]
[JsonDerivedType(typeof(WeatherForecastWithTimeSeries), 1)]
[JsonDerivedType(typeof(WeatherForecastWithLocalNews), 2)]
public class WeatherForecastBase { }

var json = JsonSerializer.Serialize<WeatherForecastBase>(new
WeatherForecastWithTimeSeries());
Console.WriteLine(json);
// Sample output:
// {
//   "$type" : 1,
//   // Omitted for brevity...
// }
```

While the API supports mixing and matching type discriminator configurations, it's not recommended. The general recommendation is to use either all `string` type discriminators, all `int` type discriminators, or no discriminators at all. The following example shows how to mix and match type discriminator configurations:

C#

```
[JsonDerivedType(typeof(ThreeDimensionalPoint), typeDiscriminator: 3)]
[JsonDerivedType(typeof(FourDimensionalPoint), typeDiscriminator: "4d")]
public class BasePoint
{
    public int X { get; set; }
    public int Y { get; set; }
}

public class ThreeDimensionalPoint : BasePoint
{
    public int Z { get; set; }
}

public sealed class FourDimensionalPoint : ThreeDimensionalPoint
{
    public int W { get; set; }
}
```

In the preceding example, the `BasePoint` type doesn't have a type discriminator, while the `ThreeDimensionalPoint` type has an `int` type discriminator, and the `FourDimensionalPoint` has a `string` type discriminator.

ⓘ Important

For polymorphic serialization to work, the type of the serialized value should be that of the polymorphic base type. This includes using the base type as the generic type parameter when serializing root-level values, as the declared type of serialized properties, or as the collection element in serialized collections.

C#

```
using System.Text.Json;
using System.Text.Json.Serialization;

PerformRoundTrip<BasePoint>();
PerformRoundTrip<ThreeDimensionalPoint>();
PerformRoundTrip<FourDimensionalPoint>();

static void PerformRoundTrip<T>() where T : BasePoint, new()
{
    var json = JsonSerializer.Serialize<BasePoint>(new T());
    Console.WriteLine(json);

    BasePoint? result = JsonSerializer.Deserialize<BasePoint>(json);
    Console.WriteLine($"result is {typeof(T)}; // {result is T}");
    Console.WriteLine();
```

```
}

// Sample output:
// { "X": 541, "Y": 503 }
// result is BasePoint; // True
//
// { "$type": 3, "Z": 399, "X": 835, "Y": 78 }
// result is ThreeDimensionalPoint; // True
//
// { "$type": "4d", "W": 993, "Z": 427, "X": 508, "Y": 741 }
// result is FourDimensionalPoint; // True
```

Customize the type discriminator name

The default property name for the type discriminator is `$type`. To customize the property name, use the [JsonPolymorphicAttribute](#) as shown in the following example:

C#

```
[JsonPolymorphic(TypeDiscriminatorPropertyName = "$discriminator")]
[JsonDerivedType(typeof(ThreeDimensionalPoint), typeDiscriminator: "3d")]
public class BasePoint
{
    public int X { get; set; }
    public int Y { get; set; }
}

public sealed class ThreeDimensionalPoint : BasePoint
{
    public int Z { get; set; }
}
```

In the preceding code, the `JsonPolymorphic` attribute configures the `TypeDiscriminatorPropertyName` to the `"$discriminator"` value. With the type discriminator name configured, the following example shows the `ThreeDimensionalPoint` type serialized as JSON:

C#

```
BasePoint point = new ThreeDimensionalPoint { X = 1, Y = 2, Z = 3 };
var json = JsonSerializer.Serialize<BasePoint>(point);
Console.WriteLine(json);
// Sample output:
// { "$discriminator": "3d", "X": 1, "Y": 2, "Z": 3 }
```

 Tip

Avoid using a `JsonPolymorphicAttribute.TypeDiscriminatorPropertyName` that conflicts with a property in your type hierarchy.

Handle unknown derived types

To handle unknown derived types, you must opt into such support using an annotation on the base type. Consider the following type hierarchy:

C#

```
[JsonDerivedType(typeof(ThreeDimensionalPoint))]
public class BasePoint
{
    public int X { get; set; }
    public int Y { get; set; }
}

public class ThreeDimensionalPoint : BasePoint
{
    public int Z { get; set; }
}

public class FourDimensionalPoint : ThreeDimensionalPoint
{
    public int W { get; set; }
}
```

Since the configuration does not explicitly opt-in support for `FourDimensionalPoint`, attempting to serialize instances of `FourDimensionalPoint` as `BasePoint` will result in a run-time exception:

C#

```
JsonSerializer.Serialize<BasePoint>(new FourDimensionalPoint()); // throws
NotSupportedException
```

You can change the default behavior by using the `JsonUnknownDerivedTypeHandling` enum, which can be specified as follows:

C#

```
[JsonPolymorphic(
    UnknownDerivedTypeHandling =
    JsonUnknownDerivedTypeHandling.FallBackToBaseType)]
[JsonDerivedType(typeof(ThreeDimensionalPoint))]
public class BasePoint
{
```

```

    public int X { get; set; }
    public int Y { get; set; }
}

public class ThreeDimensionalPoint : BasePoint
{
    public int Z { get; set; }
}

public class FourDimensionalPoint : ThreeDimensionalPoint
{
    public int W { get; set; }
}

```

Instead of falling back to the base type, you can use the `FallBackToNearestAncestor` setting to fall back to the contract of the nearest declared derived type:

C#

```

[JsonPolymorphic(
    UnknownDerivedTypeHandling =
    JsonUnknownDerivedTypeHandling.FallBackToNearestAncestor)]
[JsonDerivedType(typeof(BasePoint))]
public interface IPoint { }

public class BasePoint : IPoint { }

public class ThreeDimensionalPoint : BasePoint { }

```

With a configuration like the preceding example, the `ThreeDimensionalPoint` type will be serialized as `BasePoint`:

C#

```

// Serializes using the contract for BasePoint
JsonSerializer.Serialize<IPoint>(new ThreeDimensionalPoint());

```

However, falling back to the nearest ancestor admits the possibility of "diamond" ambiguity. Consider the following type hierarchy as an example:

C#

```

[JsonPolymorphic(
    UnknownDerivedTypeHandling =
    JsonUnknownDerivedTypeHandling.FallBackToNearestAncestor)]
[JsonDerivedType(typeof(BasePoint))]
[JsonDerivedType(typeof(IPointWithTimeSeries))]
public interface IPoint { }

```

```
public interface IPoIntWithTimeSeries : IPoInt { }

public class BasePoInt : IPoInt { }

public class BasePoIntWithTimeSeries : BasePoInt, IPoIntWithTimeSeries { }
```

In this case, the `BasePoIntWithTimeSeries` type could be serialized as either `BasePoInt` or `IPoIntWithTimeSeries` since they are both direct ancestors. This ambiguity will cause the [NotSupportedException](#) to be thrown when attempting to serialize an instance of `BasePoIntWithTimeSeries` as `IPoInt`.

C#

```
// throws NotSupportedException
JsonSerializer.Serialize<IPoInt>(new BasePoIntWithTimeSeries());
```

Configure polymorphism with the contract model

For use cases where attribute annotations are impractical or impossible (such as large domain models, cross-assembly hierarchies, or hierarchies in third-party dependencies), to configure polymorphism use the [contract model](#). The contract model is a set of APIs that can be used to configure polymorphism in a type hierarchy by creating a custom [DefaultJsonTypeInfoResolver](#) subclass that dynamically provides polymorphic configuration per type, as shown in the following example:

C#

```
public class PolymorphicTypeResolver : DefaultJsonTypeInfoResolver
{
    public override JsonTypeInfo GetTypeInfo(Type type,
JsonSerializerOptions options)
    {
        JsonTypeInfo jsonTypeInfo = base.GetTypeInfo(type, options);

        Type basePoIntType = typeof(BasePoInt);
        if (jsonTypeInfo.Type == basePoIntType)
        {
            jsonTypeInfo.PolymorphismOptions = new JsonPolymorphismOptions
            {
                TypeDiscriminatorPropertyName = "$point-type",
                IgnoreUnrecognizedTypeDiscriminators = true,
                UnknownDerivedTypeHandling =
JsonUnknownDerivedTypeHandling.FailSerialization,
                DerivedTypes =
            {

```

```
        new JsonDerivedType(typeof(ThreeDimensionalPoint),  
    "3d"),  
        new JsonDerivedType(typeof(FourDimensionalPoint), "4d")  
    }  
};  
  
return jsonTypeInfo;  
}  
}
```

Additional polymorphic serialization details

- Polymorphic serialization supports derived types that have been explicitly opted in via the [JsonDerivedTypeAttribute](#). Undeclared types will result in a run-time exception. The behavior can be changed by configuring the [JsonPolymorphicAttribute.UnknownDerivedTypeHandling](#) property.
- Polymorphic configuration specified in derived types is not inherited by polymorphic configuration in base types. The base type must be configured independently.
- Polymorphic hierarchies are supported for both `interface` and `class` types.
- Polymorphism using type discriminators is only supported for type hierarchies that use the default converters for objects, collections, and dictionary types.
- Polymorphism is supported in metadata-based source generation, but not fast-path source generation.

How to use a JSON document object model in System.Text.Json

Article • 05/26/2023

This article shows how to use a [JSON document object model \(DOM\)](#) for random access to data in a JSON payload.

JSON DOM choices

Working with a DOM is an alternative to deserialization with [JsonSerializer](#) when:

- You don't have a type to deserialize into.
- The JSON you receive doesn't have a fixed schema and must be inspected to know what it contains.

`System.Text.Json` provides two ways to build a JSON DOM:

- [JsonDocument](#) provides the ability to build a read-only DOM by using `Utf8JsonReader`. The JSON elements that compose the payload can be accessed via the [JsonElement](#) type. The `JsonElement` type provides array and object enumerators along with APIs to convert JSON text to common .NET types. `JsonDocument` exposes a [RootElement](#) property. For more information, see [Use JsonDocument](#) later in this article.
- [JsonNode](#) and the classes that derive from it in the [System.Text.Json.Nodes](#) namespace provide the ability to create a mutable DOM. The JSON elements that compose the payload can be accessed via the [JsonNode](#), [JsonObject](#), [JsonArray](#), [JsonValue](#), and [JsonElement](#) types. For more information, see [Use JsonNode](#) later in this article.

Consider the following factors when choosing between `JsonDocument` and `JsonNode`:

- The `JsonNode` DOM can be changed after it's created. The `JsonDocument` DOM is immutable.
- The `JsonDocument` DOM provides faster access to its data.

Use `JsonNode`

The following example shows how to use `JsonNode` and the other types in the [System.Text.Json.Nodes](#) namespace to:

- Create a DOM from a JSON string
- Write JSON from a DOM.
- Get a value, object, or array from a DOM.

C#

```
using System.Text.Json;
using System.Text.Json.Nodes;

namespace JsonNodeFromStringExample;

public class Program
{
    public static void Main()
    {
        string jsonString =
@"{
    ""Date"": ""2019-08-01T00:00:00"",
    ""Temperature"": 25,
    ""Summary"": ""Hot"",
    ""DatesAvailable"": [
        ""2019-08-01T00:00:00"",
        ""2019-08-02T00:00:00""
    ],
    ""TemperatureRanges"": {
        ""Cold"": {
            ""High"": 20,
            ""Low"": -10
        },
        ""Hot"": {
            ""High"": 60,
            ""Low"": 20
        }
    }
};

// Create a JsonNode DOM from a JSON string.
JsonNode forecastNode = JsonNode.Parse(jsonString);

// Write JSON from a JsonNode
var options = new JsonSerializerOptions { WriteIndented = true };
Console.WriteLine(forecastNode!.ToString(options));
// output:
//{
//    "Date": "2019-08-01T00:00:00",
//    "Temperature": 25,
//    "Summary": "Hot",
//    "DatesAvailable": [
//        "2019-08-01T00:00:00",
//        "2019-08-02T00:00:00"
//    ],
//    "TemperatureRanges": {
//        "Cold": {
//            "High": 20,
//            "Low": -10
//        },
//        "Hot": {
//            "High": 60,
//            "Low": 20
//        }
//    }
}
```

```

        //      "High": 20,
        //      "Low": -10
        //    },
        //    "Hot": {
        //      "High": 60,
        //      "Low": 20
        //    }
        //}
      }

      // Get value from a JsonNode.
JsonNode temperatureNode = forecastNode!["Temperature"]!;
Console.WriteLine($"Type={temperatureNode.GetType()}");
Console.WriteLine($"JSON={temperatureNode.ToString()}");
//output:
//Type =
System.Text.Json.Nodes.JsonValue`1[System.Text.Json.JsonElement]
//JSON = 25

      // Get a typed value from a JsonNode.
int temperatureInt = (int)forecastNode!["Temperature"]!;
Console.WriteLine($"Value={temperatureInt}");
//output:
//Value=25

      // Get a typed value from a JsonNode by using GetValue<T>.
temperatureInt = forecastNode!["Temperature"]!.GetValue<int>();
Console.WriteLine($"TemperatureInt={temperatureInt}");
//output:
//Value=25

      // Get a JSON object from a JsonNode.
JsonNode temperatureRanges = forecastNode!["TemperatureRanges"]!;
Console.WriteLine($"Type={temperatureRanges.GetType()}");
Console.WriteLine($"JSON={temperatureRanges.ToString()}");
//output:
//Type = System.Text.Json.Nodes.JsonObject
//JSON = { "Cold":{ "High":20,"Low":-10}, "Hot":{ "High":60,"Low":20}
}

      // Get a JSON array from a JsonNode.
JsonNode datesAvailable = forecastNode!["DatesAvailable"]!;
Console.WriteLine($"Type={datesAvailable.GetType()}");
Console.WriteLine($"JSON={datesAvailable.ToString()}");
//output:
//datesAvailable Type = System.Text.Json.Nodes.JsonArray
//datesAvailable JSON =[{"2019-08-01T00:00:00", "2019-08-
02T00:00:00"}]

      // Get an array element value from a JSONArray.
JsonNode firstDateAvailable = datesAvailable[0]!;
Console.WriteLine($"Type={firstDateAvailable.GetType()}");
Console.WriteLine($"JSON={firstDateAvailable.ToString()}");
//output:
//Type =

```

```

System.Text.Json.Nodes.JsonValue`1[System.Text.Json.JsonElement]
//JSON = "2019-08-01T00:00:00"

    // Get a typed value by chaining references.
    int coldHighTemperature = (int)forecastNode["TemperatureRanges"]![
    ["Cold"]![["High"]!];
        Console.WriteLine($"TemperatureRanges.Cold.High={coldHighTemperature}");
        //output:
        //TemperatureRanges.Cold.High = 20

        // Parse a JSON array
        var datesNode = JsonNode.Parse(@"[\"2019-08-01T00:00:00\", \"2019-08-
02T00:00:00\"]");
        JsonNode firstDate = datesNode![0]!.GetValue<DateTime>();
        Console.WriteLine($"firstDate={ firstDate}");
        //output:
        //firstDate = "2019-08-01T00:00:00"
    }
}

```

Create a JsonNode DOM with object initializers and make changes

The following example shows how to:

- Create a DOM by using object initializers.
- Make changes to a DOM.

C#

```

using System.Text.Json;
using System.Text.Json.Nodes;

namespace JsonNodeFromObjectExample;

public class Program
{
    public static void Main()
    {
        // Create a new JsonObject using object initializers.
        var forecastObject = new JsonObject
        {
            ["Date"] = new DateTime(2019, 8, 1),
            ["Temperature"] = 25,
            ["Summary"] = "Hot",
            ["DatesAvailable"] = new JsonArray(
                new DateTime(2019, 8, 1), new DateTime(2019, 8, 2)),
            ["TemperatureRanges"] = new JsonObject
            {
                ["Cold"] = new JsonObject

```

```

        [
            ["High"] = 20,
            ["Low"] = -10
        }
    },
    ["SummaryWords"] = new JsonArray("Cool", "Windy", "Humid")
};

// Add an object.
forecastObject!["TemperatureRanges"]!["Hot"] =
    new JsonObject { ["High"] = 60, ["Low"] = 20 };

// Remove a property.
forecastObject.Remove("SummaryWords");

// Change the value of a property.
forecastObject["Date"] = new DateTime(2019, 8, 3);

var options = new JsonSerializerOptions { WriteIndented = true };
Console.WriteLine(forecastObject.ToString(options));
//output:
//{
//    "Date": "2019-08-03T00:00:00",
//    "Temperature": 25,
//    "Summary": "Hot",
//    "DatesAvailable": [
//        "2019-08-01T00:00:00",
//        "2019-08-02T00:00:00"
//    ],
//    "TemperatureRanges": {
//        "Cold": {
//            "High": 20,
//            "Low": -10
//        },
//        "Hot": {
//            "High": 60,
//            "Low": 20
//        }
//    }
//}
}
}

```

Deserialize subsections of a JSON payload

The following example shows how to use [JsonNode](#) to navigate to a subsection of a JSON tree and deserialize a single value, a custom type, or an array from that subsection.

```
using System.Text.Json;
using System.Text.Json.Nodes;

namespace JsonNodePOCOExample;

public class TemperatureRanges : Dictionary<string, HighLowTemps>
{
}

public class HighLowTemps
{
    public int High { get; set; }
    public int Low { get; set; }
}

public class Program
{
    public static DateTime[]? DatesAvailable { get; set; }

    public static void Main()
    {
        string jsonString =
@"{
    ""Date"": ""2019-08-01T00:00:00"",
    ""Temperature"": 25,
    ""Summary"": ""Hot"",
    ""DatesAvailable"": [
        ""2019-08-01T00:00:00"",
        ""2019-08-02T00:00:00""
    ],
    ""TemperatureRanges"": {
        ""Cold"": {
            ""High"": 20,
            ""Low"": -10
        },
        ""Hot"": {
            ""High"": 60,
            ""Low"": 20
        }
    }
};";
        // Parse all of the JSON.
        JsonNode forecastNode = JsonNode.Parse(jsonString)!;

        // Get a single value
        int hotHigh = forecastNode["TemperatureRanges"]!["Hot"]!
            ["High"]!.GetValue<int>();
        Console.WriteLine($"Hot.High={hotHigh}");
        // output:
        //Hot.High=60

        // Get a subsection and deserialize it into a custom type.
        JsonObject temperatureRangesObject = forecastNode!
```

```

["TemperatureRanges"]!.AsObject();
    using var stream = new MemoryStream();
    using var writer = new Utf8JsonWriter(stream);
    temperatureRangesObject.WriteTo(writer);
    writer.Flush();
    TemperatureRanges? temperatureRanges =
        JsonSerializer.Deserialize<TemperatureRanges>(stream.ToArray());
    Console.WriteLine($"Cold.Low={temperatureRanges!["Cold"].Low},
Hot.High={temperatureRanges["Hot"].High}");
    // output:
    //Cold.Low=-10, Hot.High=60

    // Get a subsection and deserialize it into an array.
    JSONArray datesAvailable = forecastNode!
    ["DatesAvailable"]!.AsArray()!;
    Console.WriteLine($"DatesAvailable[0]={datesAvailable[0]}");
    // output:
    //DatesAvailable[0]=8/1/2019 12:00:00 AM
}
}

```

JsonNode average grade example

The following example selects a JSON array that has integer values and calculates an average value:

C#

```

using System.Text.Json.Nodes;

namespace JsonNodeAverageGradeExample;

public class Program
{
    public static void Main()
    {
        string jsonString =
@"
{
    ""Class Name"": ""Science"",
    ""Teacher\u0027s Name"": ""Jane"",
    ""Semester"": ""2019-01-01"",
    ""Students"": [
        {
            ""Name"": ""John"",
            ""Grade"": 94.3
        },
        {
            ""Name"": ""James"",
            ""Grade"": 81.0
        },
        {
            ""Name"": ""Julia"",

```

```

        """Grade"": 91.9
    },
    {
        """Name"": """",
        """Grade"": 72.4
    },
    {
        """Name"": """Johnathan"""
    }
],
"""Final"": true
}
";
    double sum = 0;
    int count = 0;

    JsonNode document = JsonNode.Parse(jsonString)!;

    JsonNode root = document.Root;
    JsonArray studentsArray = root["Students"]!.AsArray();

    count = studentsArray.Count;

    foreach (JsonNode? student in studentsArray)
    {
        if (student?["Grade"] is JsonNode gradeNode)
        {
            sum += (double)gradeNode;
        }
        else
        {
            sum += 70;
        }
    }

    double average = sum / count;
    Console.WriteLine( $"Average grade : {average}");
}
}
// output:
//Average grade : 81.92

```

The preceding code:

- Calculates an average grade for objects in a `Students` array that have a `Grade` property.
- Assigns a default grade of 70 for students who don't have a grade.
- Gets the number of students from the `Count` property of `JsonArray`.

`JsonNode` with `JsonSerializerOptions`

You can use `JsonSerializer` to serialize and deserialize an instance of `JsonNode`. However, if you use an overload that takes `JsonSerializerOptions`, the options instance is only used to get custom converters. Other features of the options instance are not used. For example, if you set `JsonSerializerOptions.DefaultIgnoreCondition` to `WhenWritingNull` and call `JsonSerializer` with an overload that takes `JsonSerializerOptions`, null properties won't be ignored.

The same limitation applies to the `JsonNode` methods that take a `JsonSerializerOptions` parameter: `WriteTo(Utf8JsonWriter, JsonSerializerOptions)` and `ToJsonObject(JsonSerializerOptions)`. These APIs use `JsonSerializerOptions` only to get custom converters.

The following example illustrates the result of using methods that take a `JsonSerializerOptions` parameter and serialize a `JsonNode` instance:

C#

```
using System.Text;
using System.Text.Json;
using System.Text.Json.Nodes;
using System.Text.Json.Serialization;

namespace JsonNodeWithJsonSerializerOptions;

public class Program
{
    public static void Main()
    {
        Person person = new Person { Name = "Nancy" };

        // Default serialization - Address property included with null
        // token.
        // Output: {"Name":"Nancy","Address":null}
        string personJsonWithNull = JsonSerializer.Serialize(person);
        Console.WriteLine(personJsonWithNull);

        // Serialize and ignore null properties - null Address property is
        // omitted
        // Output: {"Name":"Nancy"}
        JsonSerializerOptions options = new()
        {
            DefaultIgnoreCondition = JsonIgnoreCondition.WhenWritingNull
        };
        string personJsonWithoutNull = JsonSerializer.Serialize(person,
options);
        Console.WriteLine(personJsonWithoutNull);

        // Ignore null properties doesn't work when serializing JsonNode
        // instance
        // by using JsonSerializer.
```

```

        // Output: {"Name":"Nancy", "Address":null}
        var personJsonNode = JsonSerializer.Deserialize<JsonNode>
(personJsonWithNull);
        personJsonWithNull = JsonSerializer.Serialize(personJsonNode,
options);
        Console.WriteLine(personJsonWithNull);

        // Ignore null properties doesn't work when serializing JsonNode
instance
        // by using JsonNode.ToString method.
        // Output: {"Name":"Nancy", "Address":null}
        personJsonWithNull = personJsonNode!.ToString(options);
        Console.WriteLine(personJsonWithNull);

        // Ignore null properties doesn't work when serializing JsonNode
instance
        // by using JsonNode.WriteTo method.
        // Output: {"Name":"Nancy", "Address":null}
        using var stream = new MemoryStream();
        using var writer = new Utf8JsonWriter(stream);
        personJsonNode!.WriteTo(writer, options);
        writer.Flush();
        personJsonWithNull = Encoding.UTF8.GetString(stream.ToArray());
        Console.WriteLine(personJsonWithNull);
    }
}

public class Person
{
    public string? Name { get; set; }
    public string? Address { get; set; }
}

```

If you need features of `JsonSerializerOptions` other than custom converters, use `JsonSerializer` with strongly typed targets (such as the `Person` class in this example) rather than `JsonNode`.

Use `JsonDocument`

The following example shows how to use the `JsonDocument` class for random access to data in a JSON string:

C#

```

double sum = 0;
int count = 0;

using (JsonDocument document = JsonDocument.Parse(jsonString))
{
    JsonElement root = document.RootElement;
    JsonElement studentsElement = root.GetProperty("Students");

```

```

foreach (JsonElement student in studentsElement.EnumerateArray())
{
    if (student.TryGetProperty("Grade", out JsonElement gradeElement))
    {
        sum += gradeElement.GetDouble();
    }
    else
    {
        sum += 70;
    }
    count++;
}

double average = sum / count;
Console.WriteLine($"Average grade : {average}");

```

The preceding code:

- Assumes the JSON to analyze is in a string named `jsonString`.
- Calculates an average grade for objects in a `students` array that have a `Grade` property.
- Assigns a default grade of 70 for students who don't have a grade.
- Creates the `JsonDocument` instance in a `using statement` because `JsonDocument` implements `IDisposable`. After a `JsonDocument` instance is disposed, you lose access to all of its `JsonElement` instances also. To retain access to a `JsonElement` instance, make a copy of it before the parent `JsonDocument` instance is disposed. To make a copy, call `JsonElement.Clone`. For more information, see [JsonDocument is IDisposable](#).

The preceding example code counts students by incrementing a `count` variable with each iteration. An alternative is to call `GetArrayLength`, as shown in the following example:

C#

```

double sum = 0;
int count = 0;

using (JsonDocument document = JsonDocument.Parse(jsonString))
{
    JsonElement root = document.RootElement;
    JsonElement studentsElement = root.GetProperty("Students");

    count = studentsElement.GetArrayLength();

    foreach (JsonElement student in studentsElement.EnumerateArray())
    {

```

```
        if (student.TryGetProperty("Grade", out JsonElement gradeElement))
    {
        sum += gradeElement.GetDouble();
    }
    else
    {
        sum += 70;
    }
}

double average = sum / count;
Console.WriteLine($"Average grade : {average}");
```

Here's an example of the JSON that this code processes:

JSON

```
{
    "Class Name": "Science",
    "Teacher\u0027s Name": "Jane",
    "Semester": "2019-01-01",
    "Students": [
        {
            "Name": "John",
            "Grade": 94.3
        },
        {
            "Name": "James",
            "Grade": 81.0
        },
        {
            "Name": "Julia",
            "Grade": 91.9
        },
        {
            "Name": "Jessica",
            "Grade": 72.4
        },
        {
            "Name": "Johnathan"
        }
    ],
    "Final": true
}
```

For a similar example that uses `JsonNode` instead of `JsonDocument`, see [JsonNode average grade example](#).

How to search a `JsonDocument` and `JsonElement` for sub-elements

Searches on `JsonElement` require a sequential search of the properties and hence are relatively slow (for example when using `TryGetProperty`). `System.Text.Json` is designed to minimize initial parse time rather than lookup time. Therefore, use the following approaches to optimize performance when searching through a `JsonDocument` object:

- Use the built-in enumerators (`EnumerateArray` and `EnumerateObject`) rather than doing your own indexing or loops.
- Don't do a sequential search on the whole `JsonDocument` through every property by using `RootElement`. Instead, search on nested JSON objects based on the known structure of the JSON data. For example, the preceding code examples look for a `Grade` property in `Student` objects by looping through the `Student` objects and getting the value of `Grade` for each, rather than searching through all `JsonElement` objects looking for `Grade` properties. Doing the latter would result in unnecessary passes over the same data.

Use `JsonDocument` to write JSON

The following example shows how to write JSON from a `JsonDocument`:

C#

```
string jsonString = File.ReadAllText(inputFileName);

var writerOptions = new JsonWriterOptions
{
    Indented = true
};

var documentOptions = new JsonDocumentOptions
{
    CommentHandling = JsonCommentHandling.Skip
};

using FileStream fs = File.Create(outputFileName);
using var writer = new Utf8JsonWriter(fs, options: writerOptions);
using JsonDocument document = JsonDocument.Parse(jsonString,
documentOptions);

JsonElement root = document.RootElement;

if (root.ValueKind == JsonValueKind.Object)
{
    writer.WriteStartObject();
```

```

    }

    else
    {
        return;
    }

    foreach (JsonProperty property in root.EnumerateObject())
    {
        property.WriteTo(writer);
    }

    writer.WriteEndObject();

    writer.Flush();

```

The preceding code:

- Reads a JSON file, loads the data into a `JsonDocument`, and writes formatted (pretty-printed) JSON to a file.
- Uses `JsonDocumentOptions` to specify that comments in the input JSON are allowed but ignored.
- When finished, calls `Flush` on the writer. An alternative is to let the writer auto-flush when it's disposed.

Here's an example of JSON input to be processed by the example code:

JSON

```
{"Class Name": "Science", "Teacher's Name": "Jane", "Semester": "2019-01-01", "Students": [{"Name": "John", "Grade": 94.3}, {"Name": "James", "Grade": 81.0}, {"Name": "Julia", "Grade": 91.9}, {"Name": "Jessica", "Grade": 72.4}, {"Name": "Johnathan"}], "Final": true}
```

The result is the following pretty-printed JSON output:

JSON

```
{
    "Class Name": "Science",
    "Teacher\u0027s Name": "Jane",
    "Semester": "2019-01-01",
    "Students": [
        {
            "Name": "John",
            "Grade": 94.3
        },
        {
            "Name": "James",
            "Grade": 81.0
        }
    ]
}
```

```
        },
        {
            "Name": "Julia",
            "Grade": 91.9
        },
        {
            "Name": "Jessica",
            "Grade": 72.4
        },
        {
            "Name": "Johnathan"
        }
    ],
    "Final": true
}
```

JsonDocument is IDisposable

`JsonDocument` builds an in-memory view of the data into a pooled buffer. Therefore the `JsonDocument` type implements `IDisposable` and needs to be used inside a `using` block.

Only return a `JsonDocument` from your API if you want to transfer lifetime ownership and dispose responsibility to the caller. In most scenarios, that isn't necessary. If the caller needs to work with the entire JSON document, return the `Clone` of the `RootElement`, which is a `JsonElement`. If the caller needs to work with a particular element within the JSON document, return the `Clone` of that `JsonElement`. If you return the `RootElement` or a sub-element directly without making a `clone`, the caller won't be able to access the returned `JsonElement` after the `JsonDocument` that owns it is disposed.

Here's an example that requires you to make a `Clone`:

C#

```
public JsonElement LookAndFeel(JsonElement source)
{
    string json =
File.ReadAllText(source.GetProperty("fileName").GetString());

    using (JsonDocument doc = JsonDocument.Parse(json))
    {
        return doc.RootElement.Clone();
    }
}
```

The preceding code expects a `JsonElement` that contains a `fileName` property. It opens the JSON file and creates a `JsonDocument`. The method assumes that the caller wants to

work with the entire document, so it returns the `Clone` of the `RootElement`.

If you receive a `JsonElement` and are returning a sub-element, it's not necessary to return a `Clone` of the sub-element. The caller is responsible for keeping alive the `JsonDocument` that the passed-in `JsonElement` belongs to. For example:

C#

```
public JsonElement ReturnFileName(JsonElement source)
{
    return source.GetProperty("fileName");
}
```

JsonDocument with JsonSerializerOptions

You can use `JsonSerializer` to serialize and deserialize an instance of `JsonDocument`. However, the implementation for reading and writing `JsonDocument` instances by using `JsonSerializer` is a wrapper over the `JsonDocument.ParseValue(Utf8JsonReader)` and `JsonDocument.WriteTo(Utf8JsonWriter)`. This wrapper does not forward any `JsonSerializerOptions` (serializer features) to `Utf8JsonReader` or `Utf8JsonWriter`. For example, if you set `JsonSerializerOptions.DefaultIgnoreCondition` to `WhenWritingNull` and call `JsonSerializer` with an overload that takes `JsonSerializerOptions`, null properties won't be ignored.

The following example illustrates the result of using methods that take a `JsonSerializerOptions` parameter and serialize a `JsonDocument` instance:

C#

```
using System.Text;
using System.Text.Json;
using System.Text.Json.Nodes;
using System.Text.Json.Serialization;

namespace JsonDocumentWithJsonSerializerOptions;

public class Program
{
    public static void Main()
    {
        Person person = new Person { Name = "Nancy" };

        // Default serialization - Address property included with null token.
        // Output: {"Name":"Nancy","Address":null}
        string personJsonWithNull = JsonSerializer.Serialize(person);
```

```

        Console.WriteLine(personJsonWithNull);

        // Serialize and ignore null properties - null Address property is
omitted
        // Output: {"Name":"Nancy"}
        JsonSerializerOptions options = new()
        {
            DefaultIgnoreCondition = JsonIgnoreCondition.WhenWritingNull
        };
        string personJsonWithoutNull = JsonSerializer.Serialize(person,
options);
        Console.WriteLine(personJsonWithoutNull);

        // Ignore null properties doesn't work when serializing JsonDocument
instance
        // by using JsonSerializer.
        // Output: {"Name":"Nancy","Address":null}
        var personJsonDocument = JsonSerializer.Deserialize<JsonDocument>
(personJsonWithNull);
        personJsonWithNull = JsonSerializer.Serialize(personJsonDocument,
options);
        Console.WriteLine(personJsonWithNull);
    }
}

public class Person
{
    public string? Name { get; set; }

    public string? Address { get; set; }
}

```

If you need features of `JsonSerializerOptions`, use `JsonSerializer` with strongly typed targets (such as the `Person` class in this example) rather than `JsonDocument`.

How to use Utf8JsonWriter in System.Text.Json

Article • 05/26/2023

This article shows how to use the [Utf8JsonWriter](#) type for building custom serializers.

[Utf8JsonWriter](#) is a high-performance way to write UTF-8 encoded JSON text from common .NET types like `String`, `Int32`, and `DateTime`. The writer is a low-level type that can be used to build custom serializers. The [JsonSerializer.Serialize](#) method uses `Utf8JsonWriter` under the covers.

The following example shows how to use the [Utf8JsonWriter](#) class:

C#

```
var options = new JsonWriterOptions
{
    Indented = true
};

using var stream = new MemoryStream();
using var writer = new Utf8JsonWriter(stream, options);

writer.WriteStartObject();
writer.WriteString("date", DateTimeOffset.UtcNow);
writer.WriteNumber("temp", 42);
writer.WriteEndObject();
writer.Flush();

string json = Encoding.UTF8.GetString(stream.ToArray());
Console.WriteLine(json);
```

Write with UTF-8 text

To achieve the best possible performance while using the `Utf8JsonWriter`, write JSON payloads already encoded as UTF-8 text rather than as UTF-16 strings. Use [JsonEncodedText](#) to cache and pre-encode known string property names and values as statics, and pass those to the writer, rather than using UTF-16 string literals. This is faster than caching and using UTF-8 byte arrays.

This approach also works if you need to do custom escaping. `System.Text.Json` doesn't let you disable escaping while writing a string. However, you could pass in your own custom [JavaScriptEncoder](#) as an option to the writer, or create your own

`JsonEncodedText` that uses your `JavascriptEncoder` to do the escaping, and then write the `JsonEncodedText` instead of the string. For more information, see [Customize character encoding](#).

Write raw JSON

In some scenarios, you might want to write "raw" JSON to a JSON payload that you're creating with `Utf8JsonWriter`. You can use `Utf8JsonWriter.WriteRawValue` to do that. Here are typical scenarios:

- You have an existing JSON payload that you want to enclose in new JSON.
- You want to format values differently from the default `Utf8JsonWriter` formatting.

For example, you might want to customize number formatting. By default, `System.Text.Json` omits the decimal point for whole numbers, writing `1` rather than `1.0`, for example. The rationale is that writing fewer bytes is good for performance. But suppose the consumer of your JSON treats numbers with decimals as doubles, and numbers without decimals as integers. You might want to ensure that the numbers in an array are all recognized as doubles, by writing a decimal point and zero for whole numbers. The following example shows how to do that:

C#

```
using System.Text;
using System.Text.Json;

namespace WriteRawJson;

public class Program
{
    public static void Main()
    {
        JsonWriterOptions writerOptions = new() { Indented = true, };

        using MemoryStream stream = new();
        using Utf8JsonWriter writer = new(stream, writerOptions);

        writer.WriteStartObject();

        writer.WriteStartArray("defaultJsonFormatting");
        foreach (double number in new double[] { 50.4, 51 })
        {
            writer.WriteStartObject();
            writer.WritePropertyName("value");
            writer.WriteNumberValue(number);
            writer.WriteEndObject();
        }
    }
}
```

```

        }

        writer.WriteEndArray();

        writer.WriteStartArray("customJsonFormatting");
        foreach (double result in new double[] { 50.4, 51 })
        {
            writer.WriteStartObject();
            writer.WritePropertyName("value");
            writer.WriteRawValue(
                FormatNumberValue(result), skipInputValidation: true);
            writer.WriteEndObject();
        }
        writer.WriteEndArray();

        writer.WriteEndObject();
        writer.Flush();

        string json = Encoding.UTF8.GetString(stream.ToArray());
        Console.WriteLine(json);
    }
    static string FormatNumberValue(double numberValue)
    {
        return numberValue == Convert.ToInt32(numberValue) ?
            numberValue.ToString() + ".0" : numberValue.ToString();
    }
}

// output:
//{
//  "defaultJsonFormatting": [
//    {
//      "value": 50.4
//    },
//    {
//      "value": 51
//    }
//  ],
//  "customJsonFormatting": [
//    {
//      "value": 50.4
//    },
//    {
//      "value": 51.0
//    }
//  ]
//}

```

Customize character escaping

The [StringEscapeHandling](#) setting of `JsonTextWriter` offers options to escape all non-ASCII characters or HTML characters. By default, `Utf8JsonWriter` escapes all non-ASCII and HTML characters. This escaping is done for defense-in-depth security reasons. To

specify a different escaping policy, create a `JavaScriptEncoder` and set `JsonWriterOptions.Encoder`. For more information, see [Customize character encoding](#).

Write null values

To write null values by using `Utf8JsonWriter`, call:

- `WriteNull` to write a key-value pair with null as the value.
- `WriteNullValue` to write null as an element of a JSON array.

For a string property, if the string is null, `WriteString` and `WriteStringValue` are equivalent to `WriteNull` and `WriteNullValue`.

Write Timespan, Uri, or char values

To write `Timespan`, `Uri`, or `char` values, format them as strings (by calling `ToString()`, for example) and call `WriteStringValue`.

How to use Utf8JsonReader in System.Text.Json

Article • 06/21/2023

This article shows how you can use the [Utf8JsonReader](#) type for building custom parsers and deserializers.

[Utf8JsonReader](#) is a high-performance, low allocation, forward-only reader for UTF-8 encoded JSON text, read from a `ReadOnlySpan<byte>` or `ReadOnlySequence<byte>`. The [Utf8JsonReader](#) is a low-level type that can be used to build custom parsers and deserializers. The [JsonSerializer.Deserialize](#) methods use [Utf8JsonReader](#) under the covers.

`Utf8JsonReader` can't be used directly from Visual Basic code. For more information, see [Visual Basic support](#).

The following example shows how to use the [Utf8JsonReader](#) class:

C#

```
var options = new JsonReaderOptions
{
    AllowTrailingCommas = true,
    CommentHandling = JsonCommentHandling.Skip
};
var reader = new Utf8JsonReader(jsonUtf8Bytes, options);

while (reader.Read())
{
    Console.Write(reader.TokenType);

    switch (reader.TokenType)
    {
        case JsonTokenType.PropertyName:
        case JsonTokenType.String:
            {
                string? text = reader.GetString();
                Console.Write(" ");
                Console.Write(text);
                break;
            }

        case JsonTokenType.Number:
            {
                int intValue = reader.GetInt32();
                Console.Write(" ");
            }
    }
}
```

```

        Console.WriteLine(intValue);
        break;
    }

    // Other token types elided for brevity
}
Console.WriteLine();
}

```

The preceding code assumes that the `jsonUtf8` variable is a byte array that contains valid JSON, encoded as UTF-8.

Filter data using `Utf8JsonReader`

The following example shows how to synchronously read a file and search for a value.

C#

```

using System.Text;
using System.Text.Json;

namespace SystemTextJsonSamples
{
    public class Utf8ReaderFromFile
    {
        private static readonly byte[] s_nameUtf8 =
Encoding.UTF8.GetBytes("name");
        private static ReadOnlySpan<byte> Utf8Bom => new byte[] { 0xEF,
0xBB, 0xBF };

        public static void Run()
        {
            // ReadAllBytes if the file encoding is UTF-8:
            string fileName = "UniversitiesUtf8.json";
            ReadOnlySpan<byte> jsonReadOnlySpan =
File.ReadAllBytes(fileName);

            // Read past the UTF-8 BOM bytes if a BOM exists.
            if (jsonReadOnlySpan.StartsWith(Utf8Bom))
            {
                jsonReadOnlySpan = jsonReadOnlySpan.Slice(Utf8Bom.Length);
            }

            // Or read as UTF-16 and transcode to UTF-8 to convert to a
ReadOnlySpan<byte>
            //string fileName = "Universities.json";
            //string jsonString = File.ReadAllText(fileName);
            //ReadOnlySpan<byte> jsonReadOnlySpan =
Encoding.UTF8.GetBytes(jsonString);

            int count = 0;

```

```

int total = 0;

var reader = new Utf8JsonReader(jsonReadOnlySpan);

while (reader.Read())
{
    JsonTokenType tokenType = reader.TokenType;

    switch (tokenType)
    {
        case JsonTokenType.StartObject:
            total++;
            break;
        case JsonTokenType.PropertyName:
            if (reader.ValueTextEquals(s_nameUtf8))
            {
                // Assume valid JSON, known schema
                reader.Read();
                if (reader.GetString()!.EndsWith("University"))
                {
                    count++;
                }
            }
            break;
    }
}

Console.WriteLine($"{count} out of {total} have names that end
with 'University'");
}
}
}

```

For an asynchronous version of this example, see [.NET samples JSON project](#).

The preceding code:

- Assumes the JSON contains an array of objects and each object might contain a "name" property of type string.
- Counts objects and "name" property values that end with "University".
- Assumes the file is encoded as UTF-16 and transcodes it into UTF-8. A file encoded as UTF-8 can be read directly into a `ReadOnlySpan<byte>` by using the following code:

C#

```
ReadOnlySpan<byte> jsonReadOnlySpan = File.ReadAllBytes(fileName);
```

If the file contains a UTF-8 byte order mark (BOM), remove it before passing the bytes to the `Utf8JsonReader`, since the reader expects text. Otherwise, the BOM is considered invalid JSON, and the reader throws an exception.

Here's a JSON sample that the preceding code can read. The resulting summary message is "2 out of 4 have names that end with 'University'" :

```
JSON
[  
  {  
    "web_pages": [ "https://contoso.edu/" ],  
    "alpha_two_code": "US",  
    "state-province": null,

    "domains": [ "fabrikamuniversity.edu" ],  
    "name": "Fabrikam University"  
  }  
]
```

Read from a stream using `Utf8JsonReader`

When reading a large file (a gigabyte or more in size, for example), you might want to avoid having to load the entire file into memory at once. For this scenario, you can use a `FileStream`.

When using the `Utf8JsonReader` to read from a stream, the following rules apply:

- The buffer containing the partial JSON payload must be at least as large as the largest JSON token within it so that the reader can make forward progress.
- The buffer must be at least as large as the largest sequence of white space within the JSON.
- The reader doesn't keep track of the data it has read until it completely reads the next `TokenType` in the JSON payload. So when there are bytes left over in the buffer, you have to pass them to the reader again. You can use `BytesConsumed` to determine how many bytes are left over.

The following code illustrates how to read from a stream. The example shows a `MemoryStream`. Similar code will work with a `FileStream`, except when the `FileStream` contains a UTF-8 BOM at the start. In that case, you need to strip those three bytes from the buffer before passing the remaining bytes to the `Utf8JsonReader`. Otherwise the reader would throw an exception, since the BOM is not considered a valid part of the JSON.

The sample code starts with a 4 KB buffer and doubles the buffer size each time it finds that the size is not large enough to fit a complete JSON token, which is required for the reader to make forward progress on the JSON payload. The JSON sample provided in the snippet triggers a buffer size increase only if you set a very small initial buffer size, for example, 10 bytes. If you set the initial buffer size to 10, the `Console.WriteLine` statements illustrate the cause and effect of buffer size increases. At the 4 KB initial buffer size, the entire sample JSON is shown by each `Console.WriteLine`, and the buffer size never has to be increased.

C#

```
using System.Text;
using System.Text.Json;

namespace SystemTextJsonSamples
{
    public class Utf8ReaderPartialRead
    {
        public static void Run()
        {
            var jsonString = @"
                ""Date"": ""2019-08-01T00:00:00-07:00"",
                ""Temperature"": 25,
                ""TemperatureRanges"": {
                    ""Cold"": { ""High"": 20, ""Low"": -10 },
                    ""Hot"": { ""High"": 60, ""Low"": 20 }
                },
                ""Summary"": ""Hot"",
            ";
            // ...
        }
    }
}
```

```
    }";

    byte[] bytes = Encoding.UTF8.GetBytes(jsonString);
    var stream = new MemoryStream(bytes);

    var buffer = new byte[4096];

    // Fill the buffer.
    // For this snippet, we're assuming the stream is open and has
data.
    // If it might be closed or empty, check if the return value is
0.
    stream.Read(buffer);

    // We set isFinalBlock to false since we expect more data in a
subsequent read from the stream.
    var reader = new Utf8JsonReader(buffer, isFinalBlock: false,
state: default);
    Console.WriteLine($"String in buffer is:
{Encoding.UTF8.GetString(buffer)}");

    // Search for "Summary" property name
    while (reader.TokenType != JsonTokenType.PropertyName ||
!reader.ValueTextEquals("Summary"))
    {
        if (!reader.Read())
        {
            // Not enough of the JSON is in the buffer to complete a
read.
            GetMoreBytesFromStream(stream, ref buffer, ref reader);
        }
    }

    // Found the "Summary" property name.
    Console.WriteLine($"String in buffer is:
{Encoding.UTF8.GetString(buffer)}");
    while (!reader.Read())
    {
        // Not enough of the JSON is in the buffer to complete a
read.
        GetMoreBytesFromStream(stream, ref buffer, ref reader);
    }
    // Display value of Summary property, that is, "Hot".
    Console.WriteLine($"Got property value: {reader.GetString()}");
}

private static void GetMoreBytesFromStream(
    MemoryStream stream, ref byte[] buffer, ref Utf8JsonReader
reader)
{
    int bytesRead;
    if (reader.BytesConsumed < buffer.Length)
    {
        ReadOnlySpan<byte> leftover =
buffer.AsSpan((int)reader.BytesConsumed);
```

```

        if (leftover.Length == buffer.Length)
        {
            Array.Resize(ref buffer, buffer.Length * 2);
            Console.WriteLine($"Increased buffer size to
{buffer.Length}");
        }

        leftover.CopyTo(buffer);
        bytesRead = stream.Read(buffer.AsSpan(leftover.Length));
    }
    else
    {
        bytesRead = stream.Read(buffer);
    }
    Console.WriteLine($"String in buffer is:
{Encoding.UTF8.GetString(buffer)}");
    reader = new Utf8JsonReader(buffer, isFinalBlock: bytesRead ==
0, reader.CurrentState);
}
}
}

```

The preceding example sets no limit to how large the buffer can grow. If the token size is too large, the code could fail with an [OutOfMemoryException](#) exception. This can happen if the JSON contains a token that is around 1 GB or more in size, because doubling the 1 GB size results in a size that is too large to fit into an `int32` buffer.

ref struct limitations

Because the `Utf8JsonReader` type is a *ref struct*, it has [certain limitations](#). For example, it can't be stored as a field on a class or struct other than a ref struct.

To achieve high performance, this type must be a `ref struct` since it needs to cache the input `ReadOnlySpan<byte>`, which itself is a ref struct. In addition, the `Utf8JsonReader` type is mutable since it holds state. Therefore, **pass it by reference** rather than by value. Passing it by value would result in a struct copy and the state changes would not be visible to the caller.

For more information about how to use ref structs, see [Avoid allocations](#).

Read UTF-8 text

To achieve the best possible performance while using `Utf8JsonReader`, read JSON payloads already encoded as UTF-8 text rather than as UTF-16 strings. For a code example, see [Filter data using Utf8JsonReader](#).

Read with multi-segment `ReadOnlySequence`

If your JSON input is a `ReadOnlySpan<byte>`, each JSON element can be accessed from the `ValueSpan` property on the reader as you go through the read loop. However, if your input is a `ReadOnlySequence<byte>` (which is the result of reading from a `PipeReader`), some JSON elements might straddle multiple segments of the `ReadOnlySequence<byte>` object. These elements would not be accessible from `ValueSpan` in a contiguous memory block. Instead, whenever you have a multi-segment `ReadOnlySequence<byte>` as input, poll the `HasValueSequence` property on the reader to figure out how to access the current JSON element. Here's a recommended pattern:

C#

```
while (reader.Read())
{
    switch (reader.TokenType)
    {
        // ...
        ReadOnlySpan<byte> jsonElement = reader.HasValueSequence ?
            reader.ValueSequence.ToArray() :
            reader.ValueSpan;
        // ...
    }
}
```

Use `ValueTextEquals` for property name lookups

Don't use `ValueSpan` to do byte-by-byte comparisons by calling `SequenceEqual` for property name lookups. Call `ValueTextEquals` instead, because that method unescapes any characters that are escaped in the JSON. Here's an example that shows how to search for a property that's named "name":

C#

```
private static readonly byte[] s_nameUtf8 = Encoding.UTF8.GetBytes("name");
```

C#

```
while (reader.Read())
{
    switch (reader.TokenType)
    {
        case JsonTokenType.StartObject:
```

```
        total++;
        break;
    case JsonTokenType.PropertyName:
        if (reader.ValueTextEquals(s_nameUtf8))
        {
            count++;
        }
        break;
    }
}
```

Read null values into nullable value types

The built-in `System.Text.Json` APIs return only non-nullable value types. For example, `Utf8JsonReader.GetBoolean` returns a `bool`. It throws an exception if it finds `Null` in the JSON. The following examples show two ways to handle nulls, one by returning a nullable value type and one by returning the default value:

C#

```
public bool? ReadAsNullableBoolean()
{
    _reader.Read();
    if (_reader.TokenType == JsonTokenType.Null)
    {
        return null;
    }
    if (_reader.TokenType != JsonTokenType.True && _reader.TokenType != JsonTokenType.False)
    {
        throw new JsonException();
    }
    return _reader.GetBoolean();
}
```

C#

```
public bool ReadAsBoolean(bool defaultValue)
{
    _reader.Read();
    if (_reader.TokenType == JsonTokenType.Null)
    {
        return defaultValue;
    }
    if (_reader.TokenType != JsonTokenType.True && _reader.TokenType != JsonTokenType.False)
    {
        throw new JsonException();
    }
}
```

```
        return _reader.GetBoolean();
    }
```

Skip children of token

Use the [Utf8JsonReader.Skip\(\)](#) method to skip the children of the current JSON token. If the token type is [JsonTokenType.PropertyName](#), the reader moves to the property value. The following code snippet shows an example of using [Utf8JsonReader.Skip\(\)](#) to move the reader to the value of a property.

C#

```
var weatherForecast = new WeatherForecast
{
    Date = DateTime.Parse("2019-08-01"),
    TemperatureCelsius = 25,
    Summary = "Hot"
};

byte[] jsonUtf8Bytes = JsonSerializer.SerializeToUtf8Bytes(weatherForecast);

var reader = new Utf8JsonReader(jsonUtf8Bytes);

int temp;
while (reader.Read())
{
    switch (reader.TokenType)
    {
        case JsonTokenType.PropertyName:
            {
                if (reader.ValueTextEquals("TemperatureCelsius"))
                {
                    reader.Skip();
                    temp = reader.GetInt32();

                    Console.WriteLine($"Temperature is {temp} degrees.");
                }
                continue;
            }
        default:
            continue;
    }
}
```

Consume decoded JSON strings

Starting in .NET 7, you can use the [Utf8JsonReader.CopyString](#) method instead of [Utf8JsonReader.GetString\(\)](#) to consume a decoded JSON string. Unlike [GetString\(\)](#), which always allocates a new string, [CopyString](#) lets you copy the unescaped string to a buffer that you own. The following code snippet shows an example of consuming a UTF-16 string using [CopyString](#).

C#

```
var reader = new Utf8JsonReader( /* jsonReadOnlySpan */ );  
  
int valueLength = reader.HasValueSequence  
    ? checked((int)reader.ValueSequence.Length)  
    : reader.ValueSpan.Length;  
  
char[] buffer = ArrayPool<char>.Shared.Rent(valueLength);  
int charsRead = reader.CopyString(buffer);  
ReadOnlySpan<char> source = buffer.AsSpan(0, charsRead);  
  
// Handle the unescaped JSON string.  
ParseUnescapedString(source);  
ArrayPool<char>.Shared.Return(buffer, clearArray: true);  
  
void ParseUnescapedString(ReadOnlySpan<char> source)  
{  
    // ...  
}
```

Related APIs

- To deserialize a custom type from a `Utf8JsonReader` instance, call `JsonSerializer.Deserialize< TValue >(Utf8JsonReader, JsonSerializerOptions)` or `JsonSerializer.Deserialize< TValue >(Utf8JsonReader, JsonTypeInfo< TValue >)`. For an example, see [Deserialize from UTF-8](#).
- `JsonNode` and the classes that derive from it provide the ability to create a mutable DOM. You can convert a `Utf8JsonReader` instance to a `JsonNode` by calling `JsonNode.Parse(Utf8JsonReader, Nullable<JsonNodeOptions>)`. The following code snippet shows an example.

C#

```
using System.Text.Json;  
using System.Text.Json.Nodes;  
  
namespace Utf8ReaderToJsonNode  
{  
    public class WeatherForecast
```

```

    }

    public DateTimeOffset Date { get; set; }
    public int TemperatureCelsius { get; set; }
    public string? Summary { get; set; }
}

public class Program
{
    public static void Main()
    {
        var weatherForecast = new WeatherForecast
        {
            Date = DateTime.Parse("2019-08-01"),
            TemperatureCelsius = 25,
            Summary = "Hot"
        };

        byte[] jsonUtf8Bytes =
JsonSerializer.SerializeToUtf8Bytes(weatherForecast);

        var utf8Reader = new Utf8JsonReader(jsonUtf8Bytes);
        JsonNode? node = JsonNode.Parse(ref utf8Reader);
        Console.WriteLine(node);
    }
}

```

- [JsonDocument](#) provides the ability to build a read-only DOM by using `Utf8JsonReader`. Call the `JsonDocument.ParseValue(Utf8JsonReader)` method to parse a `JsonDocument` from a `Utf8JsonReader` instance. You can access the JSON elements that compose the payload via the `JsonElement` type. For example code that uses `JsonDocument.ParseValue(Utf8JsonReader)`, see [RoundtripDataTable.cs](#) and the code snippet in [Deserialize inferred types to object properties](#).
- You can also parse a `Utf8JsonReader` instance to a `JsonElement`, which represents a specific JSON value, by calling `JsonElement.ParseValue(Utf8JsonReader)`.

Visual Basic support

Article • 09/23/2022

Parts of System.Text.Json use [ref structs](#), which are not supported by Visual Basic. If you try to use System.Text.Json ref struct APIs with Visual Basic you get BC40000 compiler errors. The error message indicates that the problem is an obsolete API, but the actual issue is lack of ref struct support in the compiler. The following parts of System.Text.Json aren't usable from Visual Basic:

- The [Utf8JsonReader](#) class. Since the [JsonConverter<T>.Read](#) method takes a `Utf8JsonReader` parameter, this limitation means you can't use Visual Basic to write custom converters. A workaround for this is to implement custom converters in a C# library assembly, and reference that assembly from your VB project. This assumes that all you do in Visual Basic is register the converters into the serializer. You can't call the `Read` methods of the converters from Visual Basic code.
- Overloads of other APIs that include a [ReadOnlySpan<T>](#) type. Most methods include overloads that use `String` instead of `ReadOnlySpan`.

These restrictions are in place because ref structs cannot be used safely without language support, even when just "passing data through." Subverting this error will result in Visual Basic code that can corrupt memory and should not be done.

Supported collection types in System.Text.Json

Article • 12/05/2023

This article gives an overview of which collections are supported for serialization and deserialization. [System.Text.Json.JsonSerializer](#) supports a collection type for serialization if it:

- Derives from [IEnumerable](#) or [IAsyncEnumerable<T>](#)
- Contains elements that are serializable.

The serializer calls the [GetEnumerator\(\)](#) method and writes the elements.

Deserialization is more complicated and is not supported for some collection types.

The following sections are organized by namespace and show which types are supported for serialization and deserialization.

System.Array namespace

[] Expand table

| Type | Serialization | Deserialization |
|---------------------------|---------------|-----------------|
| Single-dimensional arrays | ✓ | ✓ |
| Multi-dimensional arrays | ✗ | ✗ |
| Jagged arrays | ✓ | ✓ |

‡ See [Support round trip for Stack types](#).

IAsyncEnumerable<T>

The following examples use streams as a representation of any async source of data. The source could be files on a local machine, or results from a database query or web service API call.

Stream serialization

`System.Text.Json` supports serializing [IAsyncEnumerable<T>](#) values as JSON arrays, as shown in the following example:

```
C#  
  
using System.Text.Json;  
  
namespace IAsyncEnumerableSerialize;  
  
public class Program  
{  
    public static async Task Main()  
    {  
        using Stream stream = Console.OpenStandardOutput();  
        var data = new { Data = PrintNumbers(3) };  
        await JsonSerializer.SerializeAsync(stream, data);  
    }  
}  
  
private static string PrintNumbers(int count)  
{  
    var numbers = new List<int>();  
    for (int i = 0; i < count; i++)  
    {  
        numbers.Add(i);  
    }  
    return string.Join(", ", numbers);  
}
```

```
}

    static async IAsyncEnumerable<int> PrintNumbers(int n)
    {
        for (int i = 0; i < n; i++)
        {
            await Task.Delay(1000);
            yield return i;
        }
    }
// output:
// {"Data": [0,1,2]}
```

`IAsyncEnumerable<T>` values are only supported by the asynchronous serialization methods, such as [JsonSerializer.SerializeAsync](#).

Stream deserialization

The `DeserializeAsyncEnumerable` method supports streaming deserialization, as shown in the following example:

C#

```
using System.Text;
using System.Text.Json;

namespace IAsyncEnumerableDeserialize;

public class Program
{
    public static async Task Main()
    {
        using var stream = new MemoryStream(Encoding.UTF8.GetBytes("[0,1,2,3,4]"));
        await foreach (int item in
JsonSerializer.DeserializeAsyncEnumerable<int>(stream))
        {
            Console.WriteLine(item);
        }
    }
// output:
//0
//1
//2
//3
//4
```

The `DeserializeAsyncEnumerable` method only supports reading from root-level JSON arrays.

The `DeserializeAsync` method supports `IAsyncEnumerable<T>`, but its signature doesn't allow streaming. It returns the final result as a single value, as shown in the following example.

C#

```
using System.Text;
using System.Text.Json;

namespace IAsyncEnumerableDeserializeNonStreaming;

public class MyPoco
{
    public IAsyncEnumerable<int>? Data { get; set; }
}

public class Program
{
    public static async Task Main()
    {
        using var stream = new MemoryStream(Encoding.UTF8.GetBytes(@"
{""Data""::[0,1,2,3,4]}"));
        MyPoco? result = await JsonSerializer.DeserializeAsync<MyPoco>
(stream)!;
        await foreach (int item in result!.Data!)
        {
            Console.WriteLine(item);
        }
    }
}
// output:
//0
//1
//2
//3
//4
```

In this example, the deserializer buffers all `IAsyncEnumerable<T>` contents in memory before returning the deserialized object. This behavior is necessary because the deserializer needs to read the entire JSON payload before returning a result.

System.Collections.Immutable namespace

* Non-`string` keys are not supported.

Custom collections

Any collection type that isn't in one of the preceding namespaces is considered a custom collection. Such types include user-defined types and types defined by ASP.NET Core. For example, [Microsoft.Extensions.Primitives](#) is in this group.

All custom collections (everything that derives from `IEnumerable`) are supported for serialization, as long as their element types are supported.

Custom collections with deserialization support

A custom collection is supported for deserialization if it:

- Isn't an interface or abstract.
- Has a parameterless constructor.
- Contains element types that are supported by [JsonSerializer](#).
- Implements or inherits one or more of the following interfaces or classes:
 - [ConcurrentQueue<T>](#)
 - [ConcurrentStack<T>](#) *
 - [ICollection<T>](#)
 - [IDictionary](#)
 - [IDictionary<TKey,TValue>](#) †
 - [IList](#)
 - [IList<T>](#)
 - [Queue](#)
 - [Queue<T>](#)
 - [Stack](#) *
 - [Stack<T>](#) *

* See [Support round trip for Stack types](#).

† See [Supported key types](#).

Custom collections with known issues

There are known issues with the following custom collections:

- [ExpandoObject](#): See [dotnet/runtime#29690](#) ↴.
- [DynamicObject](#): See [dotnet/runtime#1808](#) ↴.
- [DataTable](#): See [dotnet/docs#21366](#) ↴.
- [Microsoft.AspNetCore.Http.FormFile](#): See [dotnet/runtime#1559](#) ↴.
- [Microsoft.AspNetCore.Http.IFormCollection](#): See [dotnet/runtime#1559](#) ↴.

For more information about known issues, see the [open issues in System.Text.Json](#).

Supported key types

Supported types for the keys of `Dictionary` and `SortedList` types include the following:

- `Boolean`
- `Byte`
- `DateTime`
- `DateTimeOffset`
- `Decimal`
- `Double`
- `Enum`
- `Guid`
- `Int16`
- `Int32`
- `Int64`
- `Object` (Only on serialization and if the runtime type is one of the supported types in this list.)
- `SByte`
- `Single`
- `String`
- `UInt16`
- `UInt32`
- `UInt64`

System.Data namespace

There are no built-in converters for `DataSet`, `DataTable`, and related types in the `System.Data` namespace. Deserializing these types from untrusted input is not safe, as explained in [the security guidance](#). However, you can write a custom converter to support these types. For sample custom converter code that serializes and deserializes a `DataTable`, see [RoundtripDataTable.cs](#).

Reflection versus source generation in System.Text.Json

Article • 11/01/2023

This article explains the differences between reflection and source generation as it relates to `System.Text.Json` serialization. It also provides guidance on how to choose the best approach for your scenario.

Metadata collection

To serialize or deserialize a type, `JsonSerializer` needs information about how to access the members of the type. `JsonSerializer` needs the following information:

- How to access property getters and fields for serialization.
- How to access a constructor, property setters, and fields for deserialization.
- Information about which attributes have been used to customize serialization or deserialization.
- Run-time configuration from `JsonSerializerOptions`.

This information is referred to as *metadata*.

Reflection

By default, `JsonSerializer` collects metadata at run time by using `reflection`. Whenever `JsonSerializer` has to serialize or deserialize a type for the first time, it collects and caches this metadata. The metadata collection process takes time and uses memory.

Source generation

As an alternative, `System.Text.Json` can use the C# `source generation` feature to improve performance, reduce private memory usage, and facilitate `assembly trimming`, which reduces app size. In addition, certain reflection APIs can't be used in `Native AOT applications`, so you must use source generation for those apps.

Source generation can be used in two modes:

- **Metadata-based mode**

During compilation, `System.Text.Json` collects the information needed for serialization and generates source code files that populate JSON contract metadata for the requested types.

- **Serialization-optimization (fast path) mode**

`JsonSerializer` features that customize the output of serialization, such as naming policies and reference preservation, carry a performance overhead. In serialization-optimization mode, `System.Text.Json` generates optimized serialization code that uses `Utf8JsonWriter` directly. This optimized or *fast path* code increases serialization throughput.

Fast-path *deserialization* isn't currently available. For more information, see [dotnet/runtime issue 55043 ↗](#).

Source generation for `System.Text.Json` requires C# 9.0 or a later version.

Feature comparison

Choose reflection or source-generation modes based on the following benefits that each one offers:

| Benefit | Reflection | Source generation (Metadata-based mode) | Source generation (Serialization-optimization mode) |
|--|------------|--|--|
| Simpler to code. | ✓ | ✗ | ✗ |
| Simpler to debug. | ✗ | ✓ | ✓ |
| Supports non-public members. | ✓ | ✓ [*] | ✓ [*] |
| Supports all available serialization customizations. | ✓ | ✗ [†] | ✗ [†] |
| Reduces start-up time. | ✗ | ✓ | ✓ |
| Reduces private memory usage. | ✗ | ✓ | ✓ |
| Eliminates run-time reflection. | ✗ | ✓ | ✓ |
| Facilitates trim-safe app size reduction. | ✗ | ✓ | ✓ |
| Increases serialization throughput. | ✗ | ✗ | ✓ |

* The source generator supports *some* non-public members, for example, internal types in the same assembly. † Source-generated contracts can be modified using the contract customization API.

Source-generation modes in System.Text.Json

Article • 11/01/2023

Source generation can be used in two modes: metadata-based and serialization optimization. This article describes the different modes.

For information about how to use source generation modes, see [How to use source generation in System.Text.Json](#).

Metadata-based mode

You can use source generation to move the metadata collection process from run time to compile time. During compilation, the metadata is collected and source code files are generated. The generated source code files are automatically compiled as an integral part of the application. This technique eliminates run-time metadata collection, which improves performance of both serialization and deserialization.

The performance improvements provided by source generation can be substantial. For example, [test results](#) have shown up to 40% or more startup time reduction, private memory reduction, throughput speed increase (in serialization optimization mode), and app size reduction.

Known issues

Only `public` properties and fields are supported by default in either serialization mode. However, reflection mode supports the use of `private` members and `private accessors`, while source-generation mode doesn't. For example, if you apply the `JsonInclude attribute` to a `private` property or a property that has a `private` setter or getter, it will be serialized in reflection mode. Source-generation mode supports only `public` or `internal` members and `public` or `internal` accessors of `public` properties. If you set `[JsonInclude]` on `private` members or accessors and choose source-generation mode, a `NotSupportedException` will be thrown at run time.

For information about other known issues with source generation, see the [GitHub issues that are labeled "source-generator"](#) in the `dotnet/runtime` repository.

Serialization-optimization (fast path) mode

`JsonSerializer` has many features that customize the output of serialization, such as [naming policies](#) and [preserving references](#). Support for all those features causes some performance overhead. Source generation can improve serialization performance by generating optimized code that uses [Utf8JsonWriter](#) directly.

The optimized code doesn't support all of the serialization features that `JsonSerializer` supports. The serializer detects whether the optimized code can be used and falls back to default serialization code if unsupported options are specified. For example, [JsonNumberHandling.AllowReadingFromString](#) isn't applicable to writing, so specifying this option doesn't cause a fallback to default code.

The following table shows which options in `JsonSerializerOptions` are supported by fast-path serialization:

| Serialization option | Supported for fast-path |
|---------------------------------------|-------------------------|
| <code>AllowTrailingCommas</code> | ✓ |
| <code>Converters</code> | ✗ |
| <code>DefaultBufferSize</code> | ✓ |
| <code>DefaultIgnoreCondition</code> | ✓ |
| <code>DictionaryKeyPolicy</code> | ✗ |
| <code>Encoder</code> | ✗ |
| <code>IgnoreNullValues</code> | ✗ |
| <code>IgnoreReadOnlyFields</code> | ✓ |
| <code>IgnoreReadOnlyProperties</code> | ✓ |
| <code>IncludeFields</code> | ✓ |
| <code>MaxDepth</code> | ✓ |
| <code>NumberHandling</code> | ✗ |
| <code>PropertyNamingPolicy</code> | ✓ |
| <code>ReferenceHandler</code> | ✗ |
| <code>TypeInfoResolver</code> | ✓ |
| <code>WriteIndented</code> | ✓ |

(The following options aren't supported because they apply only to *deserialization*: [PropertyNameCaseInsensitive](#), [ReadCommentHandling](#), and [UnknownTypeHandling](#).)

The following table shows which attributes are supported by fast-path serialization:

| Attribute | Supported for fast-path |
|---|-------------------------|
| JsonConstructorAttribute | ✗ |
| JsonConverterAttribute | ✗ |
| JsonDerivedTypeAttribute | ✓ |
| JsonExtensionDataAttribute | ✗ |
| JsonIgnoreAttribute | ✓ |
| JsonIncludeAttribute | ✓ |
| JsonNumberHandlingAttribute | ✗ |
| JsonPolymorphicAttribute | ✓ |
| JsonPropertyNameAttribute | ✓ |
| JsonPropertyOrderAttribute | ✗ |
| JsonRequiredAttribute | ✓ |

If a non-supported option or attribute is specified for a type, the serializer falls back to metadata mode, assuming that the source generator has been configured to generate metadata. In that case, the optimized code isn't used when serializing that type but may be used for other types. Therefore it's important to do performance testing with your options and workloads to determine how much benefit you can actually get from serialization-optimization mode. Also, the ability to fall back to `JsonSerializer` code requires metadata-collection mode. If you select only serialization-optimization mode, serialization might fail for types or options that need to fall back to `JsonSerializer` code.

How to use source generation in System.Text.Json

Article • 12/16/2023

Source generation in System.Text.Json is available in .NET 6 and later versions. When used in an app, the app's language version must be C# 9.0 or later. This article shows you how to use source-generation-backed serialization in your apps.

For information about the different source-generation modes, see [Source-generation modes](#).

Use source-generation defaults

To use source generation with all defaults (both modes, default options):

1. Create a partial class that derives from [JsonSerializerContext](#).
2. Specify the type to serialize or deserialize by applying [JsonSerializableAttribute](#) to the context class.
3. Call a [JsonSerializer](#) method that either:
 - Takes a [JsonTypeInfo<T>](#) instance, or
 - Takes a [JsonSerializerContext](#) instance, or
 - Takes a [JsonSerializerOptions](#) instance and you've set its [JsonSerializerOptions.TypeInfoResolver](#) property to the `Default` property of the context type (.NET 7 and later only).

By default, both source generation modes are used if you don't specify one. For information about how to specify the mode to use, see [Specify source generation mode](#) later in this article.

Here's the type that is used in the following examples:

C#

```
public class WeatherForecast
{
    public DateTime Date { get; set; }
    public int TemperatureCelsius { get; set; }
    public string? Summary { get; set; }
}
```

Here's the context class configured to do source generation for the preceding `WeatherForecast` class:

C#

```
[JsonSourceGenerationOptions(WriteIndented = true)]
[JsonSerializable(typeof(WeatherForecast))]
internal partial class SourceGenerationContext : JsonSerializerContext
{}
```

The types of `WeatherForecast` members don't need to be explicitly specified with `[JsonSerializable]` attributes. Members declared as `object` are an exception to this rule. The runtime type for a member declared as `object` needs to be specified. For example, suppose you have the following class:

C#

```
public class WeatherForecast
{
    public object? Data { get; set; }
    public List<object>? DataList { get; set; }
}
```

And you know that at runtime it may have `boolean` and `int` objects:

C#

```
WeatherForecast wf = new() { Data = true, DataList = new List<object> {
    true, 1 } };
```

Then `boolean` and `int` have to be declared as `[JsonSerializable]`:

C#

```
[JsonSerializable(typeof(WeatherForecast))]
[JsonSerializable(typeof(bool))]
[JsonSerializable(typeof(int))]
public partial class WeatherForecastContext : JsonSerializerContext
{}
```

To specify source generation for a collection, use `[JsonSerializable]` with the collection type. For example: `[JsonSerializable(typeof(List<WeatherForecast>))]`.

JsonSerializer methods that use source generation

In the following examples, the static `Default` property of the context type provides an instance of the context type with default options. The context instance provides a `WeatherForecast` property that returns a `JsonTypeInfo<WeatherForecast>` instance. You can specify a different name for this property by using the `TypeInfoPropertyName` property of the `[JsonSerializable]` attribute.

Serialization examples

Using `JsonTypeInfo<T>`:

C#

```
jsonString = JsonSerializer.Serialize(
    weatherForecast!, SourceGenerationContext.Default.WeatherForecast);
```

Using `JsonSerializerContext`:

C#

```
jsonString = JsonSerializer.Serialize(
    weatherForecast, typeof(WeatherForecast),
    SourceGenerationContext.Default);
```

Using `JsonSerializerOptions`:

C#

```
sourceGenOptions = new JsonSerializerOptions
{
    TypeInfoResolver = SourceGenerationContext.Default
};

jsonString = JsonSerializer.Serialize(
    weatherForecast, typeof(WeatherForecast), sourceGenOptions);
```

Deserialization examples

Using `JsonTypeInfo<T>`:

C#

```
weatherForecast = JsonSerializer.Deserialize<WeatherForecast>(
    jsonString, SourceGenerationContext.Default.WeatherForecast);
```

Using [JsonSerializerContext](#):

C#

```
weatherForecast = JsonSerializer.Deserialize(
    jsonString, typeof(WeatherForecast), SourceGenerationContext.Default)
    as WeatherForecast;
```

Using [JsonSerializerOptions](#):

C#

```
var sourceGenOptions = new JsonSerializerOptions
{
    TypeInfoResolver = SourceGenerationContext.Default
};
weatherForecast = JsonSerializer.Deserialize(
    jsonString, typeof(WeatherForecast), sourceGenOptions)
    as WeatherForecast;
```

Complete program example

Here are the preceding examples in a complete program:

C#

```
using System.Text.Json;
using System.Text.Json.Serialization;

namespace BothModesNoOptions
{
    public class WeatherForecast
    {
        public DateTime Date { get; set; }
        public int TemperatureCelsius { get; set; }
        public string? Summary { get; set; }
    }

    [JsonSourceGenerationOptions(WriteIndented = true)]
    [JsonSerializable(typeof(WeatherForecast))]
    internal partial class SourceGenerationContext : JsonSerializerContext
    {

    }

    public class Program
```

```
{
    public static void Main()
    {
        string jsonString =
@"{
    ""Date"": ""2019-08-01T00:00:00"",
    ""TemperatureCelsius"": 25,
    ""Summary"": ""Hot"""
}
";
        WeatherForecast? weatherForecast;

        weatherForecast = JsonSerializer.Deserialize<WeatherForecast>(
            jsonString,
SourceGenerationContext.Default.WeatherForecast);
        Console.WriteLine($"Date={weatherForecast?.Date}");
        // output:
        //Date=8/1/2019 12:00:00 AM

        weatherForecast = JsonSerializer.Deserialize(
            jsonString, typeof(WeatherForecast),
SourceGenerationContext.Default)
        as WeatherForecast;
        Console.WriteLine($"Date={weatherForecast?.Date}");
        // output:
        //Date=8/1/2019 12:00:00 AM

        var sourceGenOptions = new JsonSerializerOptions
{
    TypeInfoResolver = SourceGenerationContext.Default
};
        weatherForecast = JsonSerializer.Deserialize(
            jsonString, typeof(WeatherForecast), sourceGenOptions)
        as WeatherForecast;
        Console.WriteLine($"Date={weatherForecast?.Date}");
        // output:
        //Date=8/1/2019 12:00:00 AM

        jsonString = JsonSerializer.Serialize(
            weatherForecast!,
SourceGenerationContext.Default.WeatherForecast);
        Console.WriteLine(jsonString);
        // output:
        //{"Date":"2019-08-
01T00:00:00","TemperatureCelsius":25,"Summary":"Hot"}

        jsonString = JsonSerializer.Serialize(
            weatherForecast, typeof(WeatherForecast),
SourceGenerationContext.Default);
        Console.WriteLine(jsonString);
        // output:
        //{"Date":"2019-08-
01T00:00:00","TemperatureCelsius":25,"Summary":"Hot"}

        sourceGenOptions = new JsonSerializerOptions
```

```

    {
        TypeInfoResolver = SourceGenerationContext.Default
    };

    jsonString = JsonSerializer.Serialize(
        weatherForecast, typeof(WeatherForecast), sourceGenOptions);
    Console.WriteLine(jsonString);
    // output:
    // {"Date":"2019-08-
01T00:00:00", "TemperatureCelsius":25, "Summary":"Hot"}
}
}
}

```

Specify source-generation mode

You can specify metadata-based mode or serialization-optimization mode for an entire context, which may include multiple types. Or you can specify the mode for an individual type. If you do both, the mode specification for a type wins.

- For an entire context, use the [JsonSourceGenerationOptionsAttribute.GenerationMode](#) property.
- For an individual type, use the [JsonSerializableAttribute.GenerationMode](#) property.

Serialization-optimization (fast path) mode example

- For an entire context:

```
C#
[JsonSourceGenerationOptions\(GenerationMode =
JsonSourceGenerationMode.Serialization\)]
[JsonSerializable\(typeof\(WeatherForecast\)\)]
internal partial class SerializeOnlyContext : JsonSerializerContext
{
}
```

- For an individual type:

```
C#
[JsonSerializable\(typeof\(WeatherForecast\), GenerationMode =
JsonSourceGenerationMode.Serialization\)]
internal partial class SerializeOnlyWeatherForecastOnlyContext : JsonSerializerContext
```

```
{  
}
```

- Complete program example

```
C#
```

```
using System.Text.Json;  
using System.Text.Json.Serialization;  
  
namespace SerializeOnlyNoOptions  
{  
    public class WeatherForecast  
    {  
        public DateTime Date { get; set; }  
        public int TemperatureCelsius { get; set; }  
        public string? Summary { get; set; }  
    }  
  
    [JsonSourceGenerationOptions(GenerationMode =  
JsonSourceGenerationMode.Serialization)]  
    [JsonSerializable(typeof(WeatherForecast))]  
    internal partial class SerializeOnlyContext : JsonSerializerContext  
    {  
    }  
  
    [JsonSerializable(typeof(WeatherForecast), GenerationMode =  
JsonSourceGenerationMode.Serialization)]  
    internal partial class SerializeOnlyWeatherForecastOnlyContext :  
JsonSerializerContext  
    {  
    }  
  
    public class Program  
    {  
        public static void Main()  
        {  
            string jsonString;  
            WeatherForecast weatherForecast = new()  
            { Date = DateTime.Parse("2019-08-01"),  
TemperatureCelsius = 25, Summary = "Hot" };  
  
            // Use context that selects Serialization mode only for  
WeatherForecast.  
            jsonString = JsonSerializer.Serialize(weatherForecast,  
SerializeOnlyWeatherForecastOnlyContext.Default.WeatherForecast);  
            Console.WriteLine(jsonString);  
            // output:  
            //{"Date":"2019-08-  
01T00:00:00","TemperatureCelsius":25,"Summary":"Hot"}  
  
            // Use a context that selects Serialization mode.
```

```
        jsonString = JsonSerializer.Serialize(weatherForecast,
            SerializeOnlyContext.Default.WeatherForecast);
        Console.WriteLine(jsonString);
        // output:
        // {"Date":"2019-08-
01T00:00:00","TemperatureCelsius":25,"Summary":"Hot"}
    }
}
```

Metadata-based mode example

- For an entire context:

C#

```
[JsonSourceGenerationOptions(GenerationMode =
JsonSourceGenerationMode.Metadata)]
[JsonSerializable(typeof(WeatherForecast))]
internal partial class MetadataOnlyContext : JsonSerializerContext
{}
```

C#

```
jsonString = JsonSerializer.Serialize(
    weatherForecast!, MetadataOnlyContext.Default.WeatherForecast);
```

C#

```
weatherForecast = JsonSerializer.Deserialize<WeatherForecast>(
    jsonString, MetadataOnlyContext.Default.WeatherForecast);
```

- For an individual type:

C#

```
[JsonSerializable(typeof(WeatherForecast), GenerationMode =
JsonSourceGenerationMode.Metadata)]
internal partial class MetadataOnlyWeatherForecastOnlyContext :
JsonSerializerContext
{}
```

C#

```
jsonString = JsonSerializer.Serialize(
    weatherForecast!,
    MetadataOnlyWeatherForecastOnlyContext.Default.WeatherForecast);
```

C#

```
weatherForecast = JsonSerializer.Deserialize<WeatherForecast>(
    jsonString,
    MetadataOnlyWeatherForecastOnlyContext.Default.WeatherForecast);
```

- Complete program example

C#

```
using System.Text.Json;
using System.Text.Json.Serialization;

namespace MetadataOnlyNoOptions
{
    public class WeatherForecast
    {
        public DateTime Date { get; set; }
        public int TemperatureCelsius { get; set; }
        public string? Summary { get; set; }
    }

    [JsonSerializable(typeof(WeatherForecast), GenerationMode =
JsonSourceGenerationMode.Metadata)]
    internal partial class MetadataOnlyWeatherForecastOnlyContext : JsonSerializerContext
    {
    }

    [JsonSourceGenerationOptions(GenerationMode =
JsonSourceGenerationMode.Metadata)]
    [JsonSerializable(typeof(WeatherForecast))]
    internal partial class MetadataOnlyContext : JsonSerializerContext
    {
    }

    public class Program
    {
        public static void Main()
        {
            string jsonString =
@"
{
    ""Date"": ""2019-08-01T00:00:00"",
    ""TemperatureCelsius"": 25,
    ""Summary"": ""Hot""
}
";
```

```

        WeatherForecast? weatherForecast;

        // Deserialize with context that selects metadata mode only
        // for WeatherForecast only.
        weatherForecast =
JsonSerializer.Deserialize<WeatherForecast>(
            jsonString,
MetadataOnlyWeatherForecastOnlyContext.Default.WeatherForecast);
            Console.WriteLine($"Date={weatherForecast?.Date}");
            // output:
            //Date=8/1/2019 12:00:00 AM

        // Serialize with context that selects metadata mode only
        // for WeatherForecast only.
        jsonString = JsonSerializer.Serialize(
            weatherForecast!,

MetadataOnlyWeatherForecastOnlyContext.Default.WeatherForecast);
            Console.WriteLine(jsonString);
            // output:
            //{"Date":"2019-08-
01T00:00:00","TemperatureCelsius":25,"Summary":"Hot"}

        // Deserialize with context that selects metadata mode
        // only.
        weatherForecast =
JsonSerializer.Deserialize<WeatherForecast>(
            jsonString,
MetadataOnlyContext.Default.WeatherForecast);
            Console.WriteLine($"Date={weatherForecast?.Date}");
            // output:
            //Date=8/1/2019 12:00:00 AM

        // Serialize with context that selects metadata mode only.
        jsonString = JsonSerializer.Serialize(
            weatherForecast!,
MetadataOnlyContext.Default.WeatherForecast);
            Console.WriteLine(jsonString);
            // output:
            //{"Date":"2019-08-
01T00:00:00","TemperatureCelsius":0,"Summary":"Hot"}
        }
    }
}

```

Source-generation support in ASP.NET Core

In Blazor apps, use overloads of [HttpClientJsonExtensions.GetFromJsonAsync](#) and [HttpClientJsonExtensions.PostAsJsonAsync](#) extension methods that take a source generation context or `TypeInfo< TValue >`.

Starting with .NET 8, you can also use overloads of `HttpClientJsonExtensions.GetFromJsonAsAsyncEnumerable` extension methods that accept a source generation context or `TypeInfo< TValue >`.

In Razor Pages, MVC, SignalR, and Web API apps, use the `JsonSerializerOptions.TypeInfoResolver` property to specify the context.

C#

```
[JsonSerializable(typeof(WeatherForecast[]))]
internal partial class MyJsonContext : JsonSerializerContext { }
```

C#

```
var serializerOptions = new JsonSerializerOptions
{
    TypeInfoResolver = MyJsonContext.Default;
};

services.AddControllers().AddJsonOptions(
    static options =>

    options.JsonSerializerOptions.TypeInfoResolverChain.Add(MyJsonContext.Default));

```

ⓘ Note

`JsonSourceGenerationMode.Serialization`, or fast-path serialization, isn't supported for asynchronous serialization.

In .NET 7 and earlier versions, this limitation also applies to synchronous overloads of `JsonSerializer.Serialize` that accept a `Stream`. Starting with .NET 8, even though streaming serialization requires metadata-based models, it will fall back to fast-path if the payloads are known to be small enough to fit in the predetermined buffer size. For more information, see <https://devblogs.microsoft.com/dotnet/performance-improvements-in-net-8/#json>.

Disable reflection defaults

Because `System.Text.Json` uses reflection by default, calling a basic serialization method can break Native AOT apps, which doesn't support all required reflection APIs. These breaks can be challenging to diagnose since they can be unpredictable, and apps are

often debugged using the CoreCLR runtime, where reflection works. Instead, if you explicitly disable reflection-based serialization, breaks are easier to diagnose. Code that uses reflection-based serialization will cause an [InvalidOperationException](#) with a descriptive message to be thrown at run time.

To disable default reflection in your app, set the

`JsonSerializerIsReflectionEnabledByDefault` MSBuild property to `false` in your project file:

XML

```
<PropertyGroup>

<JsonSerializerIsReflectionEnabledByDefault>false</JsonSerializerIsReflectionEnabledByDefault>
</PropertyGroup>
```

- The behavior of this property is consistent regardless of runtime, either CoreCLR or Native AOT.
- If you don't specify this property and [PublishTrimmed](#) is enabled, reflection-based serialization is automatically disabled.

You can programmatically check whether reflection is disabled by using the `JsonSerializer.IsReflectionEnabledByDefault` property. The following code snippet shows how you might configure your serializer depending on whether reflection is enabled:

C#

```
static JsonSerializerOptions CreateDefaultOptions()
{
    return new()
    {
        TypeInfoResolver = JsonSerializer.IsReflectionEnabledByDefault
            ? new DefaultJsonTypeInfoResolver()
            : MyContext.Default
    };
}
```

Because the property is treated as a link-time constant, the previous method doesn't root the reflection-based resolver in applications that run in Native AOT.

Specify options

In .NET 8 and later versions, most options that you can set using `JsonSerializerOptions` can also be set using the `JsonSourceGenerationOptionsAttribute` attribute. The

advantage to setting options via the attribute is that the configuration is specified at compile time, which ensures that the generated `MyContext.Default` property is preconfigured with all the relevant options set.

The following code shows how to set options using the `JsonSourceGenerationOptionsAttribute` attribute.

```
C#
```

```
[JsonSourceGenerationOptions(
    WriteIndented = true,
    PropertyNamingPolicy = JsonKnownNamingPolicy.CamelCase,
    GenerationMode = JsonSourceGenerationMode.Serialization)]
[JsonSerializable(typeof(WeatherForecast))]
internal partial class SerializationModeOptionsContext : 
JsonSerializerContext
{
}
```

When using `JsonSourceGenerationOptionsAttribute` to specify serialization options, call one of the following serialization methods:

- A `JsonSerializer.Serialize` method that takes a `TypeInfo<TValue>`. Pass it the `Default.<TypeName>` property of your context class:

```
C#
```

```
jsonString = JsonSerializer.Serialize(
    weatherForecast,
    SerializationModeOptionsContext.Default.WeatherForecast);
```

- A `JsonSerializer.Serialize` method that takes a context. Pass it the `Default` static property of your context class.

```
C#
```

```
jsonString = JsonSerializer.Serialize(
    weatherForecast, typeof(WeatherForecast),
    SerializationModeOptionsContext.Default);
```

If you call a method that lets you pass in your own instance of `Utf8JsonWriter`, the writer's `Indented` setting is honored instead of the `JsonSourceGenerationOptionsAttribute.WriteIndented` option.

If you create and use a context instance by calling the constructor that takes a `JsonSerializerOptions` instance, the supplied instance will be used instead of the options specified by `JsonSourceGenerationOptionsAttribute`.

Here are the preceding examples in a complete program:

C#

```
using System.Text.Json;
using System.Text.Json.Serialization;

namespace SerializeOnlyWithOptions
{
    public class WeatherForecast
    {
        public DateTime Date { get; set; }
        public int TemperatureCelsius { get; set; }
        public string? Summary { get; set; }
    }

    [JsonSourceGenerationOptions(
        WriteIndented = true,
        PropertyNamingPolicy = JsonKnownNamingPolicy.CamelCase,
        GenerationMode = JsonSourceGenerationMode.Serialization)]
    [JsonSerializable(typeof(WeatherForecast))]
    internal partial class SerializationModeOptionsContext : 
JsonSerializerContext
    {
    }

    public class Program
    {
        public static void Main()
        {
            string jsonString;
            WeatherForecast weatherForecast = new()
                { Date = DateTime.Parse("2019-08-01"), TemperatureCelsius =
25, Summary = "Hot" };

            // Serialize using TypeInfo<TValue> provided by the context
            // and options specified by [JsonSourceGenerationOptions].
            jsonString = JsonSerializer.Serialize(
                weatherForecast,
                SerializationModeOptionsContext.Default.WeatherForecast);
            Console.WriteLine(jsonString);
            // output:
            //{
            //   "date": "2019-08-01T00:00:00",
            //   "temperatureCelsius": 0,
            //   "summary": "Hot"
            //}

            // Serialize using Default context
            // and options specified by [JsonSourceGenerationOptions].
        }
    }
}
```

```

        jsonString = JsonSerializer.Serialize(
            weatherForecast, typeof(WeatherForecast),
            SerializationModeOptionsContext.Default);
        Console.WriteLine(jsonString);
        // output:
        //{
        //   "date": "2019-08-01T00:00:00",
        //   "temperatureCelsius": 0,
        //   "summary": "Hot"
        //}
    }
}

```

Combine source generators

You can combine contracts from multiple source-generated contexts inside a single [JsonSerializerOptions](#) instance. Use the [JsonSerializerOptions.TypeInfoResolver](#) property to chain multiple contexts that have been combined by using the [JsonTypeInfoResolver.Combine\(IJsonTypeInfoResolver\[\]\)](#) method.

C#

```

var options = new JsonSerializerOptions
{
    TypeInfoResolver = JsonTypeInfoResolver.Combine(ContextA.Default,
ContextB.Default, ContextC.Default);
};

```

Starting in .NET 8, if you later want to prepend or append another context, you can do so using the [JsonSerializerOptions.TypeInfoResolverChain](#) property. The ordering of the chain is significant: [JsonSerializerOptions](#) queries each of the resolvers in their specified order and returns the first result that's non-null.

C#

```

options.TypeInfoResolverChain.Add(ContextD.Default); // Append to the end of
// the list.
options.TypeInfoResolverChain.Insert(0, ContextE.Default); // Insert at the
// beginning of the list.

```

Any change made to the [TypeInfoResolverChain](#) property is reflected by [TypeInfoResolver](#) and vice versa.

Serialize enum fields as strings

By default, enums are serialized as numbers. To [serialize a specific enum's fields as strings](#) when using source generation, annotate it with the `JsonStringEnumConverter<TEnum>` converter. Or to set a [blanket policy](#) for all enumerations, use the `JsonSourceGenerationOptionsAttribute` attribute.

JsonStringEnumConverter<T> converter

To serialize enum names as strings using source generation, use the `JsonStringEnumConverter<TEnum>` converter. (The non-generic `JsonStringEnumConverter` type is not supported by the Native AOT runtime.)

Annotate the enumeration type with the `JsonStringEnumConverter<TEnum>` converter using the `JsonConverterAttribute` attribute:

C#

```
public class WeatherForecastWithPrecipEnum
{
    public DateTimeOffset Date { get; set; }
    public int TemperatureCelsius { get; set; }
    public Precipitation? Precipitation { get; set; }
}

[JsonConverter(typeof(JsonStringEnumConverter<Precipitation>))]
public enum Precipitation
{
    Drizzle, Rain, Sleet, Hail, Snow
}
```

Create a `JsonSerializerContext` class and annotate it with the `JsonSerializableAttribute` attribute:

C#

```
[JsonSerializable(typeof(WeatherForecastWithPrecipEnum))]
public partial class Context1 : JsonSerializerContext { }
```

The following code serializes the enum names instead of the numeric values:

C#

```
var weatherForecast = new WeatherForecastWithPrecipEnum
{
    Date = DateTime.Parse("2019-08-01"),
    TemperatureCelsius = 25,
    Precipitation = Precipitation.Sleet
};
```

```
var options = new JsonSerializerOptions
{
    WriteIndented = true,
    TypeInfoResolver = Context1.Default,
};
string? jsonString = JsonSerializer.Serialize(weatherForecast, options);
```

The resulting JSON looks like the following example:

JSON

```
{
    "Date": "2019-08-01T00:00:00-07:00",
    "TemperatureCelsius": 25,
    "Precipitation": "Sleet"
}
```

Blanket policy

Instead of using the `JsonStringEnumConverter<TEnum>` type, you can apply a blanket policy to serialize enums as strings by using the `JsonSourceGenerationOptionsAttribute`. Create a `JsonSerializerContext` class and annotate it with the `JsonSerializableAttribute` and `JsonSourceGenerationOptionsAttribute` attributes:

C#

```
[JsonSourceGenerationOptions(UseStringEnumConverter = true)]
[JsonSerializable(typeof(WeatherForecast2WithPrecipEnum))]
public partial class Context2 : JsonSerializerContext { }
```

Notice that the enum doesn't have the `JsonConverterAttribute`:

C#

```
public class WeatherForecast2WithPrecipEnum
{
    public DateTimeOffset Date { get; set; }
    public int TemperatureCelsius { get; set; }
    public Precipitation2? Precipitation { get; set; }
}

public enum Precipitation2
{
    Drizzle, Rain, Sleet, Hail, Snow
}
```

How to customize character encoding with System.Text.Json

Article • 05/26/2023

By default, the serializer escapes all non-ASCII characters. That is, it replaces them with `\uxxxx` where `xxxx` is the Unicode code of the character. For example, if the `Summary` property in the following JSON is set to Cyrillic `жарко`, the `WeatherForecast` object is serialized as shown in this example:

JSON

```
{  
    "Date": "2019-08-01T00:00:00-07:00",  
    "TemperatureCelsius": 25,  
    "Summary": "\u0436\u0430\u0440\u043A\u043E"  
}
```

Serialize language character sets

To serialize the character set(s) of one or more languages without escaping, specify [Unicode range\(s\)](#) when creating an instance of [System.Text.Encodings.Web.JavaScriptEncoder](#), as shown in the following example:

C#

```
using System.Text.Encodings.Web;  
using System.Text.Json;  
using System.Text.Unicode;
```

C#

```
var options1 = new JsonSerializerOptions  
{  
    Encoder = JavaScriptEncoder.Create(UnicodeRanges.BasicLatin,  
    UnicodeRanges.Cyrillic),  
    WriteIndented = true  
};  
jsonString = JsonSerializer.Serialize(weatherForecast, options1);
```

This code doesn't escape Cyrillic or Greek characters. If the `Summary` property is set to Cyrillic `жарко`, the `WeatherForecast` object is serialized as shown in this example:

JSON

```
{  
    "Date": "2019-08-01T00:00:00-07:00",  
    "TemperatureCelsius": 25,  
    "Summary": "жарко"  
}
```

By default, the encoder is initialized with the [BasicLatin](#) range.

To serialize all language sets without escaping, use [UnicodeRanges.All](#).

Serialize specific characters

An alternative is to specify individual characters that you want to allow through without being escaped. The following example serializes only the first two characters of жарко:

C#

```
using System.Text_ENCODINGS.Web;  
using System.Text.Json;  
using System.Text.Unicode;
```

C#

```
var encoderSettings = new TextEncoderSettings();  
encoderSettings.AllowCharacters('\u0436', '\u0430');  
encoderSettings.AllowRange(UnicodeRanges.BasicLatin);  
var options2 = new JsonSerializerOptions  
{  
    Encoder = JavaScriptEncoder.Create(encoderSettings),  
    WriteIndented = true  
};  
jsonString = JsonSerializer.Serialize(weatherForecast, options2);
```

Here's an example of JSON produced by the preceding code:

JSON

```
{  
    "Date": "2019-08-01T00:00:00-07:00",  
    "TemperatureCelsius": 25,  
    "Summary": "\u043A\u0430\u043B\u043E\u0436\u0435\u043D\u0438\u044F"  
}
```

Block lists

The preceding sections show how to specify allow lists of code points or ranges that you don't want to be escaped. However, there are global and encoder-specific block lists that can override certain code points in your allow list. Code points in a block list are always escaped, even if they're included in your allow list.

Global block list

The global block list includes things like private-use characters, control characters, undefined code points, and certain Unicode categories, such as the [Space_Separator category](#), excluding `U+0020 SPACE`. For example, `U+3000 IDEOGRAPHIC SPACE` is escaped even if you specify Unicode range [CJK Symbols and Punctuation \(U+3000-U+303F\)](#) as your allow list.

The global block list is an implementation detail that has changed in every release of .NET. Don't take a dependency on a character being a member of (or not being a member of) the global block list.

Encoder-specific block lists

Examples of encoder-specific blocked code points include `'<'` and `'&'` for the [HTML encoder](#), `'\'` for the [JSON encoder](#), and `'%'` for the [URL encoder](#). For example, the HTML encoder always escapes ampersands (`'&'`), even though the ampersand is in the `BasicLatin` range and all the encoders are initialized with `BasicLatin` by default.

Serialize all characters

To minimize escaping you can use [JavaScriptEncoder.UnsafeRelaxedJsonEscaping](#), as shown in the following example:

C#

```
using System.Text.Encodings.Web;
using System.Text.Json;
using System.Text.Unicode;
```

C#

```
var options3 = new JsonSerializerOptions
{
    Encoder = JavaScriptEncoder.UnsafeRelaxedJsonEscaping,
```

```
        WriteIndented = true
    };
jsonString = JsonSerializer.Serialize(weatherForecast, options3);
```

✖ Caution

Compared to the default encoder, the `UnsafeRelaxedJsonEscaping` encoder is more permissive about allowing characters to pass through unescaped:

- It doesn't escape HTML-sensitive characters such as `<`, `>`, `&`, and `'`.
- It doesn't offer any additional defense-in-depth protections against XSS or information disclosure attacks, such as those which might result from the client and server disagreeing on the `charset`.

Use the unsafe encoder only when it's known that the client will be interpreting the resulting payload as UTF-8 encoded JSON. For example, you can use it if the server is sending the response header `Content-Type: application/json; charset=utf-8`.

Never allow the raw `UnsafeRelaxedJsonEscaping` output to be emitted into an HTML page or a `<script>` element.

How to write custom converters for JSON serialization (marshalling) in .NET

Article • 05/23/2023

This article shows how to create custom converters for the JSON serialization classes that are provided in the [System.Text.Json](#) namespace. For an introduction to [System.Text.Json](#), see [How to serialize and deserialize JSON in .NET](#).

A *converter* is a class that converts an object or a value to and from JSON. The [System.Text.Json](#) namespace has built-in converters for most primitive types that map to JavaScript primitives. You can write custom converters:

- To override the default behavior of a built-in converter. For example, you might want `DateTime` values to be represented by mm/dd/yyyy format. By default, ISO 8601-1:2019 is supported, including the RFC 3339 profile. For more information, see [DateTime and DateTimeOffset support in System.Text.Json](#).
- To support a custom value type. For example, a `PhoneNumber` struct.

You can also write custom converters to customize or extend [System.Text.Json](#) with new functionality. The following scenarios are covered later in this article:

- [Deserialize inferred types to object properties](#).
- [Support polymorphic deserialization](#).
- [Support round trip for Stack types](#).
- [Use default system converter](#).

Visual Basic can't be used to write custom converters but can call converters that are implemented in C# libraries. For more information, see [Visual Basic support](#).

Custom converter patterns

There are two patterns for creating a custom converter: the basic pattern and the factory pattern. The factory pattern is for converters that handle type `Enum` or open generics. The basic pattern is for non-generic and closed generic types. For example, converters for the following types require the factory pattern:

- `Dictionary<TKey,TValue>`
- `Enum`
- `List<T>`

Some examples of types that can be handled by the basic pattern include:

- `Dictionary<int, string>`
- `WeekdaysEnum`
- `List<DateTimeOffset>`
- `DateTime`
- `Int32`

The basic pattern creates a class that can handle one type. The factory pattern creates a class that determines, at run time, which specific type is required and dynamically creates the appropriate converter.

Sample basic converter

The following sample is a converter that overrides default serialization for an existing data type. The converter uses mm/dd/yyyy format for `DateTimeOffset` properties.

C#

```
using System.Globalization;
using System.Text.Json;
using System.Text.Json.Serialization;

namespace SystemTextJsonSamples
{
    public class DateTimeOffsetJsonConverter : JsonConverter<DateTimeOffset>
    {
        public override DateTimeOffset Read(
            ref Utf8JsonReader reader,
            Type typeToConvert,
            JsonSerializerOptions options) =>
            DateTimeOffset.ParseExact(reader.GetString()!,
                "MM/dd/yyyy", CultureInfo.InvariantCulture);

        public override void Write(
            Utf8JsonWriter writer,
            DateTimeOffset dateTimeValue,
            JsonSerializerOptions options) =>
            writer.WriteStringValue(dateTimeValue.ToString(
                "MM/dd/yyyy", CultureInfo.InvariantCulture));
    }
}
```

Sample factory pattern converter

The following code shows a custom converter that works with `Dictionary<Enum, TValue>`. The code follows the factory pattern because the first generic type parameter is `Enum`.

and the second is open. The `CanConvert` method returns `true` only for a `Dictionary` with two generic parameters, the first of which is an `Enum` type. The inner converter gets an existing converter to handle whichever type is provided at run time for `TValue`.

C#

```
using System.Reflection;
using System.Text.Json;
using System.Text.Json.Serialization;

namespace SystemTextJsonSamples
{
    public class DictionaryTKeyEnumTValueConverter : JsonConverterFactory
    {
        public override bool CanConvert(Type typeToConvert)
        {
            if (!typeToConvert.IsGenericType)
            {
                return false;
            }

            if (typeToConvert.GetGenericTypeDefinition() !=
typeof(Dictionary<,>))
            {
                return false;
            }

            return typeToConvert.GetGenericArguments()[0].IsEnum;
        }

        public override JsonConverter CreateConverter(
            Type type,
            JsonSerializerOptions options)
        {
            Type keyType = type.GetGenericArguments()[0];
            Type valueType = type.GetGenericArguments()[1];

            JsonConverter converter =
(JsonConverter)Activator.CreateInstance(
            typeof(DictionaryEnumConverterInner<,>).MakeGenericType(
                new Type[] { keyType, valueType }),
            BindingFlags.Instance | BindingFlags.Public,
            binder: null,
            args: new object[] { options },
            culture: null);

            return converter;
        }

        private class DictionaryEnumConverterInner<TKey, TValue> :
            JsonConverter<Dictionary<TKey, TValue>> where TKey : struct,
        Enum
        {

```

```

private readonly JsonConverter< TValue> _valueConverter;
private readonly Type _keyType;
private readonly Type _valueType;

public DictionaryEnumConverterInner(JsonSerializerOptions
options)
{
    // For performance, use the existing converter.
    _valueConverter = (JsonConverter< TValue>)options
        .GetConverter(typeof(TValue));

    // Cache the key and value types.
    _keyType = typeof(TKey);
    _valueType = typeof(TValue);
}

public override Dictionary< TKey, TValue> Read(
    ref Utf8JsonReader reader,
    Type typeToConvert,
    JsonSerializerOptions options)
{
    if (reader.TokenType != JsonTokenType.StartObject)
    {
        throw new JsonException();
    }

    var dictionary = new Dictionary< TKey, TValue>();

    while (reader.Read())
    {
        if (reader.TokenType == JsonTokenType.EndObject)
        {
            return dictionary;
        }

        // Get the key.
        if (reader.TokenType != JsonTokenType.PropertyName)
        {
            throw new JsonException();
        }

        string? propertyName = reader.GetString();

        // For performance, parse with ignoreCase:false first.
        if (!Enum.TryParse(propertyName, ignoreCase: false, out
TKey key) &&
            !Enum.TryParse(propertyName, ignoreCase: true, out
key))
        {
            throw new JsonException(
                $"Unable to convert \'{propertyName}\' to Enum
{(_keyType).ToString()}");
        }

        // Get the value.

```

```
        reader.Read();
        TValue value = _valueConverter.Read(ref reader,
_valueType, options)!;

        // Add to dictionary.
        dictionary.Add(key, value);
    }

    throw new JsonException();
}

public override void Write(
    Utf8JsonWriter writer,
    Dictionary<TKey, TValue> dictionary,
    JsonSerializerOptions options)
{
    writer.WriteStartObject();

    foreach ((TKey key, TValue value) in dictionary)
    {
        var propertyName = key.ToString();
        writer.WritePropertyName

(options.PropertyNamingPolicy?.ConvertName(propertyName) ?? propertyName);

        _valueConverter.Write(writer, value, options);
    }

    writer.WriteEndObject();
}
}
```

Steps to follow the basic pattern

The following steps explain how to create a converter by following the basic pattern:

- Create a class that derives from `JsonConverter<T>` where `T` is the type to be serialized and deserialized.
 - Override the `Read` method to deserialize the incoming JSON and convert it to type `T`. Use the `Utf8JsonReader` that's passed to the method to read the JSON. You don't have to worry about handling partial data, as the serializer passes all the data for the current JSON scope. So it isn't necessary to call `Skip` or `TrySkip` or to validate that `Read` returns `true`.
 - Override the `Write` method to serialize the incoming object of type `T`. Use the `Utf8JsonWriter` that is passed to the method to write the JSON.

- Override the `CanConvert` method only if necessary. The default implementation returns `true` when the type to convert is of type `T`. Therefore, converters that support only type `T` don't need to override this method. For an example of a converter that does need to override this method, see the [polymorphic deserialization](#) section later in this article.

You can refer to the [built-in converters source code](#) as reference implementations for writing custom converters.

Steps to follow the factory pattern

The following steps explain how to create a converter by following the factory pattern:

- Create a class that derives from [JsonConverterFactory](#).
- Override the `CanConvert` method to return `true` when the type to convert is one that the converter can handle. For example, if the converter is for `List<T>`, it might only handle `List<int>`, `List<string>`, and `List<DateTime>`.
- Override the `CreateConverter` method to return an instance of a converter class that will handle the type-to-convert that is provided at run time.
- Create the converter class that the `CreateConverter` method instantiates.

The factory pattern is required for open generics because the code to convert an object to and from a string isn't the same for all types. A converter for an open generic type (`List<T>`, for example) has to create a converter for a closed generic type (`List<DateTime>`, for example) behind the scenes. Code must be written to handle each closed-generic type that the converter can handle.

The `Enum` type is similar to an open generic type: a converter for `Enum` has to create a converter for a specific `Enum` (`WeekdaysEnum`, for example) behind the scenes.

The use of `Utf8JsonReader` in the `Read` method

If your converter is converting a JSON object, the `Utf8JsonReader` will be positioned on the begin object token when the `Read` method begins. You must then read through all the tokens in that object and exit the method with the reader positioned on **the corresponding end object token**. If you read beyond the end of the object, or if you stop before reaching the corresponding end token, you get a `JsonException` exception indicating that:

The converter 'ConverterName' read too much or not enough.

For an example, see the preceding factory pattern sample converter. The `Read` method starts by verifying that the reader is positioned on a start object token. It reads until it finds that it is positioned on the next end object token. It stops on the next end object token because there are no intervening start object tokens that would indicate an object within the object. The same rule about begin token and end token applies if you are converting an array. For an example, see the [Stack<T>](#) sample converter later in this article.

Error handling

The serializer provides special handling for exception types [JsonException](#) and [NotSupportedException](#).

JsonException

If you throw a `JsonException` without a message, the serializer creates a message that includes the path to the part of the JSON that caused the error. For example, the statement `throw new JsonException()` produces an error message like the following example:

Output

```
Unhandled exception. System.Text.Json.JsonException:  
The JSON value could not be converted to System.Object.  
Path: $.Date | LineNumber: 1 | BytePositionInLine: 37.
```

If you do provide a message (for example, `throw new JsonException("Error occurred")`), the serializer still sets the [Path](#), [LineNumber](#), and [BytePositionInLine](#) properties.

NotSupportedException

If you throw a `NotSupportedException`, you always get the path information in the message. If you provide a message, the path information is appended to it. For example, the statement `throw new NotSupportedException("Error occurred.")` produces an error message like the following example:

Output

```
Error occurred. The unsupported member type is located on type  
'System.Collections.Generic.Dictionary`2[Samples.SummaryWords, System.Int32]'
```

```
.
```

```
Path: $.TemperatureRanges | LineNumber: 4 | BytePositionInLine: 24
```

When to throw which exception type

When the JSON payload contains tokens that are not valid for the type being deserialized, throw a `JsonException`.

When you want to disallow certain types, throw a `NotSupportedException`. This exception is what the serializer automatically throws for types that are not supported. For example, `System.Type` is not supported for security reasons, so an attempt to deserialize it results in a `NotSupportedException`.

You can throw other exceptions as needed, but they don't automatically include JSON path information.

Register a custom converter

Register a custom converter to make the `Serialize` and `Deserialize` methods use it. Choose one of the following approaches:

- Add an instance of the converter class to the `JsonSerializerOptions.Converters` collection.
- Apply the `[JsonConverter]` attribute to the properties that require the custom converter.
- Apply the `[JsonConverter]` attribute to a class or a struct that represents a custom value type.

Registration sample - Converters collection

Here's an example that makes the `DateTimeOffsetJsonConverter` the default for properties of type `DateTimeOffset`:

```
C#
```

```
var serializeOptions = new JsonSerializerOptions
{
    WriteIndented = true,
    Converters =
    {
        new DateTimeOffsetJsonConverter()
    }
};
```

```
jsonString = JsonSerializer.Serialize(weatherForecast, serializeOptions);
```

Suppose you serialize an instance of the following type:

C#

```
public class WeatherForecast
{
    public DateTimeOffset Date { get; set; }
    public int TemperatureCelsius { get; set; }
    public string? Summary { get; set; }
}
```

Here's an example of JSON output that shows the custom converter was used:

JSON

```
{
    "Date": "08/01/2019",
    "TemperatureCelsius": 25,
    "Summary": "Hot"
}
```

The following code uses the same approach to deserialize using the custom `DateTimeOffset` converter:

C#

```
var deserializeOptions = new JsonSerializerOptions();
deserializeOptions.Converters.Add(new DateTimeOffsetJsonConverter());
weatherForecast = JsonSerializer.Deserialize<WeatherForecast>(jsonString,
deserializeOptions);
```

Registration sample - [JsonConverter] on a property

The following code selects a custom converter for the `Date` property:

C#

```
public class WeatherForecastWithConverterAttribute
{
    [JsonConverter(typeof(DateTimeOffsetJsonConverter))]
    public DateTimeOffset Date { get; set; }
```

```
    public int TemperatureCelsius { get; set; }
    public string? Summary { get; set; }
}
```

The code to serialize `WeatherForecastWithConverterAttribute` doesn't require the use of `JsonSerializeOptions.Converters`:

```
C#  
  
var serializeOptions = new JsonSerializerOptions
{
    WriteIndented = true
};
jsonString = JsonSerializer.Serialize(weatherForecast, serializeOptions);
```

The code to deserialize also doesn't require the use of `Converters`:

```
C#  
  
weatherForecast =
JsonSerializer.Deserialize<WeatherForecastWithConverterAttribute>
(jsonString);
```

Registration sample - [JsonConverter] on a type

Here's code that creates a struct and applies the `[JsonConverter]` attribute to it:

```
C#  
  
using System.Text.Json.Serialization;  
  
namespace SystemTextJsonSamples
{
    [JsonConverter(typeof(TemperatureConverter))]
    public struct Temperature
    {
        public Temperature(int degrees, bool celsius)
        {
            Degrees = degrees;
            IsCelsius = celsius;
        }

        public int Degrees { get; }
        public bool IsCelsius { get; }
        public bool IsFahrenheit => !IsCelsius;
    }
}
```

```

        public override string ToString() =>
            $"{{Degrees}}{{(IsCelsius ? "C" : "F")}}";

        public static Temperature Parse(string input)
        {
            int degrees = int.Parse(input.Substring(0, input.Length - 1));
            bool celsius = input.Substring(input.Length - 1) == "C";

            return new Temperature(degrees, celsius);
        }
    }
}

```

Here's the custom converter for the preceding struct:

C#

```

using System.Text.Json;
using System.Text.Json.Serialization;

namespace SystemTextJsonSamples
{
    public class TemperatureConverter : JsonConverter<Temperature>
    {
        public override Temperature Read(
            ref Utf8JsonReader reader,
            Type typeToConvert,
            JsonSerializerOptions options) =>
            Temperature.Parse(reader.GetString()!);

        public override void Write(
            Utf8JsonWriter writer,
            Temperature temperature,
            JsonSerializerOptions options) =>
            writer.WriteStringValue(temperature.ToString());
    }
}

```

The `[JsonConverter]` attribute on the struct registers the custom converter as the default for properties of type `Temperature`. The converter is automatically used on the `TemperatureCelsius` property of the following type when you serialize or deserialize it:

C#

```

public class WeatherForecastWithTemperatureStruct
{
    public DateTimeOffset Date { get; set; }
    public Temperature TemperatureCelsius { get; set; }
    public string? Summary { get; set; }
}

```

Converter registration precedence

During serialization or deserialization, a converter is chosen for each JSON element in the following order, listed from highest priority to lowest:

- `[JsonConverter]` applied to a property.
- A converter added to the `Converters` collection.
- `[JsonConverter]` applied to a custom value type or POCO.

If multiple custom converters for a type are registered in the `Converters` collection, the first converter that returns `true` for `CanConvert` is used.

A built-in converter is chosen only if no applicable custom converter is registered.

Converter samples for common scenarios

The following sections provide converter samples that address some common scenarios that built-in functionality doesn't handle.

- [Deserialize inferred types to object properties](#).
- [Support round trip for Stack types](#).
- [Use default system converter](#).

For a sample `DataTable` converter, see [Supported collection types](#).

Deserialize inferred types to object properties

When deserializing to a property of type `object`, a `JsonElement` object is created. The reason is that the deserializer doesn't know what CLR type to create, and it doesn't try to guess. For example, if a JSON property has "true", the deserializer doesn't infer that the value is a `Boolean`, and if an element has "01/01/2019", the deserializer doesn't infer that it's a `DateTime`.

Type inference can be inaccurate. If the deserializer parses a JSON number that has no decimal point as a `long`, that might result in out-of-range issues if the value was originally serialized as a `ulong` or `BigInteger`. Parsing a number that has a decimal point as a `double` might lose precision if the number was originally serialized as a `decimal`.

For scenarios that require type inference, the following code shows a custom converter for `object` properties. The code converts:

- `true` and `false` to `Boolean`

- Numbers without a decimal to `long`
- Numbers with a decimal to `double`
- Dates to `DateTime`
- Strings to `string`
- Everything else to `JsonElement`

C#

```
using System.Text.Json;
using System.Text.Json.Serialization;

namespace CustomConverterInferredTypesToObject
{
    public class ObjectToInferredTypesConverter : JsonConverter<object>
    {
        public override object Read(
            ref Utf8JsonReader reader,
            Type typeToConvert,
            JsonSerializerOptions options) => reader.TokenType switch
        {
            JsonTokenType.True => true,
            JsonTokenType.False => false,
            JsonTokenType.Number when reader.TryGetInt64(out long l) =>
l,
            JsonTokenType.Number => reader.GetDouble(),
            JsonTokenType.String when reader.TryGetDateTime(out DateTime
datetime) => datetime,
            JsonTokenType.String => reader.GetString()!,
            _ => JsonDocument.ParseValue(ref reader).RootElement.Clone()
        };

        public override void Write(
            Utf8JsonWriter writer,
            object objectToWrite,
            JsonSerializerOptions options) =>
            JsonSerializer.Serialize(writer, objectToWrite,
objectToWrite.GetType(), options);
    }

    public class WeatherForecast
    {
        public object? Date { get; set; }
        public object? TemperatureCelsius { get; set; }
        public object? Summary { get; set; }
    }

    public class Program
    {
        public static void Main()
        {
            string jsonString = @"
""Date"": ""2019-08-01T00:00:00-07:00"",
            "Temperature": 65,
            "Summary": "Partly Cloudy"
        }
    }
}
```

```

        "TemperatureCelsius": 25,
        "Summary": "Hot"
    };

    WeatherForecast weatherForecast =
JsonSerializer.Deserialize<WeatherForecast>(jsonString)!;
    Console.WriteLine($"Type of Date property no converter =
{weatherForecast.Date!.GetType()}");

    var options = new JsonSerializerOptions();
    options.WriteIndented = true;
    options.Converters.Add(new ObjectToInferredTypesConverter());
    weatherForecast = JsonSerializer.Deserialize<WeatherForecast>
(jsonString, options)!;
    Console.WriteLine($"Type of Date property with converter =
{weatherForecast.Date!.GetType()}");

    Console.WriteLine(JsonSerializer.Serialize(weatherForecast,
options));
}
}

// Produces output like the following example:
//
//Type of Date property no converter = System.Text.Json.JsonElement
//Type of Date property with converter = System.DateTime
//{
//  "Date": "2019-08-01T00:00:00-07:00",
//  "TemperatureCelsius": 25,
//  "Summary": "Hot"
//}

```

The example shows the converter code and a `WeatherForecast` class with `object` properties. The `Main` method deserializes a JSON string into a `WeatherForecast` instance, first without using the converter, and then using the converter. The console output shows that without the converter, the run-time type for the `Date` property is `JsonElement`; with the converter, the run-time type is `DateTime`.

The [unit tests folder](#) in the `System.Text.Json.Serialization` namespace has more examples of custom converters that handle deserialization to `object` properties.

Support polymorphic deserialization

.NET 7 provides support for both [polymorphic serialization and deserialization](#). However, in previous .NET versions, there was limited polymorphic serialization support and no support for deserialization. If you're using .NET 6 or an earlier version, deserialization requires a custom converter.

Suppose, for example, you have a `Person` abstract base class, with `Employee` and `Customer` derived classes. Polymorphic deserialization means that at design time you can specify `Person` as the deserialization target, and `Customer` and `Employee` objects in the JSON are correctly deserialized at run time. During deserialization, you have to find clues that identify the required type in the JSON. The kinds of clues available vary with each scenario. For example, a discriminator property might be available or you might have to rely on the presence or absence of a particular property. The current release of `System.Text.Json` doesn't provide attributes to specify how to handle polymorphic deserialization scenarios, so custom converters are required.

The following code shows a base class, two derived classes, and a custom converter for them. The converter uses a discriminator property to do polymorphic deserialization. The type discriminator isn't in the class definitions but is created during serialization and is read during deserialization.

ⓘ Important

The example code requires JSON object name/value pairs to stay in order, which is not a standard requirement of JSON.

C#

```
public class Person
{
    public string? Name { get; set; }
}

public class Customer : Person
{
    public decimal CreditLimit { get; set; }
}

public class Employee : Person
{
    public string? OfficeNumber { get; set; }
}
```

C#

```
using System.Text.Json;
using System.Text.Json.Serialization;

namespace SystemTextJsonSamples
{
    public class PersonConverterWithTypeDiscriminator :
        JsonConverter<Person>
```

```
{  
    enum TypeDiscriminator  
    {  
        Customer = 1,  
        Employee = 2  
    }  
  
    public override bool CanConvert(Type typeToConvert) =>  
        typeof(Person).IsAssignableFrom(typeToConvert);  
  
    public override Person Read(  
        ref Utf8JsonReader reader, Type typeToConvert,  
        JsonSerializerOptions options)  
    {  
        if (reader.TokenType != JsonTokenType.StartObject)  
        {  
            throw new JsonException();  
        }  
  
        reader.Read();  
        if (reader.TokenType != JsonTokenType.PropertyName)  
        {  
            throw new JsonException();  
        }  
  
        string? propertyName = reader.GetString();  
        if (propertyName != "TypeDiscriminator")  
        {  
            throw new JsonException();  
        }  
  
        reader.Read();  
        if (reader.TokenType != JsonTokenType.Number)  
        {  
            throw new JsonException();  
        }  
  
        TypeDiscriminator typeDiscriminator =  
(TypeDiscriminator)reader.GetInt32();  
        Person person = typeDiscriminator switch  
        {  
            TypeDiscriminator.Customer => new Customer(),  
            TypeDiscriminator.Employee => new Employee(),  
            _ => throw new JsonException()  
        };  
  
        while (reader.Read())  
        {  
            if (reader.TokenType == JsonTokenType.EndObject)  
            {  
                return person;  
            }  
  
            if (reader.TokenType == JsonTokenType.PropertyName)  
            {  
                throw new JsonException();  
            }  
        }  
    }  
}
```

```

        propertyName = reader.GetString();
        reader.Read();
        switch (propertyName)
        {
            case "CreditLimit":
                decimal creditLimit = reader.GetDecimal();
                ((Customer)person).CreditLimit = creditLimit;
                break;
            case "OfficeNumber":
                string? officeNumber = reader.GetString();
                ((Employee)person).OfficeNumber = officeNumber;
                break;
            case "Name":
                string? name = reader.GetString();
                person.Name = name;
                break;
        }
    }

    throw new JsonException();
}

public override void Write(
    Utf8JsonWriter writer, Person person, JsonSerializerOptions
options)
{
    writer.WriteStartObject();

    if (person is Customer customer)
    {
        writer.WriteNumber("TypeDiscriminator",
(int)TypeDiscriminator.Customer);
        writer.WriteNumber("CreditLimit", customer.CreditLimit);
    }
    else if (person is Employee employee)
    {
        writer.WriteNumber("TypeDiscriminator",
(int)TypeDiscriminator.Employee);
        writer.WriteString("OfficeNumber", employee.OfficeNumber);
    }

    writer.WriteString("Name", person.Name);

    writer.WriteEndObject();
}
}
}

```

The following code registers the converter:

C#

```
var serializeOptions = new JsonSerializerOptions();
serializeOptions.Converters.Add(new PersonConverterWithTypeDiscriminator());
```

The converter can deserialize JSON that was created by using the same converter to serialize, for example:

JSON

```
[  
  {  
    "TypeDiscriminator": 1,  
    "CreditLimit": 10000,  
    "Name": "John"  
  },  
  {  
    "TypeDiscriminator": 2,  
    "OfficeNumber": "555-1234",  
    "Name": "Nancy"  
  }  
]
```

The converter code in the preceding example reads and writes each property manually. An alternative is to call `Deserialize` or `Serialize` to do some of the work. For an example, see [this StackOverflow post](#).

An alternative way to do polymorphic deserialization

You can call `Deserialize` in the `Read` method:

- Make a clone of the `Utf8JsonReader` instance. Since `Utf8JsonReader` is a struct, this just requires an assignment statement.
- Use the clone to read through the discriminator tokens.
- Call `Deserialize` using the original `Reader` instance once you know the type you need. You can call `Deserialize` because the original `Reader` instance is still positioned to read the begin object token.

A disadvantage of this method is you can't pass in the original options instance that registers the converter to `Deserialize`. Doing so would cause a stack overflow, as explained in [Required properties](#). The following example shows a `Read` method that uses this alternative:

C#

```

public override Person Read(
    ref Utf8JsonReader reader, Type typeToConvert, JsonSerializerOptions
options)
{
    Utf8JsonReader readerClone = reader;

    if (readerClone.TokenType != JsonTokenType.StartObject)
    {
        throw new JsonException();
    }

    readerClone.Read();
    if (readerClone.TokenType != JsonTokenType.PropertyName)
    {
        throw new JsonException();
    }

    string? propertyName = readerClone.GetString();
    if (propertyName != "TypeDiscriminator")
    {
        throw new JsonException();
    }

    readerClone.Read();
    if (readerClone.TokenType != JsonTokenType.Number)
    {
        throw new JsonException();
    }

    TypeDiscriminator typeDiscriminator =
(TypeDiscriminator)readerClone.GetInt32();
    Person person = typeDiscriminator switch
    {
        TypeDiscriminator.Customer => JsonSerializer.Deserialize<Customer>
(ref reader)!, 
        TypeDiscriminator.Employee => JsonSerializer.Deserialize<Employee>
(ref reader)!, 
        _ => throw new JsonException()
    };
    return person;
}

```

Support round trip for `Stack` types

If you deserialize a JSON string into a `Stack` object and then serialize that object, the contents of the stack are in reverse order. This behavior applies to the following types and interfaces, and user-defined types that derive from them:

- `Stack`
- `Stack<T>`

- [ConcurrentStack<T>](#)
- [ImmutableStack<T>](#)
- [IImmutableStack<T>](#)

To support serialization and deserialization that retains the original order in the stack, a custom converter is required.

The following code shows a custom converter that enables round-tripping to and from `Stack<T>` objects:

C#

```
using System.Diagnostics;
using System.Reflection;
using System.Text.Json;
using System.Text.Json.Serialization;

namespace SystemTextJsonSamples
{
    public class JsonConverterFactoryForStackOfT : JsonConverterFactory
    {
        public override bool CanConvert(Type typeToConvert)
            => typeToConvert.IsGenericType
            && typeToConvert.GetGenericTypeDefinition() == typeof(Stack<>);

        public override JsonConverter CreateConverter(
            Type typeToConvert, JsonSerializerOptions options)
        {
            Debug.Assert(typeToConvert.IsGenericType &&
                typeToConvert.GetGenericTypeDefinition() ==
typeof(Stack<>));

            Type elementType = typeToConvert.GetGenericArguments()[0];

            JsonConverter converter =
(JsonConverter)Activator.CreateInstance(
    typeof(JsonConverterForStackOfT<>)
        .MakeGenericType(new Type[] { elementType }),
    BindingFlags.Instance | BindingFlags.Public,
    binder: null,
    args: null,
    culture: null)!;

            return converter;
        }
    }

    public class JsonConverterForStackOfT<T> : JsonConverter<Stack<T>>
    {
        public override Stack<T> Read(
            ref Utf8JsonReader reader, Type typeToConvert,
            JsonSerializerOptions options)
```

```

    {
        if (reader.TokenType != JsonTokenType.StartArray)
        {
            throw new JsonException();
        }
        reader.Read();

        var elements = new Stack<T>();

        while (reader.TokenType != JsonTokenType.EndArray)
        {
            elements.Push(JsonSerializer.Deserialize<T>(ref reader,
options)!);

            reader.Read();
        }

        return elements;
    }

    public override void Write(
        Utf8JsonWriter writer, Stack<T> value, JsonSerializerOptions
options)
{
    writer.WriteStartArray();

    var reversed = new Stack<T>(value);

    foreach (T item in reversed)
    {
        JsonSerializer.Serialize(writer, item, options);
    }

    writer.WriteEndArray();
}
}
}

```

The following code registers the converter:

```

C#

var options = new JsonSerializerOptions
{
    Converters = { new JsonConverterFactoryForStackOfT() },
};

```

Use default system converter

In some scenarios, you might want to use the default system converter in a custom converter. To do that, get the system converter from the `JsonSerializerOptions.Default` property, as shown in the following example:

C#

```
public class MyCustomConverter : JsonConverter<int>
{
    private readonly static JsonConverter<int> s_defaultConverter =
        (JsonConverter<int>)JsonSerializerOptions.Default.GetConverter(typeof(int));

    // Custom serialization logic
    public override void Write(
        Utf8JsonWriter writer, int value, JsonSerializerOptions options)
    {
        writer.WriteStringValue(value.ToString());
    }

    // Fall back to default deserialization logic
    public override int Read(
        ref Utf8JsonReader reader, Type typeToConvert, JsonSerializerOptions options)
    {
        return s_defaultConverter.Read(ref reader, typeToConvert, options);
    }
}
```

Handle null values

By default, the serializer handles null values as follows:

- For reference types and `Nullable<T>` types:
 - It does not pass `null` to custom converters on serialization.
 - It does not pass `JsonTokenType.Null` to custom converters on deserialization.
 - It returns a `null` instance on deserialization.
 - It writes `null` directly with the writer on serialization.
- For non-nullable value types:
 - It passes `JsonTokenType.Null` to custom converters on deserialization. (If no custom converter is available, a `JsonException` exception is thrown by the internal converter for the type.)

This null-handling behavior is primarily to optimize performance by skipping an extra call to the converter. In addition, it avoids forcing converters for nullable types to check for `null` at the start of every `Read` and `Write` method override.

To enable a custom converter to handle `null` for a reference or value type, override `JsonConverter<T>.HandleNull` to return `true`, as shown in the following example:

C#

```
using System.Text.Json;
using System.Text.Json.Serialization;

namespace CustomConverterHandleNull
{
    public class Point
    {
        public int X { get; set; }
        public int Y { get; set; }

        [JsonConverter(typeof(DescriptionConverter))]
        public string? Description { get; set; }
    }

    public class DescriptionConverter : JsonConverter<string>
    {
        public override bool HandleNull => true;

        public override string Read(
            ref Utf8JsonReader reader,
            Type typeToConvert,
            JsonSerializerOptions options) =>
            reader.GetString() ?? "No description provided.";

        public override void Write(
            Utf8JsonWriter writer,
            string value,
            JsonSerializerOptions options) =>
            writer.WriteStringValue(value);
    }
}

public class Program
{
    public static void Main()
    {
        string json = @"""x"":1,""y"":2,""Description"":null};

        Point point = JsonSerializer.Deserialize<Point>(json)!;
        Console.WriteLine($"Description: {point.Description}");
    }
}

// Produces output like the following example:
// 
//Description: No description provided.
```

Preserve references

By default, reference data is only cached for each call to `Serialize` or `Deserialize`. To persist references from one `Serialize/Deserialize` call to another one, root the `ReferenceResolver` instance in the call site of `Serialize/Deserialize`. The following code shows an example for this scenario:

- You write a custom converter for the `Company` type.
- You don't want to manually serialize the `Supervisor` property, which is an `Employee`. You want to delegate that to the serializer and you also want to preserve the references that you have already saved.

Here are the `Employee` and `Company` classes:

```
C#  
  
public class Employee  
{  
    public string? Name { get; set; }  
    public Employee? Manager { get; set; }  
    public List<Employee>? DirectReports { get; set; }  
    public Company? Company { get; set; }  
}  
  
public class Company  
{  
    public string? Name { get; set; }  
    public Employee? Supervisor { get; set; }  
}
```

The converter looks like this:

```
C#  
  
class CompanyConverter : JsonConverter<Company>  
{  
    public override Company Read(ref Utf8JsonReader reader, Type  
typeToConvert, JsonSerializerOptions options)  
    {  
        throw new NotImplementedException();  
    }  
  
    public override void Write(Utf8JsonWriter writer, Company value,  
JsonSerializerOptions options)  
    {  
        writer.WriteStartObject();  
  
        writer.WriteString("Name", value.Name);  
    }  
}
```

```

        writer.WritePropertyName("Supervisor");
        JsonSerializer.Serialize(writer, value.Supervisor, options);

        writer.WriteEndObject();
    }
}

```

A class that derives from [ReferenceResolver](#) stores the references in a dictionary:

C#

```

class MyReferenceResolver : ReferenceResolver
{
    private uint _referenceCount;
    private readonly Dictionary<string, object> _referenceIdToObjectMap =
    new ();
    private readonly Dictionary<object, string> _objectToReferenceIdMap =
    new (ReferenceEqualityComparer.Instance);

    public override void AddReference(string referenceId, object value)
    {
        if (!_referenceIdToObjectMap.TryAdd(referenceId, value))
        {
            throw new JsonException();
        }
    }

    public override string GetReference(object value, out bool
alreadyExists)
    {
        if (_objectToReferenceIdMap.TryGetValue(value, out string?
referenceId))
        {
            alreadyExists = true;
        }
        else
        {
            _referenceCount++;
            referenceId = _referenceCount.ToString();
            _objectToReferenceIdMap.Add(value, referenceId);
            alreadyExists = false;
        }
    }

    return referenceId;
}

public override object ResolveReference(string referenceId)
{
    if (!_referenceIdToObjectMap.TryGetValue(referenceId, out object?
value))
    {
        throw new JsonException();
    }
}

```

```
        }

        return value;
    }
}
```

A class that derives from [ReferenceHandler](#) holds an instance of [MyReferenceResolver](#) and creates a new instance only when needed (in a method named `Reset` in this example):

C#

```
class MyReferenceHandler : ReferenceHandler
{
    public MyReferenceHandler() => Reset();

    private ReferenceResolver? _rootedResolver;
    public override ReferenceResolver CreateResolver() => _rootedResolver!;
    public void Reset() => _rootedResolver = new MyReferenceResolver();

}
```

When the sample code calls the serializer, it uses a [JsonSerializerOptions](#) instance in which the [ReferenceHandler](#) property is set to an instance of [MyReferenceHandler](#). When you follow this pattern, be sure to reset the [ReferenceResolver](#) dictionary when you're finished serializing, to keep it from growing forever.

C#

```
var options = new JsonSerializerOptions();

options.Converters.Add(new CompanyConverter());
var myReferenceHandler = new MyReferenceHandler();
options.ReferenceHandler = myReferenceHandler;
options.DefaultIgnoreCondition = JsonIgnoreCondition.WhenWritingNull;
options.WriteIndented = true;

string str = JsonSerializer.Serialize(tyler, options);

// Reset after serializing to avoid out of bounds memory growth in the
// resolver.
myReferenceHandler.Reset();
```

The preceding example only does serialization, but a similar approach can be adopted for deserialization.

Other custom converter samples

The [Migrate from Newtonsoft.Json to System.Text.Json](#) article contains additional samples of custom converters.

The [unit tests folder ↗](#) in the `System.Text.Json.Serialization` source code includes other custom converter samples, such as:

- [Int32 converter that converts null to 0 on deserialize ↗](#)
- [Int32 converter that allows both string and number values on deserialize ↗](#)
- [Enum converter ↗](#)
- [List<T> converter that accepts external data ↗](#)
- [Long\[\] converter that works with a comma-delimited list of numbers ↗](#)

If you need to make a converter that modifies the behavior of an existing built-in converter, you can get [the source code of the existing converter ↗](#) to serve as a starting point for customization.

Customize a JSON contract

Article • 06/16/2023

The [System.Text.Json](#) library constructs a JSON *contract* for each .NET type, which defines how the type should be serialized and deserialized. The contract is derived from the type's shape, which includes characteristics such as its properties and fields and whether it implements the [IEnumerable](#) or [IDictionary](#) interface. Types are mapped to contracts either at run time using reflection or at compile time using the source generator.

Starting in .NET 7, you can customize these JSON contracts to provide more control over how types are converted into JSON and vice versa. The following list shows just some examples of the types of customizations you can make to serialization and deserialization:

- Serialize private fields and properties.
- Support multiple names for a single property (for example, if a previous library version used a different name).
- Ignore properties with a specific name, type, or value.
- Distinguish between explicit `null` values and the lack of a value in the JSON payload.
- Support [System.Runtime.Serialization](#) attributes, such as [DataContractAttribute](#). For more information, see [System.Runtime.Serialization attributes](#).
- Throw an exception if the JSON includes a property that's not part of the target type. For more information, see [Handle missing members](#).

How to opt in

There are two ways to plug into customization. Both involve obtaining a resolver, whose job is to provide a [JsonTypeInfo](#) instance for each type that needs to be serialized.

- By calling the [DefaultJsonTypeInfoResolver\(\)](#) constructor to obtain the [JsonSerializerOptions.TypeInfoResolver](#) and adding your [custom actions](#) to its [Modifiers](#) property.

For example:

```
C#  
  
JsonSerializerOptions options = new()  
{  
    TypeInfoResolver = new DefaultJsonTypeInfoResolver
```

```

    {
        Modifiers =
        {
            MyCustomModifier1,
            MyCustomModifier2
        }
    };
}

```

If you add multiple modifiers, they'll be called sequentially.

- By writing a custom resolver that implements [IJsonTypeInfoResolver](#).
 - If a type isn't handled, [IJsonTypeInfoResolver.GetTypeInfo](#) should return `null` for that type.
 - You can also combine your custom resolver with others, for example, the default resolver. The resolvers will be queried in order until a non-null [JsonTypeInfo](#) value is returned for the type.

Configurable aspects

The [JsonTypeInfo.Kind](#) property indicates how the converter serializes a given type—for example, as an object or as an array, and whether its properties are serialized. You can query this property to determine which aspects of a type's JSON contract you can configure. There are four different kinds:

| <code>JsonTypeInfo.Kind</code> | Description |
|---|---|
| JsonTypeInfoKind.Object | The converter will serialize the type into a JSON object and uses its properties. This kind is used for most class and struct types and allows for the most flexibility. |
| JsonTypeInfoKind.Enumerable | The converter will serialize the type into a JSON array. This kind is used for types like <code>List<T></code> and array. |
| JsonTypeInfoKind.Dictionary | The converter will serialize the type into a JSON object. This kind is used for types like <code>Dictionary<K, V></code> . |
| JsonTypeInfoKind.None | The converter doesn't specify how it will serialize the type or what <code>JsonTypeInfo</code> properties it will use. This kind is used for types like System.Object , <code>int</code> , and <code>string</code> , and for all types that use a custom converter. |

Modifiers

A modifier is an `Action<JsonTypeInfo>` or a method with a `JsonTypeInfo` parameter that gets the current state of the contract as an argument and makes modifications to the contract. For example, you could iterate through the prepopulated properties on the specified `JsonTypeInfo` to find the one you're interested in and then modify its `JsonPropertyInfo.Get` property (for serialization) or `JsonPropertyInfo.Set` property (for deserialization). Or, you can construct a new property using `JsonTypeInfo.CreateJsonPropertyInfo(Type, String)` and add it to the `JsonTypeInfo.Properties` collection.

The following table shows the modifications you can make and how to achieve them.

| Modification | Applicable <code>JsonTypeInfo.Kind</code> | How to achieve it | Example |
|---|--|---|--|
| Customize a property's value | <code>JsonTypeInfoKind.Object</code> | Modify the <code>JsonPropertyInfo.Get</code> delegate (for serialization) or <code>JsonPropertyInfo.Set</code> delegate (for deserialization) for the property. | Increment a property's value |
| Add or remove properties | <code>JsonTypeInfoKind.Object</code> | Add or remove items from the <code>JsonTypeInfo.Properties</code> list. | Serialize private fields |
| Conditionally serialize a property | <code>JsonTypeInfoKind.Object</code> | Modify the <code>JsonPropertyInfo.ShouldSerialize</code> predicate for the property. | Ignore properties with a specific type |
| Customize number handling for a specific type | <code>JsonTypeInfoKind.None</code> | Modify the <code>JsonTypeInfo.NumberHandling</code> value for the type. | Allow int values to be strings |

Example: Increment a property's value

Consider the following example where the modifier increments the value of a certain property on deserialization by modifying its `JsonPropertyInfo.Set` delegate. Besides defining the modifier, the example also introduces a new attribute that it uses to locate the property whose value should be incremented. This is an example of *customizing a property*.

C#

```
using System.Text.Json;
using System.Text.Json.Serialization.Metadata;
```

```

namespace Serialization
{
    // Custom attribute to annotate the property
    // we want to be incremented.
    [AttributeUsage(AttributeTargets.Property)]
    class SerializationCountAttribute : Attribute
    {
    }

    // Example type to serialize and deserialize.
    class Product
    {
        public string Name { get; set; } = "";
        [SerializationCount]
        public int RoundTrips { get; set; }
    }

    public class SerializationCountExample
    {
        // Custom modifier that increments the value
        // of a specific property on deserialization.
        static void IncrementCounterModifier(JsonTypeInfo typeInfo)
        {
            foreach (JsonPropertyInfo propertyInfo in typeInfo.Properties)
            {
                if (propertyInfo.PropertyType != typeof(int))
                    continue;

                object[] serializationCountAttributes =
                    propertyInfo.AttributeProvider?.GetCustomAttributes(typeof(SerializationCountAttribute), true) ?? Array.Empty<object>();
                SerializationCountAttribute? attribute =
                    serializationCountAttributes.Length == 1 ?
                    (SerializationCountAttribute)serializationCountAttributes[0] : null;

                if (attribute != null)
                {
                    Action<object, object?>? setProperty = propertyInfo.Set;
                    if (setProperty is not null)
                    {
                        propertyInfo.Set = (obj, value) =>
                        {
                            if (value != null)
                            {
                                // Increment the value by 1.
                                value = (int)value + 1;
                            }
                            setProperty (obj, value);
                        };
                    }
                }
            }
        }
    }
}

```

```

public static void RunIt()
{
    var product = new Product
    {
        Name = "Aquafresh"
    };

    JsonSerializerOptions options = new()
    {
        TypeInfoResolver = new DefaultJsonTypeInfoResolver
        {
            Modifiers = { IncrementCounterModifier }
        }
    };

    // First serialization and deserialization.
    string serialized = JsonSerializer.Serialize(product, options);
    Console.WriteLine(serialized);
    // {"Name":"Aquafresh","RoundTrips":0}

    Product deserialized = JsonSerializer.Deserialize<Product>
(serialized, options)!;
    Console.WriteLine($"{deserialized.RoundTrips}");
    // 1

    // Second serialization and deserialization.
    serialized = JsonSerializer.Serialize(deserialized, options);
    Console.WriteLine(serialized);
    // {"Name":"Aquafresh","RoundTrips":1}

    deserialized = JsonSerializer.Deserialize<Product>(serialized,
options)!;
    Console.WriteLine($"{deserialized.RoundTrips}");
    // 2
}
}

```

Notice in the output that the value of `RoundTrips` is incremented each time the `Product` instance is deserialized.

Example: Serialize private fields

By default, `System.Text.Json` ignores private fields and properties. This example adds a new class-wide attribute, `JsonIncludePrivateFieldsAttribute`, to change that default. If the modifier finds the attribute on a type, it adds all the private fields on the type as new properties to `JsonTypeInfo`.

```
using System.Reflection;
using System.Text.Json;
using System.Text.Json.Serialization;
using System.Text.Json.Serialization.Metadata;

namespace Serialization
{
    [AttributeUsage(AttributeTargets.Class | AttributeTargets.Struct)]
    public class JsonIncludePrivateFieldsAttribute : Attribute { }

    [JsonIncludePrivateFields]
    public class Human
    {
        private string _name;
        private int _age;

        public Human()
        {
            // This constructor should be used only by deserializers.
            _name = null!;
            _age = 0;
        }

        public static Human Create(string name, int age)
        {
            Human h = new()
            {
                _name = name,
                _age = age
            };

            return h;
        }

        [JsonIgnore]
        public string Name
        {
            get => _name;
            set => throw new NotSupportedException();
        }

        [JsonIgnore]
        public int Age
        {
            get => _age;
            set => throw new NotSupportedException();
        }
    }

    public class PrivateFieldsExample
    {
        static void AddPrivateFieldsModifier(JsonTypeInfo jsonTypeInfo)
        {
            if (jsonTypeInfo.Kind != JsonTypeInfoKind.Object)
```

```

        return;

        if
(!jsonTypeInfo.Type.isDefined(typeof(JsonIncludePrivateFieldsAttribute),
inherit: false))
        return;

        foreach (FieldInfo field in
jsonTypeInfo.Type.GetFields(BindingFlags.Instance | BindingFlags.NonPublic))
{
    JsonPropertyInfo json PropertyInfo =
jsonTypeInfo.CreateJsonPropertyInfo(field.FieldType, field.Name);
    json PropertyInfo.Get = field.GetValue;
    json PropertyInfo.Set = field.SetValue;

    jsonTypeInfo.Properties.Add(json PropertyInfo);
}
}

public static void RunIt()
{
    var options = new JsonSerializerOptions
{
    TypeInfoResolver = new DefaultJsonTypeInfoResolver
    {
        Modifiers = { AddPrivateFieldsModifier }
    }
};

var human = Human.Create("Julius", 37);
string json = JsonSerializer.Serialize(human, options);
Console.WriteLine(json);
// {"_name":"Julius","_age":37}

Human deserializedHuman = JsonSerializer.Deserialize<Human>
(json, options)!;
Console.WriteLine($"[Name={deserializedHuman.Name}; Age=
{deserializedHuman.Age}]");
// [Name=Julius; Age=37]
}
}
}

```

Tip

If your private field names start with underscores, consider removing the underscores from the names when you add the fields as new JSON properties.

Example: Ignore properties with a specific type

Perhaps your model has properties with specific names or types that you don't want to expose to users. For example, you might have a property that stores credentials or some information that's useless to have in the payload.

The following example shows how to filter out properties with a specific type, `SecretHolder`. It does this by using an `IList<T>` extension method to remove any properties that have the specified type from the `JsonTypeInfo.Properties` list. The filtered properties completely disappear from the contract, which means `System.Text.Json` doesn't look at them either during serialization or deserialization.

C#

```
using System.Text.Json;
using System.Text.Json.Serialization.Metadata;

namespace Serialization
{
    class ExampleClass
    {
        public string Name { get; set; } = "";
        public SecretHolder? Secret { get; set; }
    }

    class SecretHolder
    {
        public string Value { get; set; } = "";
    }

    class IgnorePropertiesWithType
    {
        private readonly Type[] _ignoredTypes;

        public IgnorePropertiesWithType(params Type[] ignoredTypes)
            => _ignoredTypes = ignoredTypes;

        public void ModifyTypeInfo(JsonTypeInfo ti)
        {
            if (ti.Kind != JsonTypeInfoKind.Object)
                return;

            ti.Properties.RemoveAll(prop =>
                _ignoredTypes.Contains(prop.PropertyType));
        }
    }

    public class IgnoreTypeExample
    {
        public static void RunIt()
        {
            var modifier = new
                IgnorePropertiesWithType(typeof(SecretHolder));
        }
    }
}
```

```

JsonSerializerOptions options = new()
{
    TypeInfoResolver = new DefaultJsonTypeInfoResolver
    {
        Modifiers = { modifier.ModifyTypeInfo }
    }
};

ExampleClass obj = new()
{
    Name = "Password",
    Secret = new SecretHolder { Value = "MySecret" }
};

string output = JsonSerializer.Serialize(obj, options);
Console.WriteLine(output);
// {"Name": "Password"}
}

public static class ListHelpers
{
    // IList<T> implementation of List<T>.RemoveAll method.
    public static void RemoveAll<T>(this IList<T> list, Predicate<T>
predicate)
    {
        for (int i = 0; i < list.Count; i++)
        {
            if (predicate(list[i]))
            {
                list.RemoveAt(i--);
            }
        }
    }
}
}

```

Example: Allow int values to be strings

Perhaps your input JSON can contain quotes around one of the numeric types but not on others. If you had control over the class, you could place [JsonNumberHandlingAttribute](#) on the type to fix this, but you don't. Before .NET 7, you'd need to write a [custom converter](#) to fix this behavior, which requires writing a fair bit of code. Using contract customization, you can customize the number handling behavior for any type.

The following example changes the behavior for all `int` values. The example can be easily adjusted to apply to any type or for a specific property of any type.

C#

```
using System.Text.Json;
using System.Text.Json.Serialization;
using System.Text.Json.Serialization.Metadata;

namespace Serialization
{
    public class Point
    {
        public int X { get; set; }
        public int Y { get; set; }
    }

    public class AllowIntsAsStringsExample
    {
        static void SetNumberHandlingModifier(JsonTypeInfo jsonTypeInfo)
        {
            if (jsonTypeInfo.Type == typeof(int))
            {
                jsonTypeInfo.NumberHandling =
JsonNumberHandling.AllowReadingFromString;
            }
        }

        public static void RunIt()
        {
            JsonSerializerOptions options = new()
            {
                TypeInfoResolver = new DefaultJsonTypeInfoResolver
                {
                    Modifiers = { SetNumberHandlingModifier }
                }
            };

            // Triple-quote syntax is a C# 11 feature.
            Point point = JsonSerializer.Deserialize<Point>("""
{ "X": "12", "Y": "3" }""", options)!;
            Console.WriteLine($"({point.X},{point.Y})");
            // (12,3)
        }
    }
}
```

Without the modifier to allow reading `int` values from a string, the program would have ended with an exception:

Unhandled exception. System.Text.Json.JsonException: The JSON value could not be converted to System.Int32. Path: \$.X | LineNumber: 0 | BytePositionInLine: 9.

Other ways to customize serialization

Besides customizing a contract, there are other ways to influence serialization and deserialization behavior, including the following:

- By using attributes derived from [JsonAttribute](#), for example, [JsonIgnoreAttribute](#) and [JsonPropertyOrderAttribute](#).
- By modifying [JsonSerializerOptions](#), for example, to set a naming policy or serialize enumeration values as strings instead of numbers.
- By writing a custom converter that does the actual work of writing the JSON and, during deserialization, constructing an object.

Contract customization is an improvement over these pre-existing customizations because you might not have access to the type to add attributes, and writing a custom converter is complex and hurts performance.

XML and SOAP serialization

Article • 04/05/2023

XML serialization converts (serializes) the public fields and properties of an object, and the parameters and return values of methods, into an XML stream that conforms to a specific XML Schema definition language (XSD) document. XML serialization results in strongly typed classes with public properties and fields that are converted to a serial format (in this case, XML) for storage or transport.

Because XML is an open standard, the XML stream can be processed by any application, as needed, regardless of platform. For example, XML Web services created using ASP.NET use the [XmlSerializer](#) class to create XML streams that pass data between XML Web service applications throughout the Internet or on intranets. Conversely, deserialization takes such an XML stream and reconstructs the object.

XML serialization can also be used to serialize objects into XML streams that conform to the SOAP specification. SOAP is a protocol based on XML, designed specifically to transport procedure calls using XML.

To serialize or deserialize objects, use the [XmlSerializer](#) class. To create the classes to be serialized, use the XML Schema Definition tool.

XML serialization

Article • 04/05/2023

Serialization is the process of converting an object into a form that can be readily transported. For example, you can serialize an object and transport it over the Internet using HTTP between a client and a server. On the other end, deserialization reconstructs the object from the stream.

XML serialization serializes only the public fields and property values of an object into an XML stream. XML serialization does not include type information. For example, if you have a **Book** object that exists in the **Library** namespace, there is no guarantee that it is deserialized into an object of the same type.

ⓘ Note

XML serialization does not convert methods, indexers, private fields, or read-only properties (except read-only collections). To serialize all an object's fields and properties, both public and private, use the **DataContractSerializer** instead of XML serialization.

The central class in XML serialization is the **XmlSerializer** class, and the most important methods in this class are the **Serialize** and **Deserialize** methods. The **XmlSerializer** creates C# files and compiles them into .dll files to perform this serialization. The [XML Serializer Generator Tool \(Sgen.exe\)](#) is designed to generate these serialization assemblies in advance to be deployed with your application and improve startup performance. The XML stream generated by the **XmlSerializer** is compliant with the World Wide Web Consortium (W3C) [XML Schema definition language \(XSD\) 1.0 recommendation](#). Furthermore, the data types generated are compliant with the document titled "XML Schema Part 2: Datatypes."

The data in your objects is described using programming language constructs like classes, fields, properties, primitive types, arrays, and even embedded XML in the form of **XmlElement** or **XmlAttribute** objects. You have the option of creating your own classes, annotated with attributes, or using the XML Schema Definition tool to generate the classes based on an existing XML Schema.

If you have an XML Schema, you can run the XML Schema Definition tool to produce a set of classes that are strongly typed to the schema and annotated with attributes. When an instance of such a class is serialized, the generated XML adheres to the XML Schema. Provided with such a class, you can program against an easily manipulated

object model while being assured that the generated XML conforms to the XML schema. This is an alternative to using other classes in .NET, such as the **XmlReader** and **XmlWriter** classes, to parse and write an XML stream. For more information, see [XML Documents and Data](#). These classes allow you to parse any XML stream. In contrast, use the **XmlSerializer** when the XML stream is expected to conform to a known XML Schema.

Attributes control the XML stream generated by the **XmlSerializer** class, allowing you to set the XML namespace, element name, attribute name, and so on, of the XML stream. For more information about these attributes and how they control XML serialization, see [Controlling XML Serialization Using Attributes](#). For a table of those attributes that are used to control the generated XML, see [Attributes That Control XML Serialization](#).

The **XmlSerializer** class can further serialize an object and generate an encoded SOAP XML stream. The generated XML adheres to section 5 of the World Wide Web Consortium document titled "Simple Object Access Protocol (SOAP) 1.1." For more information about this process, see [How to: Serialize an Object as a SOAP-Encoded XML Stream](#). For a table of the attributes that control the generated XML, see [Attributes That Control Encoded SOAP Serialization](#).

The **XmlSerializer** class generates the SOAP messages created by, and passed to, XML Web services. To control the SOAP messages, you can apply attributes to the classes, return values, parameters, and fields found in an XML Web service file (.asmx). You can use both the attributes listed in "Attributes That Control XML Serialization" and "Attributes That Control Encoded SOAP Serialization" because an XML Web service can use either the literal or encoded SOAP style. For more information about using attributes to control the XML generated by an XML Web service, see [XML Serialization with XML Web Services](#). For more information about SOAP and XML Web services, see [Customizing SOAP Message Formatting](#).

Security Considerations for **XmlSerializer** Applications

When creating an application that uses the **XmlSerializer**, be aware of the following items and their implications:

- The **XmlSerializer** creates C# (.cs) files and compiles them into .dll files in the directory named by the TEMP environment variable; serialization occurs with those DLLs.

Note

These serialization assemblies can be generated in advance and signed by using the SGGen.exe tool. This does not work on a server of Web services. In other words, it is only for client use and for manual serialization.

The code and the DLLs are vulnerable to a malicious process at the time of creation and compilation. It might be possible for two or more users to share the TEMP directory. Sharing a TEMP directory is dangerous if the two accounts have different security privileges and the higher-privilege account runs an application using the **XmlSerializer**. In this case, one user can breach the computer's security by replacing either the .cs or .dll file that is compiled. To eliminate this concern, always be sure that each account on the computer has its own profile. By default, the TEMP environment variable points to a different directory for each account.

- If a malicious user sends a continuous stream of XML data to a Web server (a denial of service attack), then the **XmlSerializer** continues to process the data until the computer runs low on resources.

This kind of attack is eliminated if you are using a computer running Internet Information Services (IIS), and your application is running within IIS. IIS features a gate that does not process streams longer than a set amount (the default is 4 KB). If you create an application that does not use IIS and deserializes with the **XmlSerializer**, you should implement a similar gate that prevents a denial of service attack.

- The **XmlSerializer** serializes data and runs any code using any type given to it.

There are two ways in which a malicious object presents a threat. It could run malicious code or it could inject malicious code into the C# file created by the **XmlSerializer**. In the second case, there is a theoretical possibility that a malicious object may somehow inject code into the C# file created by the **XmlSerializer**. Although this issue has been examined thoroughly, and such an attack is considered unlikely, you should take the precaution of never serializing data with an unknown and untrusted type.

- Serialized sensitive data might be vulnerable.

After the **XmlSerializer** has serialized data, it can be stored as an XML file or other data store. If your data store is available to other processes, or is visible on an intranet or the Internet, the data can be stolen and used maliciously. For example, if you create an application that serializes orders that include credit card numbers, the data is highly sensitive. To help prevent this, always protect the store for your data and take steps to keep it private.

Serialization of a Simple Class

The following code example shows a basic class with a public field.

C#

```
public class OrderForm
{
    public DateTime OrderDate;
}
```

When an instance of this class is serialized, it might resemble the following.

XML

```
<OrderForm>
    <OrderDate>12/12/01</OrderDate>
</OrderForm>
```

For more examples of serialization, see [Examples of XML Serialization](#).

Items That Can Be Serialized

The following items can be serialized using the `XmlSerializer` class:

- Public read/write properties and fields of public classes.
- Classes that implement `ICollection` or `IEnumerable`.

 **Note**

Only collections are serialized, not public properties.

- `XmlElement` objects.
- `XmlNode` objects.
- `DataSet` objects.

For more information about serializing or deserializing objects, see [How to: Serialize an Object](#) and [How to: Deserialize an Object](#).

Advantages of Using XML Serialization

The **XmlSerializer** class gives you complete and flexible control when you serialize an object as XML. If you are creating an XML Web service, you can apply attributes that control serialization to classes and members to ensure that the XML output conforms to a specific schema.

For example, **XmlSerializer** enables you to:

- Specify whether a field or property should be encoded as an attribute or an element.
- Specify an XML namespace to use.
- Specify the name of an element or attribute if a field or property name is inappropriate.

Another advantage of XML serialization is that you have no constraints on the applications you develop, as long as the XML stream that is generated conforms to a given schema. Imagine a schema that is used to describe books. It features a title, author, publisher, and ISBN number element. You can develop an application that processes the XML data in any way you want, for example, as a book order, or as an inventory of books. In either case, the only requirement is that the XML stream conforms to the specified XML Schema definition language (XSD) schema.

XML Serialization Considerations

The following should be considered when using the **XmlSerializer** class:

- The Sgen.exe tool is expressly designed to generate serialization assemblies for optimum performance.
- The serialized data contains only the data itself and the structure of your classes. Type identity and assembly information are not included.
- Only public properties and fields can be serialized. Properties must have public accessors (get and set methods). If you must serialize non-public data, use the [DataContractSerializer](#) class rather than XML serialization.
- A class must have a parameterless constructor to be serialized by **XmlSerializer**.
- Methods cannot be serialized.
- **XmlSerializer** can process classes that implement **IEnumerable** or **ICollection** differently if they meet certain requirements, as follows.

A class that implements **IEnumerable** must implement a public **Add** method that takes a single parameter. The **Add** method's parameter must be consistent (polymorphic) with the type returned from the **IEnumerator.Current** property returned from the **GetEnumerator** method.

A class that implements **ICollection** in addition to **IEnumerable** (such as **CollectionBase**) must have a public **Item** indexed property (an indexer in C#) that takes an integer and it must have a public **Count** property of type **integer**. The parameter passed to the **Add** method must be the same type as that returned from the **Item** property, or one of that type's bases.

For classes that implement **ICollection**, values to be serialized are retrieved from the indexed **Item** property rather than by calling **GetEnumerator**. Also, public fields and properties are not serialized, with the exception of public fields that return another collection class (one that implements **ICollection**). For an example, see [Examples of XML Serialization](#).

XSD Data Type Mapping

The W3C document titled [XML Schema Part 2: Datatypes](#) specifies the simple data types that are allowed in an XML Schema definition language (XSD) schema. For many of these (for example, **int** and **decimal**), there is a corresponding data type in .NET. However, some XML data types do not have a corresponding .NET data type, for example, the **NMTOKEN** data type. In such cases, if you use the XML Schema Definition tool ([XML Schema Definition Tool \(Xsd.exe\)](#)) to generate classes from a schema, an appropriate attribute is applied to a member of type **string**, and its **DataType** property is set to the XML data type name. For example, if a schema contains an element named "MyToken" with the XML data type **NMTOKEN**, the generated class might contain a member as shown in the following example.

C#

```
[XmlElement(DataType = "NMTOKEN")]
public string MyToken;
```

Similarly, if you are creating a class that must conform to a specific XML Schema (XSD), you should apply the appropriate attribute and set its **DataType** property to the desired XML data type name.

For a complete list of type mappings, see the **DataType** property for any of the following attribute classes:

Examples of XML Serialization

Article • 03/18/2023

XML serialization can take more than one form, from simple to complex. For example, you can serialize a class that simply consists of public fields and properties, as shown in [Introducing XML Serialization](#). The following code examples address various advanced scenarios, including how to use XML serialization to generate an XML stream that conforms to a specific XML Schema (XSD) document.

Serializing a DataSet

Besides serializing an instance of a public class, you can also serialize an instance of a [DataSet](#), as shown in the following code example:

C#

```
private void SerializeDataSet(string filename)
{
    XmlSerializer ser = new XmlSerializer(typeof(DataSet));

    // Creates a DataSet; adds a table, column, and ten rows.
    DataSet ds = new DataSet("myDataSet");
    DataTable t = new DataTable("table1");
    DataColumn c = new DataColumn("thing");
    t.Columns.Add(c);
    ds.Tables.Add(t);
    DataRow r;

    for (int i = 0; i < 10; i++) {
        r = t.NewRow();
        r[0] = "Thing " + i;
        t.Rows.Add(r);
    }

    TextWriter writer = new StreamWriter(filename);
    ser.Serialize(writer, ds);
    writer.Close();
}
```

Serializing an XElement and XmlNode

You can also serialize instances of an [XmlElement](#) or [XmlNode](#) class, as shown in the following code example:

C#

```

private void SerializeElement(string filename)
{
    XmlSerializer ser = new XmlSerializer(typeof(XmlElement));
    XmlElement myElement = new XmlDocument().CreateElement("MyElement",
    "ns");
    myElement.InnerText = "Hello World";
    TextWriter writer = new StreamWriter(filename);
    ser.Serialize(writer, myElement);
    writer.Close();
}

private void SerializeNode(string filename)
{
    XmlSerializer ser = new XmlSerializer(typeof(XmlNode));
    XmlNode myNode = new XmlDocument();
    CreateNode(XmlNodeType.Element, "MyNode", "ns");
    myNode.InnerText = "Hello Node";
    TextWriter writer = new StreamWriter(filename);
    ser.Serialize(writer, myNode);
    writer.Close();
}

```

Serializing a class that contains a field returning a complex object

If a property or field returns a complex object (such as an array or a class instance), the `XmlSerializer` converts it to an element nested within the main XML document. For example, the first class in the following code example returns an instance of the second class:

C#

```

public class PurchaseOrder
{
    public Address MyAddress;
}

public record Address
{
    public string FirstName;
}

```

The serialized XML output might look like this:

XML

```
<PurchaseOrder>
  <MyAddress>
    <FirstName>George</FirstName>
  </MyAddress>
</PurchaseOrder>
```

Serializing an array of objects

You can also serialize a field that returns an array of objects, as shown in the following code example:

```
C#
public class PurchaseOrder
{
    public Item [] ItemsOrders;
}

public class Item
{
    public string ItemID;
    public decimal ItemPrice;
}
```

If two items are ordered, the serialized class instance might look like the following code:

XML

```
<PurchaseOrder xmlns:xsi="http://www.w3.org/2001/XMLSchema-instance"
  xmlns:xsd="http://www.w3.org/2001/XMLSchema">
  <ItemsOrders>
    <Item>
      <ItemID>aaa111</ItemID>
      <ItemPrice>34.22</ItemPrice>
    </Item>
    <Item>
      <ItemID>bbb222</ItemID>
      <ItemPrice>2.89</ItemPrice>
    </Item>
  </ItemsOrders>
</PurchaseOrder>
```

Serializing a class that implements the ICollection interface

You can create your own collection classes by implementing the [ICollection](#) interface and using the [XmlSerializer](#) to serialize instances of these classes.

① Note

When a class implements the [ICollection](#) interface, only the collection contained by the class is serialized. Any public properties or fields added to the class won't be serialized. To be serialized, the class must include an **Add** method and an **Item** property (C# indexer).

C#

```
using System;
using System.Collections;
using System.IO;
using System.Xml.Serialization;

public class Test
{
    static void Main()
    {
        Test t = new Test();
        t.SerializeCollection("coll.xml");
    }

    private void SerializeCollection(string filename)
    {
        Employees Emps = new Employees();
        // Note that only the collection is serialized -- not the
        // CollectionName or any other public property of the class.
        Emps.CollectionName = "Employees";
        Employee John100 = new Employee("John", "100xxx");
        Emps.Add(John100);
        XmlSerializer x = new XmlSerializer(typeof(Employees));
        TextWriter writer = new StreamWriter(filename);
        x.Serialize(writer, Emps);
    }
}

public class Employees : ICollection
{
    public string CollectionName;
    private ArrayList empArray = new ArrayList();

    public Employee this[int index] => (Employee) empArray[index];

    public void CopyTo(Array a, int index)
    {
        empArray.CopyTo(a, index);
    }
}
```

```

public int Count => empArray.Count;

public object SyncRoot => this;

public bool IsSynchronized => false;

public IEnumerator GetEnumerator() => empArray.GetEnumerator();

public void Add(Employee newEmployee)
{
    empArray.Add(newEmployee);
}
}

public class Employee
{
    public string EmpName;
    public string EmpID;

    public Employee() {}

    public Employee(string empName, string empID)
    {
        EmpName = empName;
        EmpID = empID;
    }
}

```

Purchase Order example

You can cut and paste the following example code into a text file and rename it with a .cs or .vb file name extension. Use the C# or Visual Basic compiler to compile the file. Then run it using the name of the executable.

This example uses a simple scenario to demonstrate how an instance of an object is created and serialized into a file stream using the [Serialize](#) method. The XML stream is saved to a file. The same file is then read and reconstructed into a copy of the original object using the [Deserialize](#) method.

In this example, a class named `PurchaseOrder` is serialized and then deserialized. A second class named `Address` is also included because the public field named `ShipTo` must be set to an `Address`. Similarly, an `OrderedItem` class is included because an array of `OrderedItem` objects must be set to the `OrderedItems` field. Finally, a class named `Test` contains the code that serializes and deserializes the classes.

The `CreatePO` method creates the `PurchaseOrder`, `Address`, and `OrderedItem` class objects and sets the public field values. The method also constructs an instance of the `XmlSerializer` class that's used to serialize and deserialize the `PurchaseOrder`.

ⓘ Note

The code passes the type of class that will be serialized to the constructor. The code also creates a `FileStream` that's used to write the XML stream to an XML document.

The `ReadPo` method is a little simpler. It just creates objects to deserialize and reads out their values. As with the `CreatePo` method, you must first construct an `XmlSerializer`, passing the type of class to be deserialized to the constructor. Also, a `FileStream` is required to read the XML document. To deserialize the objects, call the `Deserialize` method with the `FileStream` as an argument. The deserialized object must be cast to an object variable of type `PurchaseOrder`. The code then reads the values of the deserialized `PurchaseOrder`.

ⓘ Note

You can read the `PO.xml` file that's created to see the actual XML output.

C#

```
using System;
using System.IO;
using System.Xml;
using System.Xml.Serialization;

// The XmlRoot attribute allows you to set an alternate name
// (PurchaseOrder) for the XML element and its namespace. By
// default, the XmlSerializer uses the class name. The attribute
// also allows you to set the XML namespace for the element. Lastly,
// the attribute sets the IsNullable property, which specifies whether
// the xsi:null attribute appears if the class instance is set to
// a null reference.
[XmlRoot("PurchaseOrder", Namespace="http://www.cpandl.com",
IsNullable = false)]
public class PurchaseOrder
{
    public Address ShipTo;
    public string OrderDate;
    // The XmlArray attribute changes the XML element name
    // from the default of "OrderedItems" to "Items".
    [XmlArray("Items")]
}
```

```
    public OrderedItem[] OrderedItems;
    public decimal SubTotal;
    public decimal ShipCost;
    public decimal TotalCost;
}

public class Address
{
    // The XmlAttribute attribute instructs the XmlSerializer to serialize
    // the
    // Name field as an XML attribute instead of an XML element (XML element
    // is
    // the default behavior).
    [XmlAttribute]
    public string Name;
    public string Line1;

    // Setting the IsNullable property to false instructs the
    // XmlSerializer that the XML attribute will not appear if
    // the City field is set to a null reference.
    [XmlElement(IsNullable = false)]
    public string City;
    public string State;
    public string Zip;
}

public class OrderedItem
{
    public string ItemName;
    public string Description;
    public decimal UnitPrice;
    public int Quantity;
    public decimal LineTotal;

    // Calculate is a custom method that calculates the price per item
    // and stores the value in a field.
    public void Calculate()
    {
        LineTotal = UnitPrice * Quantity;
    }
}

public class Test
{
    public static void Main()
    {
        // Read and write purchase orders.
        Test t = new Test();
        t.CreatePO("po.xml");
        t.ReadPO("po.xml");
    }

    private void CreatePO(string filename)
    {
        // Creates an instance of the XmlSerializer class;
    }
}
```

```

// specifies the type of object to serialize.
XmlSerializer serializer = new XmlSerializer(typeof(PurchaseOrder));
TextWriter writer = new StreamWriter(filename);
PurchaseOrder po =new PurchaseOrder();

// Creates an address to ship and bill to.
Address billAddress = new Address();
billAddress.Name = "Teresa Atkinson";
billAddress.Line1 = "1 Main St.";
billAddress.City = "AnyTown";
billAddress.State = "WA";
billAddress.Zip = "00000";
// Sets ShipTo and BillTo to the same addressee.
po.ShipTo = billAddress;
po.OrderDate = System.DateTime.Now.ToString("yyyy-MM-dd");

// Creates an OrderedItem.
OrderedItem i1 = new OrderedItem();
i1.ItemName = "Widget S";
i1.Description = "Small widget";
i1.UnitPrice = (decimal) 5.23;
i1.Quantity = 3;
i1.Calculate();

// Inserts the item into the array.
OrderedItem [] items = {i1};
po.OrderedItems = items;
// Calculate the total cost.
decimal subTotal = new decimal();
foreach(OrderedItem oi in items)
{
    subTotal += oi.LineTotal;
}
po.SubTotal = subTotal;
po.ShipCost = (decimal) 12.51;
po.TotalCost = po.SubTotal + po.ShipCost;
// Serializes the purchase order, and closes the TextWriter.
serializer.Serialize(writer, po);
writer.Close();
}

protected void ReadPO(string filename)
{
    // Creates an instance of the XmlSerializer class;
    // specifies the type of object to be deserialized.
    XmlSerializer serializer = new XmlSerializer(typeof(PurchaseOrder));
    // If the XML document has been altered with unknown
    // nodes or attributes, handles them with the
    // UnknownNode and UnknownAttribute events.
    serializer.UnknownNode+= new
    XmlNodeEventHandler(serializer_UnknownNode);
    serializer.UnknownAttribute+= new
    XmlAttributeEventHandler(serializer_UnknownAttribute);

    // A FileStream is needed to read the XML document.
}

```

```

FileStream fs = new FileStream(filename, FileMode.Open);
// Declares an object variable of the type to be deserialized.
PurchaseOrder po;
// Uses the Deserialize method to restore the object's state
// with data from the XML document. */
po = (PurchaseOrder) serializer.Deserialize(fs);
// Reads the order date.
Console.WriteLine ("OrderDate: " + po.OrderDate);

// Reads the shipping address.
Address shipTo = po.ShipTo;
ReadAddress(shipTo, "Ship To:");
// Reads the list of ordered items.
OrderedItem [] items = po.OrderedItems;
Console.WriteLine("Items to be shipped:");
foreach(OrderedItem oi in items)
{
    Console.WriteLine("\t" +
        oi.ItemName + "\t" +
        oi.Description + "\t" +
        oi.UnitPrice + "\t" +
        oi.Quantity + "\t" +
        oi.LineTotal);
}
// Reads the subtotal, shipping cost, and total cost.
Console.WriteLine(
"\n\t\t\t\t Subtotal\t" + po.SubTotal +
"\n\t\t\t\t Shipping\t" + po.ShipCost +
"\n\t\t\t\t Total\t\t" + po.TotalCost
);
}

protected void ReadAddress(Address a, string label)
{
    // Reads the fields of the Address.
    Console.WriteLine(label);
    Console.Write("\t" +
        a.Name +"\n\t" +
        a.Line1 +"\n\t" +
        a.City +"\n\t" +
        a.State +"\n\t" +
        a.Zip +"\n");
}

protected void serializer_UnknownNode
(object sender, XmlNodeEventArgs e)
{
    Console.WriteLine("Unknown Node:" + e.Name + "\t" + e.Text);
}

protected void serializer_UnknownAttribute
(object sender, XmlAttributeEventArgs e)
{
    System.Xml.XmlAttribute attr = e.Attr;
    Console.WriteLine("Unknown attribute " +

```

```
        attr.Name + "=" + attr.Value + "'");
    }
}
```

The XML output might look like this:

XML

```
<?xml version="1.0" encoding="utf-8"?>
<PurchaseOrder xmlns:xsi="http://www.w3.org/2001/XMLSchema-instance"
  xmlns:xsd="http://www.w3.org/2001/XMLSchema" xmlns="http://www.cpandl.com">
  <ShipTo Name="Teresa Atkinson">
    <Line1>1 Main St.</Line1>
    <City>AnyTown</City>
    <State>WA</State>
    <Zip>00000</Zip>
  </ShipTo>
  <OrderDate>Wednesday, June 27, 2001</OrderDate>
  <Items>
    <OrderedItem>
      <ItemName>Widget S</ItemName>
      <Description>Small widget</Description>
      <UnitPrice>5.23</UnitPrice>
      <Quantity>3</Quantity>
      <LineTotal>15.69</LineTotal>
    </OrderedItem>
  </Items>
  <SubTotal>15.69</SubTotal>
  <ShipCost>12.51</ShipCost>
  <TotalCost>28.2</TotalCost>
</PurchaseOrder>
```

The XML Schema Definition Tool and XML Serialization

Article • 09/15/2021

The XML Schema Definition tool ([XML Schema Definition Tool \(Xsd.exe\)](#)) is installed along with the .NET Framework tools as part of the Windows® Software Development Kit (SDK). The tool is designed primarily for two purposes:

- To generate either C# or Visual Basic class files that conform to a specific XML Schema definition language (XSD) schema. The tool takes an XML Schema as an argument and outputs a file that contains a number of classes that, when serialized with the [XmlSerializer](#), conform to the schema. For information about how to use the tool to generate classes that conform to a specific schema, see [How to: Use the XML Schema Definition Tool to Generate Classes and XML Schema Documents](#).
- To generate an XML Schema document from a .dll file or .exe file. To see the schema of a set of files that you have either created or one that has been modified with attributes, pass the DLL or EXE as an argument to the tool to generate the XML schema. For information about how to use the tool to generate an XML Schema Document from a set of classes, see [How to: Use the XML Schema Definition Tool to Generate Classes and XML Schema Documents](#).

For more information about using the tool, see [XML Schema Definition Tool \(Xsd.exe\)](#).

Control XML serialization using attributes

Article • 10/04/2022

Attributes can be used to control the XML serialization of an object or to create an alternate XML stream from the same set of classes. For more information about creating an alternate XML stream, see [How to: Specify an Alternate Element Name for an XML Stream](#).

ⓘ Note

If the XML generated must conform to section 5 of the World Wide Web Consortium (W3C) document titled [Simple Object Access Protocol \(SOAP\) 1.1](#), use the attributes listed in [Attributes That Control Encoded SOAP Serialization](#).

By default, an XML element name is determined by the class or member name. In a class named `Book`, a field named `ISBN` will produce an XML element tag `<ISBN>`, as shown in the following example:

C#

```
public class Book
{
    public string ISBN;
}
// When an instance of the Book class is serialized, it might
// produce this XML:
// <ISBN>1234567890</ISBN>.
```

The default behavior can be changed if you want to give the element a new name. The following code shows how an attribute enables this functionality by setting the `ElementName` property of an `XmlElementAttribute`:

C#

```
public class TaxRates {
    [XmlElement(ElementName = "TaxRate")]
    public decimal ReturnTaxRate;
}
```

For more information about attributes, see [Attributes](#). For a list of attributes that control XML serialization, see [Attributes That Control XML Serialization](#).

Controlling Array Serialization

The [XmlAttribute](#) and the [XmlAttributeAttribute](#) attributes control the serialization of arrays. Using these attributes, you can control the element name, namespace, and XML Schema (XSD) data type as defined in the W3C document titled [XML Schema Part 2: Datatypes](#). You can also specify the types that can be included in an array.

The [XmlAttribute](#) will determine the properties of the enclosing XML element that results when an array is serialized. For example, by default, serializing the array below will result in an XML element named `Employees`. The `Employees` element will contain a series of elements named after the array type `Employee`.

C#

```
public class Group {
    public Employee[] Employees;
}
public class Employee {
    public string Name;
}
```

A serialized instance might resemble the following code:

XML

```
<Group>
<Employees>
    <Employee>
        <Name>Haley</Name>
    </Employee>
</Employees>
</Group>
```

By applying a [XmlAttribute](#), you can change the name of the XML element, as follows:

C#

```
public class Group {
    [XmlAttribute("TeamMembers")]
    public Employee[] Employees;
}
```

The resulting XML might resemble the following code:

XML

```
<Group>
<TeamMembers>
    <Employee>
        <Name>Haley</Name>
    </Employee>
</TeamMembers>
</Group>
```

The [XmlAttributeAttribute](#), on the other hand, controls how the items contained in the array are serialized.

ⓘ Note

The attribute is applied to the field returning the array.

C#

```
public class Group {
    [XmlAttribute("MemberName")]
    public Employee[] Employees;
}
```

The resulting XML might resemble the following code:

XML

```
<Group>
<Employees>
    <MemberName>Haley</MemberName>
</Employees>
</Group>
```

Serializing Derived Classes

Another use of the [XmlAttributeAttribute](#) is to allow the serialization of derived classes. For example, another class named `Manager` that derives from `Employee` can be added to the previous example. If you don't apply the [XmlAttributeAttribute](#), the code will fail at run time because the derived class type won't be recognized. To remedy this outcome, apply the attribute twice, each time setting the [Type](#) property for each acceptable type (base and derived).

C#

```
public class Group {
    [XmlElement(Type = typeof(Employee)),
     XmlElement(Type = typeof(Manager))]
    public Employee[] Employees;
}

public class Employee {
    public string Name;
}

public class Manager:Employee {
    public int Level;
}
```

A serialized instance might resemble the following code:

XML

```
<Group>
<Employees>
    <Employee>
        <Name>Haley</Name>
    </Employee>
    <Employee xsi:type = "Manager">
        <Name>Ann</Name>
        <Level>3</Level>
    </Employee>
</Employees>
</Group>
```

Serializing an Array as a Sequence of Elements

You can also serialize an array as a flat sequence of XML elements by applying a [XmlElementAttribute](#) to the field returning the array as follows:

C#

```
public class Group {
    [XmlElement]
    public Employee[] Employees;
}
```

A serialized instance might resemble the following code:

XML

```
<Group>
<Employees>
    <Name>Haley</Name>
```

```
</Employees>
<Employees>
    <Name>Noriko</Name>
</Employees>
<Employees>
    <Name>Marco</Name>
</Employees>
</Group>
```

Another way to differentiate the two XML streams is to use the XML Schema Definition tool to generate the XML Schema (XSD) document files from the compiled code. For more information on using the tool, see [The XML Schema Definition Tool and XML Serialization](#). When no attribute is applied to the field, the schema describes the element in the following manner:

XML

```
<xss:element minOccurs="0" maxOccurs = "1" name="Employees"
type="ArrayOfEmployee" />
```

When the [XmlElementAttribute](#) is applied to the field, the resulting schema describes the element as follows:

XML

```
<xss:element minOccurs="0" maxOccurs="unbounded" name="Employees"
type="Employee" />
```

Serializing an ArrayList

The [ArrayList](#) class can contain a collection of diverse objects. You can therefore use an [ArrayList](#) much as you use an array. Instead of creating a field that returns an array of typed objects, however, you can create a field that returns a single [ArrayList](#). However, as with arrays, you must inform the [XmlSerializer](#) of the types of objects the [ArrayList](#) contains. To accomplish this, assign multiple instances of the [XmlElementAttribute](#) to the field, as shown in the following example.

C#

```
public class Group {
    [XmlElement(Type = typeof(Employee)),
     XmlElement(Type = typeof(Manager))]
    public ArrayList Info;
}
```

Controlling Serialization of Classes Using XmlRootAttribute and XmlTypeAttribute

You can apply two attributes to a class only: [XmlRootAttribute](#) and [XmlAttribute](#).

These attributes are similar. The [XmlRootAttribute](#) can be applied to only one class: the class that, when serialized, represents the XML document's opening and closing element—in other words, the root element. The [XmlAttribute](#), on the other hand, can be applied to any class, including the root class.

For example, in the previous examples, the `Group` class is the root class, and all its public fields and properties become the XML elements found in the XML document. Therefore, you can have only one root class. By applying the [XmlRootAttribute](#), you can control the XML stream generated by the [XmlSerializer](#). For example, you can change the element name and namespace.

The [XmlAttribute](#) allows you to control the schema of the generated XML. This capability is useful when you need to publish the schema through an XML Web service. The following example applies both the [XmlAttribute](#) and the [XmlRootAttribute](#) to the same class:

```
C#  
  
[XmlRoot("NewGroupName")]
[XmlAttribute("NewTypeName")]
public class Group {
    public Employee[] Employees;
}
```

If this class is compiled, and the XML Schema Definition tool is used to generate its schema, you would find the following XML describing `Group`:

```
XML  
  
<xss:element name="NewGroupName" type="NewTypeName" />
```

In contrast, if you were to serialize an instance of the class, only `NewGroupName` would be found in the XML document:

```
XML  
  
<NewGroupName>
    ...
</NewGroupName>
```

Preventing Serialization with the `XmllgnoreAttribute`

You might come across a situation where a public property or field doesn't need to be serialized. For example, a field or property could be used to contain metadata. In such cases, apply the [XmllgnoreAttribute](#) to the field or property and the [XmlSerializer](#) will skip over it.

Attributes That Control XML Serialization

Article • 09/15/2021

You can apply the attributes in the following table to classes and class members to control the way in which the [XmlSerializer](#) serializes or deserializes an instance of the class. To understand how these attributes control XML serialization, see [Controlling XML Serialization Using Attributes](#).

These attributes can also be used to control the literal style SOAP messages generated by an XML Web service. For more information about applying these attributes to an XML Web services method, see [XML Serialization with XML Web Services](#).

For more information about attributes, see [Attributes](#).

| Attribute | Applies to | Specifies |
|---------------------------------------|---|---|
| XmlAttributeAttribute | Public field, property, parameter, or return value that returns an array of XmlAttribute objects. | When deserializing, the array will be filled with XmlAttribute objects that represent all XML attributes unknown to the schema. |
| XmlElementAttribute | Public field, property, parameter, or return value that returns an array of XmlElement objects. | When deserializing, the array is filled with XmlElement objects that represent all XML elements unknown to the schema. |
| XmlAttributeAttribute | Public field, property, parameter, or return value that returns an array of complex objects. | The members of the array will be generated as members of an XML array. |
| XmlElementAttribute | Public field, property, parameter, or return value that returns an array of complex objects. | The derived types that can be inserted into an array. Usually applied in conjunction with an XmlAttributeAttribute . |
| XmlAttributeAttribute | Public field, property, parameter, or return value. | The member will be serialized as an XML attribute. |
| XmlElementAttribute | Public field, property, parameter, or return value. | The member can be further disambiguated by using an enumeration. |
| XmlElementAttribute | Public field, property, parameter, or return value. | The field or property will be serialized as an XML element. |

| Attribute | Applies to | Specifies |
|------------------------------|--|---|
| XmlAttribute | Public field that is an enumeration identifier. | The element name of an enumeration member. |
| XmlAttribute | Public properties and fields. | The property or field should be ignored when the containing class is serialized. |
| XmlAttribute | Public derived class declarations, and return values of public methods for Web Services Description Language (WSDL) documents. | The class should be included when generating schemas (to be recognized when serialized). |
| XmlAttribute | Public class declarations. | Controls XML serialization of the attribute target as an XML root element. Use the attribute to further specify the namespace and element name. |
| XmlAttribute | Public properties and fields. | The property or field should be serialized as XML text. |
| XmlAttribute | Public class declarations. | The name and namespace of the XML type. |

In addition to these attributes, which are all found in the [System.Xml.Serialization](#) namespace, you can also apply the [DefaultValueAttribute](#) attribute to a field. The [DefaultValueAttribute](#) sets the value that will be automatically assigned to the member if no value is specified.

To control encoded SOAP XML serialization, see [Attributes That Control Encoded SOAP Serialization](#).

XML Serialization with XML Web Services

Article • 03/30/2023

XML serialization is the underlying transport mechanism used in the XML Web services architecture, performed by the [XmlSerializer](#) class. To control the XML generated by an XML Web service, you can apply the attributes listed in both [Attributes That Control XML Serialization](#) and [Attributes That Control Encoded SOAP Serialization](#) to the classes, return values, parameters, and fields of a file used to create an XML Web service (.asmx). For more information about creating an XML Web service, see [XML Web Services Using ASP.NET](#).

Literal and Encoded Styles

The XML generated by an XML Web service can be formatted in either one of two ways, either literal or encoded, as explained in [Customizing SOAP Message Formatting](#).

Therefore there are two sets of attributes that control XML serialization. The attributes listed in [Attributes That Control XML Serialization](#) are designed to control literal style XML. The attributes listed in [Attributes That Control Encoded SOAP Serialization](#) control the encoded style. By selectively applying these attributes, you can tailor an application to return either, or both styles. Furthermore, these attributes can be applied (as appropriate) to return values and parameters.

Example of Using Both Styles

When you're creating an XML Web service, you can use both sets of attributes on the methods. In the following code example, the class named `MyService` contains two XML Web service methods, `MyLiteralMethod` and `MyEncodedMethod`. Both methods perform the same function: returning an instance of the `Order` class. In the `Order` class, the [XmlAttribute](#) and the [SoapTypeAttribute](#) attributes are both applied to the `OrderID` field, and both attributes have their `ElementName` property set to different values.

To run the example, paste the code into a file with an .asmx extension, and place the file into a virtual directory managed by Internet Information Services (IIS). From a web browser, type the name of the computer, virtual directory, and file.

C#

```

<%@ WebService Language="C#" Class="MyService" %>
using System;
using System.Web.Services;
using System.Web.Services.Protocols;
using System.Xml.Serialization;
public class Order {
    // Both types of attributes can be applied. Depending on which type
    // the method used, either one will affect the call.
    [SoapElement(ElementName = "EncodedOrderID")]
    [XmlElement(ElementName = "LiteralOrderID")]
    public String OrderID;
}
public class MyService {
    [WebMethod][SoapDocumentMethod]
    public Order MyLiteralMethod(){
        Order myOrder = new Order();
        return myOrder;
    }
    [WebMethod][SoapRpcMethod]
    public Order MyEncodedMethod(){
        Order myOrder = new Order();
        return myOrder;
    }
}

```

The following code example calls `MyLiteralMethod`. The element name is changed to "LiteralOrderID".

XML

```

<?xml version="1.0" encoding="utf-8"?>
<soap:Envelope xmlns:xsi="http://www.w3.org/2001/XMLSchema-instance"
    xmlns:xsd="http://www.w3.org/2001/XMLSchema"
    xmlns:soap="http://schemas.xmlsoap.org/soap/envelope/">
    <soap:Body>
        <MyLiteralMethodResponse xmlns="http://tempuri.org/">
            <MyLiteralMethodResult>
                <LiteralOrderID>string</LiteralOrderID>
            </MyLiteralMethodResult>
        </MyLiteralMethodResponse>
    </soap:Body>
</soap:Envelope>

```

The following code example calls `MyEncodedMethod`. The element name is "EncodedOrderID".

XML

```

<?xml version="1.0" encoding="utf-8"?>
<soap:Envelope xmlns:xsi="http://www.w3.org/2001/XMLSchema-instance"
    xmlns:xsd="http://www.w3.org/2001/XMLSchema"
    xmlns:soap="http://schemas.xmlsoap.org/soap/envelope/">
    <soap:Body>
        <MyEncodedMethodResponse xmlns="http://tempuri.org/">
            <MyEncodedMethodResult>
                <EncodedOrderID>string</EncodedOrderID>
            </MyEncodedMethodResult>
        </MyEncodedMethodResponse>
    </soap:Body>
</soap:Envelope>

```

```

xmlns:xsd="http://www.w3.org/2001/XMLSchema"
xmlns:soapenc="http://schemas.xmlsoap.org/soap/encoding/"
xmlns:tns="http://tempuri.org/"
xmlns:types="http://tempuri.org/encodedTypes"
xmlns:soap="http://schemas.xmlsoap.org/soap/envelope/">
    <soap:Body>
        soap:encodingStyle="http://schemas.xmlsoap.org/soap/encoding/">
            <tns:MyEncodedMethodResponse>
                <MyEncodedMethodResult href="#id1" />
            </tns:MyEncodedMethodResponse>
            <types:Order id="id1" xsi:type="types:Order">
                <EncodedOrderID xsi:type="xsd:string">string</EncodedOrderID>
            </types:Order>
        </soap:Body>
    </soap:Envelope>

```

Applying Attributes to Return Values

You can also apply attributes to return values to control the namespace, element name, and so forth. The following code example applies the `XmlElementAttribute` attribute to the return value of the `MyLiteralMethod` method. Doing so allows you to control the namespace and element name.

C#

```

[return: XmlElement(Namespace = "http://www.cohowinery.com",
    ElementName = "BookOrder")]
[WebMethod][SoapDocumentMethod]
public Order MyLiteralMethod(){
    Order myOrder = new Order();
    return myOrder;
}

```

When invoked, the code returns XML that resembles the following.

XML

```

<?xml version="1.0" encoding="utf-8"?>
<soap:Envelope xmlns:xsi="http://www.w3.org/2001/XMLSchema-instance"
    xmlns:xsd="http://www.w3.org/2001/XMLSchema"
    xmlns:soap="http://schemas.xmlsoap.org/soap/envelope/">
    <soap:Body>
        <MyLiteralMethodResponse xmlns="http://tempuri.org/">
            <BookOrder xmlns="http://www.cohowinery.com">
                <LiteralOrderID>string</LiteralOrderID>
            </BookOrder>
        </MyLiteralMethodResponse>
    </soap:Body>

```

```
</soap:Body>
</soap:Envelope>
```

Attributes Applied to Parameters

You can also apply attributes to parameters to specify namespace, element name and so forth. The following code example adds a parameter to the `MyLiteralMethodResponse` method, and applies the `XmlAttributeAttribute` attribute to the parameter. The element name and namespace are both set for the parameter.

C#

```
[return: XmlElement(Namespace = "http://www.cohowinery.com",
ElementName = "BookOrder")]
[WebMethod][SoapDocumentMethod]
public Order MyLiteralMethod([XmlElement("MyOrderID",
Namespace="http://www.microsoft.com")] string ID){
    Order myOrder = new Order();
    myOrder.OrderID = ID;
    return myOrder;
}
```

The SOAP request would resemble the following.

XML

```
<?xml version="1.0" encoding="utf-8"?>
<soap:Envelope xmlns:xsi="http://www.w3.org/2001/XMLSchema-instance"
xmlns:xsd="http://www.w3.org/2001/XMLSchema"
xmlns:soap="http://schemas.xmlsoap.org/soap/envelope/">
    <soap:Body>
        <MyLiteralMethod xmlns="http://tempuri.org/">
            <MyOrderID xmlns="http://www.microsoft.com">string</MyOrderID>
        </MyLiteralMethod>
    </soap:Body>
</soap:Envelope>
```

Applying Attributes to Classes

If you need to control the namespace of elements that correlate to classes, you can apply `XmlAttributeAttribute`, `XmlRootAttribute`, and `SoapTypeAttribute`, as appropriate. The following code example applies all three to the `Order` class.

C#

```
[XmlAttribute("BigBooksService", Namespace = "http://www.cpandl.com")]
[SoapType("SoapBookService")]
[XmlRoot("BookOrderForm")]
public class Order {
    // Both types of attributes can be applied. Depending on which
    // the method used, either one will affect the call.
    [SoapElement(ElementName = "EncodedOrderID")]
    [XmlElement(ElementName = "LiteralOrderID")]
    public String OrderID;
}
```

The results of applying the `XmlAttribute` and `SoapTypeAttribute` can be seen when you examine the service description, as shown in the following code example.

XML

```
<s:element name="BookOrderForm" type="s0:BigBookService" />
<s:complexType name="BigBookService">
    <s:sequence>
        <s:element minOccurs="0" maxOccurs="1" name="LiteralOrderID"
type="s:string" />
    </s:sequence>

    <s:schema targetNamespace="http://tempuri.org/encodedTypes">
        <s:complexType name="SoapBookService">
            <s:sequence>
                <s:element minOccurs="1" maxOccurs="1" name="EncodedOrderID"
type="s:string" />
            </s:sequence>
        </s:complexType>
    </s:schema>
</s:complexType>
```

The effect of the `XmlAttribute` can also be seen in the HTTP GET and HTTP POST results, as follows.

XML

```
<?xml version="1.0" encoding="utf-8"?>
<BookOrderForm xmlns="http://tempuri.org/">
    <LiteralOrderID>string</LiteralOrderID>
</BookOrderForm>
```

Attributes That Control Encoded SOAP Serialization

Article • 09/15/2021

The World Wide Web Consortium (W3C) document named [Simple Object Access Protocol \(SOAP\) 1.1](#) contains an optional section (section 5) that describes how SOAP parameters can be encoded. To conform to section 5 of the specification, you must use a special set of attributes found in the [System.Xml.Serialization](#) namespace. Apply those attributes as appropriate to classes and members of classes, and then use the [XmlSerializer](#) to serialize instances of the class or classes.

The following table shows the attributes, where they can be applied, and what they do. For more information about using these attributes to control XML serialization, see [How to: Serialize an Object as a SOAP-Encoded XML Stream](#) and [How to: Override Encoded SOAP XML Serialization](#).

For more information about attributes, see [Attributes](#).

| Attribute | Applies to | Specifies |
|--|--|---|
| SoapAttributeAttribute | Public field, property, parameter, or return value. | The class member will be serialized as an XML attribute. |
| SoapElementAttribute | Public field, property, parameter, or return value. | The class will be serialized as an XML element. |
| SoapEnumAttribute | Public field that is an enumeration identifier. | The element name of an enumeration member. |
| SoapIgnoreAttribute | Public properties and fields. | The property or field should be ignored when the containing class is serialized. |
| SoapIncludeAttribute | Public-derived class declarations and public methods for Web Services Description Language (WSDL) documents. | The type should be included when generating schemas (to be recognized when serialized). |
| SoapTypeAttribute | Public class declarations. | The class should be serialized as an XML type. |

How to: Serialize an Object

Article • 09/15/2021

To serialize an object, first create the object that is to be serialized and set its public properties and fields. To do this, you must determine the transport format in which the XML stream is to be stored, either as a stream or as a file. For example, if the XML stream must be saved in a permanent form, create a [FileStream](#) object.

ⓘ Note

For more examples of XML serialization, see [Examples of XML Serialization](#).

To serialize an object

1. Create the object and set its public fields and properties.
2. Construct a [XmlSerializer](#) using the type of the object. For more information, see the [XmlSerializer](#) class constructors.
3. Call the [Serialize](#) method to generate either an XML stream or a file representation of the object's public properties and fields. The following example creates a file.

C#

```
MySerializableClass myObject = new MySerializableClass();
// Insert code to set properties and fields of the object.
XmlSerializer mySerializer = new
XmlSerializer(typeof(MySerializableClass));
// To write to a file, create a StreamWriter object.
StreamWriter myWriter = new StreamWriter("myFileName.xml");
mySerializer.Serialize(myWriter, myObject);
myWriter.Close();
```

How to deserialize an object using XmlSerializer

Article • 09/15/2021

When you deserialize an object, the transport format determines whether you will create a stream or file object. After the transport format is determined, you can call the [Serialize](#) or [Deserialize](#) methods, as required.

To deserialize an object

1. Construct a [XmlSerializer](#) using the type of the object to deserialize.
2. Call the [Deserialize](#) method to produce a replica of the object. When deserializing, you must cast the returned object to the type of the original, as shown in the following example, which deserializes the object from a file (although it could also be serialized from a stream).

C#

```
// Construct an instance of the XmlSerializer with the type
// of object that is being deserialized.
var mySerializer = new XmlSerializer(typeof(MySerializableClass));
// To read the file, create a FileStream.
using var myFileStream = new FileStream("myFileName.xml",
    FileMode.Open);
// Call the Deserialize method and cast to the object type.
var myObject =
    (MySerializableClass)mySerializer.Deserialize(myFileStream);
```

How to: Use the XML Schema Definition Tool to Generate Classes and XML Schema Documents

Article • 06/01/2023

The XML Schema Definition tool (Xsd.exe) allows you to generate an XML schema that describes a class or to generate the class defined by an XML schema. The following procedures show how to perform these operations.

The XML Schema Definition tool (Xsd.exe) usually can be found in the following path:
C:\Program Files (x86)\Microsoft SDKs\Windows\{version}\bin\NETFX {version} Tools\

To generate classes that conform to a specific schema

1. Open a command prompt.
2. Pass the XML Schema as an argument to the XML Schema Definition tool, which creates a set of classes that are precisely matched to the XML Schema, for example:

```
Console  
xsd mySchema.xsd
```

The tool can only process schemas that reference the World Wide Web Consortium XML specification of March 16, 2001. In other words, the XML Schema namespace must be "http://www.w3.org/2001/XMLSchema", as shown in the following example.

```
XML  
<?xml version="1.0" encoding="utf-8"?>  
<xss:schema attributeFormDefault="qualified"  
elementFormDefault="qualified" targetNamespace=""  
xmlns:xss="http://www.w3.org/2001/XMLSchema" />
```

3. Modify the classes with methods, properties, or fields, as necessary. For more information about modifying a class with attributes, see [Controlling XML](#)

[Serialization Using Attributes](#) and [Attributes That Control Encoded SOAP Serialization](#).

It is often useful to examine the schema of the XML stream that is generated when instances of a class (or classes) are serialized. For example, you might publish your schema for others to use, or you might compare it to a schema with which you are trying to achieve conformity.

To generate an XML Schema document from a set of classes

1. Compile the class or classes into a DLL.
2. Open a command prompt.
3. Pass the DLL as an argument to Xsd.exe, for example:

```
Console  
xsd MyFile.dll
```

The schema (or schemas) will be written, beginning with the name "schema0.xsd".

How to: Control Serialization of Derived Classes

Article • 09/15/2021

Using the **XmlElementAttribute** attribute to change the name of an XML element is not the only way to customize object serialization. You can also customize the XML stream by deriving from an existing class and instructing the **XmlSerializer** instance how to serialize the new class.

For example, given a **Book** class, you can derive from it and create an **ExpandedBook** class that has a few more properties. However, you must instruct the **XmlSerializer** to accept the derived type when serializing or deserializing. This can be done by creating a **XmlElementAttribute** instance and setting its **Type** property to the derived class type. Add the **XmlElementAttribute** to a **XmlAttribute** instance. Then add the **XmlAttribute** to a **XmlAttributeOverrides** instance, specifying the type being overridden and the name of the member that accepts the derived class. This is shown in the following example.

Example

C#

```
public class Orders
{
    public Book[] Books;
}

public class Book
{
    public string ISBN;
}

public class ExpandedBook:Book
{
    public bool NewEdition;
}

public class Run
{
    public void SerializeObject(string filename)
    {
        // Each overridden field, property, or type requires
        // an XmlAttributes instance.
        XmlAttributes attrs = new XmlAttributes();

        // Creates an XmlElementAttribute instance to override the
        // name of the Books element.
        attrs.ElementName = "MyBooks";
        attrs.Type = typeof(ExpandedBook);
        attrs.XmlElement = new XmlElementAttribute("MyBooks");
        attrs.XmlElement.Type = typeof(ExpandedBook);
    }
}
```

```

// field that returns Book objects. The overridden field
// returns Expanded objects instead.
XmlElementAttribute attr = new XmlElementAttribute();
attr.ElementName = "NewBook";
attr.Type = typeof(ExpandedBook);

// Adds the element to the collection of elements.
attrs.XmlElements.Add(attr);

// Creates the XmlAttributeOverrides instance.
XmlAttributeOverrides attrOverrides = new XmlAttributeOverrides();

// Adds the type of the class that contains the overridden
// member, as well as the XmlAttributes instance to override it
// with, to the XmlAttributeOverrides.
attrOverrides.Add(typeof(Orders), "Books", attrs);

// Creates the XmlSerializer using the XmlAttributeOverrides.
XmlSerializer s =
new XmlSerializer(typeof(Orders), attrOverrides);

// Writing the file requires a TextWriter instance.
TextWriter writer = new StreamWriter(filename);

// Creates the object to be serialized.
Orders myOrders = new Orders();

// Creates an object of the derived type.
ExpandedBook b = new ExpandedBook();
b.ISBN= "123456789";
b.NewEdition = true;
myOrders.Books = new ExpandedBook[] {b};

// Serializes the object.
s.Serialize(writer,myOrders);
writer.Close();
}

public void DeserializeObject(string filename)
{
    XmlAttributeOverrides attrOverrides =
        new XmlAttributeOverrides();
    XmlAttributes attrs = new XmlAttributes();

    // Creates an XmlElementAttribute to override the
    // field that returns Book objects. The overridden field
    // returns Expanded objects instead.
    XmlElementAttribute attr = new XmlElementAttribute();
    attr.ElementName = "NewBook";
    attr.Type = typeof(ExpandedBook);

    // Adds the XmlElementAttribute to the collection of objects.
    attrs.XmlElements.Add(attr);

    attrOverrides.Add(typeof(Orders), "Books", attrs);
}

```

```
// Creates the XmlSerializer using the XmlAttributeOverrides.
XmlSerializer s =
    new XmlSerializer(typeof(Orders), attrOverrides);

FileStream fs = new FileStream(filename, FileMode.Open);
Orders myOrders = (Orders) s.Deserialize(fs);
Console.WriteLine("ExpandedBook:");

// The difference between deserializing the overridden
// XML document and serializing it is this: To read the derived
// object values, you must declare an object of the derived type
// and cast the returned object to it.
ExpandedBook expanded;
foreach(Book b in myOrders.Books)
{
    expanded = (ExpandedBook)b;
    Console.WriteLine(
        expanded.ISBN + "\n" +
        expanded.NewEdition);
}
}
```

How to: Specify an Alternate Element Name for an XML Stream

Article • 09/15/2021

Using the [XmlSerializer](#), you can generate more than one XML stream with the same set of classes. You might want to do this because two different XML Web services require the same basic information, with only slight differences. For example, imagine two XML Web services that process orders for books, and thus both require ISBN numbers. One service uses the tag <ISBN> while the second uses the tag <BookID>. You have a class named `Book` that contains a field named `ISBN`. When an instance of the `Book` class is serialized, it will, by default, use the member name (`ISBN`) as the tag element name. For the first XML Web service, this is as expected. But to send the XML stream to the second XML Web service, you must override the serialization so that the tag's element name is `BookID`.

To create an XML stream with an alternate element name

1. Create an instance of the [XmlElementAttribute](#) class.
2. Set the [ElementName](#) of the [XmlElementAttribute](#) to "BookID".
3. Create an instance of the [XmlAttributeOverrides](#) class.
4. Add the `XmlElementAttribute` object to the collection accessed through the [XmlElements](#) property of [XmlAttributeOverrides](#) .
5. Create an instance of the [XmlAttributeOverrides](#) class.
6. Add the `XmlAttributeOverrides` to the [XmlAttributeOverrides](#), passing the type of the object to override and the name of the member being overridden.
7. Create an instance of the `XmlSerializer` class with `XmlAttributeOverrides`.
8. Create an instance of the `Book` class, and serialize or deserialize it.

Example

C#

```
public void SerializeOverride()
{
    // Creates an XmlElementAttribute with the alternate name.
    XmlElementAttribute myElementAttribute = new XmlElementAttribute();
    myElementAttribute.ElementName = "BookID";
    XmlAttributes myAttributes = new XmlAttributes();
    myAttributes.XmlElements.Add(myElementAttribute);
    XmlAttributeOverrides myOverrides = new XmlAttributeOverrides();
    myOverrides.Add(typeof(Book), "ISBN", myAttributes);
    XmlSerializer mySerializer =
        new XmlSerializer(typeof(Book), myOverrides);
    Book b = new Book();
    b.ISBN = "123456789";
    // Creates a StreamWriter to write the XML stream to.
    StreamWriter writer = new StreamWriter("Book.xml");
    mySerializer.Serialize(writer, b);
}
```

The XML stream might resemble the following.

XML

```
<Book>
    <BookID>123456789</BookID>
</Book>
```

How to qualify XML element and XML attribute names

Article • 09/15/2021

XML namespaces contained by instances of the [XmlSerializerNamespaces](#) class must conform to the World Wide Web Consortium (W3C) specification called [Namespaces in XML](#).

XML namespaces provide a method for qualifying the names of XML elements and XML attributes in XML documents. A qualified name consists of a prefix and a local name, separated by a colon. The prefix functions only as a placeholder; it is mapped to a URI that specifies a namespace. The combination of the universally managed URI namespace and the local name produces a name that is guaranteed to be universally unique.

By creating an instance of `XmlSerializerNamespaces` and adding the namespace pairs to the object, you can specify the prefixes used in an XML document.

To create qualified names in an XML document

1. Create an instance of the `XmlSerializerNamespaces` class.
2. Add all prefixes and namespace pairs to the `XmlSerializerNamespaces`.
3. Apply the appropriate `System.Xml.Serialization` attribute to each member or class that the [XmlSerializer](#) is to serialize into an XML document.
The available attributes are: [XmlElementAttribute](#), [XmlAttributeAttribute](#), [XmlAttributeItemAttribute](#), [XmlAttributeAttribute](#), [XmlElementAttribute](#), [XmlAttributeAttribute](#), and [XmlAttributeAttribute](#).
4. Set the `Namespace` property of each attribute to one of the namespace values from the `XmlSerializerNamespaces`.
5. Pass the `XmlSerializerNamespaces` to the `Serialize` method of the `XmlSerializer`.

Example

The following example creates an `XmlSerializerNamespaces`, and adds two prefix and namespace pairs to the object. The code creates an `XmlSerializer` that is used to

serialize an instance of the `Books` class. The code calls the `Serialize` method with the `XmlSerializerNamespaces`, allowing the XML to contain prefixed namespaces.

C#

```
using System;
using System.IO;
using System.Xml;
using System.Xml.Serialization;

public class Program
{
    public static void Main()
    {
        SerializeObject("XmlNamespaces.xml");
    }

    public static void SerializeObject(string filename)
    {
        var mySerializer = new XmlSerializer(typeof(Books));
        // Writing a file requires a TextWriter.
        TextWriter myWriter = new StreamWriter(filename);

        // Creates an XmlSerializerNamespaces and adds two
        // prefix-namespace pairs.
        var myNamespaces = new XmlSerializerNamespaces();
        myNamespaces.Add("books", "http://www.cpandl.com");
        myNamespaces.Add("money", "http://www.cohowinery.com");

        // Creates a Book.
        var myBook = new Book();
        myBook.TITLE = "A Book Title";
        var myPrice = new Price();
        myPrice.price = (decimal) 9.95;
        myPrice.currency = "US Dollar";
        myBook.PRICE = myPrice;
        var myBooks = new Books();
        myBooks.Book = myBook;
        mySerializer.Serialize(myWriter, myBooks, myNamespaces);
        myWriter.Close();
    }
}

public class Books
{
    [XmlElement(Namespace = "http://www.cohowinery.com")]
    public Book Book;
}

[XmlAttribute(Namespace = "http://www.cpandl.com")]
public class Book
{
    [XmlElement(Namespace = "http://www.cpandl.com")]
```

```
public string TITLE;
[XmlElement(Namespace = "http://www.cohowinery.com")]
public Price PRICE;
}

public class Price
{
    [XmlAttribute(Namespace = "http://www.cpndl.com")]
    public string currency;
    [XmlElement(Namespace = "http://www.cohowinery.com")]
    public decimal price;
}
```

How to: Serialize an Object as a SOAP-Encoded XML Stream

Article • 09/15/2021

Because a SOAP message is built using XML, the [XmlSerializer](#) class can be used to serialize classes and generate encoded SOAP messages. The resulting XML conforms to section 5 of the World Wide Web Consortium document "Simple Object Access Protocol (SOAP) 1.1" [↗](#). When you are creating an XML Web service that communicates through SOAP messages, you can customize the XML stream by applying a set of special SOAP attributes to classes and members of classes. For a list of attributes, see [Attributes That Control Encoded SOAP Serialization](#).

To serialize an object as a SOAP-encoded XML stream

1. Create the class using the [XML Schema Definition Tool \(Xsd.exe\)](#).
2. Apply one or more of the special attributes found in [System.Xml.Serialization](#).
See the list in "Attributes That Control Encoded SOAP Serialization."
3. Create an [XmlAttributeMapping](#) by creating a new [SoapReflectionImporter](#), and invoking the [ImportTypeMapping](#) method with the type of the serialized class.

The following code example calls the [ImportTypeMapping](#) method of the [SoapReflectionImporter](#) class to create an [XmlAttributeMapping](#).

C#

```
// Serializes a class named Group as a SOAP message.  
XmlAttributeMapping myTypeMapping =  
    new SoapReflectionImporter().ImportTypeMapping(typeof(Group));
```

4. Create an instance of the [XmlSerializer](#) class by passing the [XmlAttributeMapping](#) to the [XmlSerializer\(XmlTypeMapping\)](#) constructor.

C#

```
XmlAttributeMapper mySerializer = new XmlSerializer(myTypeMapping);
```

5. Call the [Serialize](#) or [Deserialize](#) method.

Example

C#

```
// Serializes a class named Group as a SOAP message.  
XmlTypeMapping myTypeMapping =  
    new SoapReflectionImporter().ImportTypeMapping(typeof(Group));  
XmlSerializer mySerializer = new XmlSerializer(myTypeMapping);
```

How to: Override Encoded SOAP XML Serialization

Article • 09/15/2021

The process for overriding XML serialization of objects as SOAP messages is similar to the process for overriding standard XML serialization. For information about overriding standard XML serialization, see [How to: Specify an Alternate Element Name for an XML Stream](#).

To override serialization of objects as SOAP messages

1. Create an instance of the `SoapAttributeOverrides` class.
2. Create a `SoapAttributes` for each class member that is being serialized.
3. Create an instance of one or more of the attributes that affect XML serialization, as appropriate, to the member being serialized. For more information, see "Attributes That Control Encoded SOAP Serialization".
4. Set the appropriate property of `SoapAttributes` to the attribute created in step 3.
5. Add `SoapAttributes` to `SoapAttributeOverrides`.
6. Create an `XmlTypeMapping` using the `SoapAttributeOverrides`. Use the `SoapReflectionImporter.ImportTypeMapping` method.
7. Create an `XmlSerializer` using `XmlTypeMapping`.
8. Serialize or deserialize the object.

Example

The following code example serializes a file in two ways: first, without overriding the `XmlSerializer` class's behavior, and second, by overriding the behavior. The example contains a class named `Group` with several members. Various attributes, such as the `SoapElementAttribute`, have been applied to class members. When the class is serialized with the `SerializeOriginal` method, the attributes control the SOAP message content. When the `SerializeOverride` method is called, the behavior of the `XmlSerializer` is

overridden by creating various attributes and setting the properties of a `SoapAttributes` to those attributes (as appropriate).

C#

```
using System;
using System.IO;
using System.Xml;
using System.Xml.Serialization;
using System.Xml.Schema;

public class Group
{
    [SoapAttribute(Namespace = "http://www.cpandl.com")]
    public string GroupName;

    [SoapAttribute(DataType = "base64Binary")]
    public Byte [] GroupNumber;

    [SoapAttribute(DataType = "date", AttributeName = "CreationDate")]
    public DateTime Today;
    [SoapElement(DataType = "nonNegativeInteger", ElementName = "PosInt")]
    public string PositiveInt;
    // This is ignored when serialized unless it is overridden.
    [SoapIgnore]
    public bool IgnoreThis;

    public GroupType GroupType;

    [SoapInclude(typeof(Car))]
    public Vehicle myCar(string licNumber)
    {
        Vehicle v;
        if(licNumber == "")
        {
            v = new Car();
            v.licenseNumber = "!!!!!!";
        }
        else
        {
            v = new Car();
            v.licenseNumber = licNumber;
        }
        return v;
    }

    public abstract class Vehicle
    {
        public string licenseNumber;
        public DateTime makeDate;
    }

    public class Car: Vehicle
```

```
{  
}  
  
public enum GroupType  
{  
    // These enums can be overridden.  
    small,  
    large  
}  
  
public class Run  
{  
    public static void Main()  
    {  
        Run test = new Run();  
        test.SerializeOriginal("SoapOriginal.xml");  
        test.SerializeOverride("SoapOverrides.xml");  
        test.DeserializeOriginal("SoapOriginal.xml");  
        test.DeserializeOverride("SoapOverrides.xml");  
  
    }  
    public void SerializeOriginal(string filename)  
    {  
        // Creates an instance of the XmlSerializer class.  
        XmlTypeMapping myMapping =  
            (new SoapReflectionImporter().ImportTypeMapping(  
                typeof(Group)));  
        XmlSerializer mySerializer =  
            new XmlSerializer(myMapping);  
  
        // Writing the file requires a TextWriter.  
        TextWriter writer = new StreamWriter(filename);  
  
        // Creates an instance of the class that will be serialized.  
        Group myGroup = new Group();  
  
        // Sets the object properties.  
        myGroup.GroupName = ".NET";  
  
        Byte [] hexByte = new Byte[2]{Convert.ToByte(100),  
            Convert.ToByte(50)};  
        myGroup.GroupNumber = hexByte;  
  
        DateTime myDate = new DateTime(2002,5,2);  
        myGroup.Today = myDate;

How to: chunk serialized data

Article • 04/05/2023

⚠ Warning

Binary serialization can be dangerous. For more information, see [BinaryFormatter security guide](#).

Two issues that occur when sending large data sets in Web service messages are:

1. A large working set (memory) due to buffering by the serialization engine.
2. Inordinate bandwidth consumption due to 33 percent inflation after Base64 encoding.

To solve these problems, implement the [IXmlSerializable](#) interface to control the serialization and deserialization. Specifically, implement the [WriteXml](#) and [ReadXml](#) methods to chunk the data.

To implement server-side chunking

1. On the server machine, the Web method must turn off ASP.NET buffering and return a type that implements [IXmlSerializable](#).
2. The type that implements [IXmlSerializable](#) chunks the data in the [WriteXml](#) method.

To implement client-side processing

1. Alter the Web method on the client proxy to return the type that implements [IXmlSerializable](#). You can use a [SchemaImporterExtension](#) to do this automatically, but this isn't shown here.
2. Implement the [ReadXml](#) method to read the chunked data stream and write the bytes to disk. This implementation also raises progress events that can be used by a graphic control, such as a progress bar.

Example

The following code example shows the Web method on the client that turns off ASP.NET buffering. It also shows the client-side implementation of the [IXmlSerializable](#) interface that chunks the data in the [WriteXml](#) method.

C#

```
[WebMethod]
[SoapDocumentMethod(ParameterStyle = SoapParameterStyle.Bare)]
public SongStream DownloadSong(DownloadAuthorization Authorization, string
filePath)
{
    // Turn off response buffering.
    System.Web.HttpContext.Current.Response.Buffer = false;
    // Return a song.
    SongStream song = new SongStream(filePath);
    return song;
}
```

C#

```
[XmlSchemaProvider("MySchema")]
public class SongStream : IXmlSerializable
{
    private const string ns = "http://demos.Contoso.com/webservices";
    private string filePath;

    public SongStream() { }

    public SongStream(string filePath)
    {
        this.filePath = filePath;
    }

    // This is the method named by the XmlSchemaProviderAttribute applied to
    // the type.
    public static XmlQualifiedName MySchema(XmlSchemaSet xs)
    {
        // This method is called by the framework to get the schema for this
        // type.
        // We return an existing schema from disk.

        XmlSerializer schemaSerializer = new
        XmlSerializer(typeof(XmlSchema));
        string xsdPath = null;
        // NOTE: replace the string with your own path.
        xsdPath =
System.Web.HttpContext.Current.Server.MapPath("SongStream.xsd");
        XmlSchema s = (XmlSchema)schemaSerializer.Deserialize(
            new XmlTextReader(xsdPath), null);
        xs.XmlResolver = new XmlUrlResolver();
        xs.Add(s);
    }
}
```

```

        return new XmlQualifiedName("songStream", ns);
    }

    void IXmlSerializable.WriteXml(System.Xml.XmlWriter writer)
    {
        // This is the chunking code.
        // ASP.NET buffering must be turned off for this to work.

        int bufferSize = 4096;
        char[] songBytes = new char[bufferSize];
        FileStream inFile = File.Open(this.filePath, FileMode.Open,
FileAccess.Read);

        long length = inFile.Length;

        // Write the file name.
        writer.WriteElementString("fileName", ns,
Path.GetFileNameWithoutExtension(this.filePath));

        // Write the size.
        writer.WriteElementString("size", ns, length.ToString());

        // Write the song bytes.
        writer.WriteStartElement("song", ns);

        StreamReader sr = new StreamReader(inFile, true);
        int readLen = sr.Read(songBytes, 0, bufferSize);

        while (readLen > 0)
        {
            writer.WriteStartElement("chunk", ns);
            writer.WriteChars(songBytes, 0, readLen);
            writer.WriteEndElement();

            writer.Flush();
            readLen = sr.Read(songBytes, 0, bufferSize);
        }

        writer.WriteEndElement();
        inFile.Close();
    }

    XmlSchema IXmlSerializable.GetSchema()
    {
        throw new NotImplementedException();
    }

    void IXmlSerializable.ReadXml(System.Xml.XmlReader reader)
    {
        throw new NotImplementedException();
    }
}

```

C#

```
public class SongFile : IXmlSerializable
{
    public static event ProgressMade OnProgress;

    public SongFile()
    { }

    private const string ns = "http://demos.teched2004.com/webservices";
    public static string MusicPath;
    private string filePath;
    private double size;

    {
        string fileName = reader.ReadElementString("fileName", ns);
        this.filePath =
            Path.Combine(MusicPath, Path.ChangeExtension(fileName, ".mp3"));
    }

    void ReadSongSize(XmlReader reader)
    {
        this.size = Convert.ToDouble(reader.ReadElementString("size", ns));
    }

    void ReadAndSaveSong(XmlReader reader)
    {
        FileStream outFile = File.Open(
            this.filePath, FileMode.Create, FileAccess.Write);

        string songBase64;
        byte[] songBytes;
        reader.ReadStartElement("song", ns);
        double totalRead = 0;
        while (true)
        {
            if (reader.IsStartElement("chunk", ns))
            {
                songBase64 = reader.ReadElementString();
                totalRead += songBase64.Length;
                songBytes = Convert.FromBase64String(songBase64);
                outFile.Write(songBytes, 0, songBytes.Length);
                outFile.Flush();
            }
        }
    }
}
```

```
        if (OnProgress != null)
    {
        OnProgress(100 * (totalRead / size));
    }
}

else
{
    break;
}
}

outFile.Close();
reader.ReadEndElement();
}

public void Play()
{
    System.Diagnostics.Process.Start(this.filePath);
}

XmlSchema IXmlSerializable.GetSchema()
{
    throw new NotImplementedException();
}

public void WriteXml(XmlWriter writer)
{
    throw new NotImplementedException();
}
}
```

<system.xml.serialization> Element

Article • 09/15/2021

The top-level element for controlling XML serialization. For more information about configuration files, see [Configuration File Schema](#).

```
<configuration>
<system.xml.serialization>
```

Syntax

XML

```
<system.xml.serialization>
</system.xml.serialization>
```

Attributes and Elements

The following sections describe attributes, child elements, and parent elements.

Attributes

None.

Child Elements

| Element | Description |
|--|---|
| <code><dateTimeSerialization> Element</code> | Determines the serialization mode of <code>DateTime</code> objects. |
| <code><schemalimporterExtensions> Element</code> | Contains types that are used by the <code>XmlSchemalimporter</code> for mapping of XSD types to .NET types. |

Parent Elements

| Element | Description |
|--|---|
| <code><configuration> Element</code> | The root element in every configuration file that is used by the common language runtime and .NET Framework applications. |

Example

The following code example illustrates how to specify the serialization mode of a `DateTime` object, and the addition of types used by the `XmlSchemaImporter` when mapping XSD types to .NET types.

XML

```
<system.xml.serialization>
  <xmleserializer checkDeserializeAdvances="false" />
  <dateTimeSerialization mode = "Local" />
  <schemaImporterExtensions>
    <add
      name = "MobileCapabilities"
      type = "System.Web.Mobile.MobileCapabilities,
      System.Web.Mobile, Version=2.0.0.0, Culture=neutral,
      PublicKeyToken=b03f5f6f11d40a3a" />
  </schemaImporterExtensions>
</system.xml.serialization>
```

<dateTimeSerialization> Element

Article • 09/15/2021

Determines the serialization mode of [DateTime](#) objects.

```
<configuration>
  <dateTimeSerialization>
```

Syntax

XML

```
<dateTimeSerialization
  mode = "Roundtrip|Local"
/>
```

Attributes and Elements

The following sections describe attributes, child elements, and parent elements.

Attributes

| Attributes | Description |
|------------|---|
| mode | Optional. Specifies the serialization mode. Set to one of the DateTimeSerializationSection.DateTimeSerializationMode values. The default is RoundTrip . |

Child Elements

None.

Parent Elements

| Element | Description |
|--------------------------|--|
| system.xml.serialization | The top-level element for controlling XML serialization. |

Remarks

When this property is set to **Local**, [DateTime](#) objects are always formatted as the local time. That is, local time zone information is always included with the serialized data.

When this property is set to **Roundtrip**, [DateTime](#) objects are examined to determine whether they are in the local, UTC, or an unspecified time zone. The [DateTime](#) objects are then serialized in such a way that this information is preserved. This is the default behavior and is the recommended behavior for all new applications that do not communicate with older versions of the framework.

<schemaImporterExtensions> element

Article • 09/15/2021

Contains types that are used by the [XmlSchemaImporter](#) for mapping of XSD types to .NET types. For more information about configuration files, see [Configuration File Schema](#).

Syntax

XML

```
<schemaImporterExtensions>
    <!-- Add types -->
</schemaImporterExtensions>
```

Child Elements

| Element | Description |
|--|---|
| <add> Element for <schemaImporterExtensions> | Adds types that are used by the XmlSchemaImporter to create mappings. |

Parent Elements

| Element | Description |
|--|--|
| <system.xml.serialization> Element | The top-level element for controlling XML serialization. |

Example

The following code example illustrates how to add types that are used by the [XmlSchemaImporter](#) when mapping XSD types to .NET types.

XML

```
<system.xml.serialization>
    <schemaImporterExtensions>
        <add name = "MobileCapabilities" type =
            "System.Web.Mobile.MobileCapabilities,
            System.Web.Mobile, Version = 2.0.0.0, Culture = neutral,
```

```
    PublicKeyToken = b03f5f6f11d40a3a" />
  </schemaImporterExtensions>
</system.xml.serialization>
```

<add> Element for <schemalimporterExtensions>

Article • 09/15/2021

Adds types used by the [XmlSchemalimporter](#) for mapping XSD types to .NET types. For more information about configuration files, see [Configuration File Schema](#).

```
<configuration>
<system.xml.serialization>
<schemalimporterExtensions>
<add>
```

Syntax

XML

```
<add name = "typeName" type="fully qualified type [,Version=version number]
[,Culture=culture] [,PublicKeyToken= token]" />
```

Attributes and Elements

The following sections describe attributes, child elements, and parent elements.

Attributes

| Attribute | Description |
|-----------|--|
| name | A simple name that is used to find the instance. |
| type | Required. Specifies the schema extension class to add. The type attribute value must be on one line, and include the fully qualified type name. When the assembly is placed in the Global Assembly Cache (GAC), it must also include the version, culture, and public key token of the signed assembly. |

Child Elements

None.

Parent Elements

| Element | Description |
|-----------------------------|--|
| <schemalimporterExtensions> | Contains the types that are used by the XmlSchemalimporter . |

Example

The following code example adds an extension type that the XmlSchemalimporter can use when mapping types.

XML

```
<configuration>
  <system.xml.serialization>
    <schemalimporterExtensions>
      <add name="contoso" type="System.Web.Mobile.MobileCapabilities,
        System.Web.Mobile, Version=2.0.0.0, Culture=neutral,
        PublicKeyToken=b03f5f7f11d50a3a" />
    </schemalimporterExtensions>
  </system.xml.serialization>
</configuration>
```

<xmlSerializer> Element

Article • 09/15/2021

Specifies whether an additional check of progress of the [XmlSerializer](#) is done.

```
<configuration>
<system.xml.serialization>
```

Syntax

XML

```
<xmlSerializer checkDeserializerAdvance = "true|false" />
```

Attributes and Elements

The following sections describe attributes, child elements, and parent elements.

Attributes

| Attribute | Description |
|----------------------------------|--|
| checkDeserializeAdvances | Specifies whether the progress of the XmlSerializer is checked. Set the attribute to "true" or "false". The default is "true". |
| useLegacySerializationGeneration | Specifies whether the XmlSerializer uses legacy serialization generation which generates assemblies by writing C# code to a file and then compiling it to an assembly. The default is false. |

Child Elements

None.

Parent Elements

| Element | Description |
|----------------------------|---|
| <system.xml.serialization> | Contains configuration settings for the XmlSerializer and |

| Element | Description |
|---------|---|
| Element | <code>XmlSchemaImporter</code> classes. |

Remarks

By default, the `XmlSerializer` provides an additional layer of security against potential denial of service attacks when deserializing untrusted data. It does so by attempting to detect infinite loops during deserialization. If such a condition is detected, an exception is thrown with the following message: "Internal error: deserialization failed to advance over underlying stream."

Receiving this message does not necessarily indicate that a denial of service attack is in progress. In some rare circumstances, the infinite loop detection mechanism produces a false positive and the exception is thrown for a legitimate incoming message. If you find that in your particular application legitimate messages are being rejected by this extra layer of protection, set `checkDeserializeAdvances` attribute to "false".

Example

The following code example sets the `checkDeserializeAdvances` attribute to "false".

XML

```
<configuration>
  <system.xml.serialization>
    <xmlSerializer checkDeserializeAdvances="false" />
  </system.xml.serialization>
</configuration>
```

XML Serializer Generator Tool (Sgen.exe)

Article • 08/12/2022

The XML Serializer Generator creates an XML serialization assembly for types in a specified assembly. The serialization assembly improves the startup performance of a [XmlSerializer](#) when it serializes or deserializes objects of the specified types.

Syntax

Run the tool from the command line.

Console

```
sgen [options]
```

Tip

For .NET Framework tools to function properly, you must either use [Visual Studio Developer Command Prompt](#) or [Visual Studio Developer PowerShell](#) or set the `Path`, `Include`, and `Lib` environment variables correctly. To set these environment variables, run `SDKVars.bat`, which is located in the `<SDK>\<version>\Bin` directory.

Parameters

| Option | Description |
|----------------------------------|---|
| <code>/a[sembly]:filename</code> | Generates serialization code for all the types contained in the assembly or executable specified by <i>filename</i> . Only one file name can be provided. If this argument is repeated, the last file name is used. |
| <code>/c[ompiler]:options</code> | Specifies the options to pass to the C# compiler. All csc.exe options are supported as they are passed to the compiler. This can be used to specify that the assembly should be signed and to specify the key file. |
| <code>/d[ebug]</code> | Generates an image that can be used with a debugger. |
| <code>/f[orce]</code> | Forces the overwriting of an existing assembly of the same name. The default is false . |

| Option | Description |
|----------------------------|---|
| /help or /? | Displays command syntax and options for the tool. |
| /k[eepl] | Suppresses the deletion of the generated source files and other temporary files after they have been compiled into the serialization assembly. This can be used to determine whether the tool is generating serialization code for a particular type. |
| /n[ologo] | Suppresses the display of the Microsoft startup banner. |
| /o[ut]:path | Specifies the directory in which to save the generated assembly. Note: The name of the generated assembly is composed of the name of the input assembly plus "xmlSerializers.dll". |
| /p[roxytypes] | Generates serialization code only for the XML Web service proxy types. |
| /r[eference]:assemblyfiles | Specifies the assemblies that are referenced by the types requiring XML serialization. Accepts multiple assembly files separated by commas. |
| /s[ilent] | Suppresses the display of success messages. |
| /t[type]:type | Generates serialization code only for the specified type. |
| /v[erbose] | Displays verbose output for debugging. Lists types from the target assembly that cannot be serialized with the XmlSerializer . |
| /? | Displays command syntax and options for the tool. |

Remarks

When the XML Serializer Generator is not used, a [XmlSerializer](#) generates serialization code and a serialization assembly for each type every time an application is run. To improve the performance of XML serialization startup, use the Sgen.exe tool to generate those assemblies in advance. These assemblies can then be deployed with the application.

The XML Serializer Generator can also improve the performance of clients that use XML Web service proxies to communicate with servers because the serialization process will not incur a performance hit when the type is loaded the first time.

These generated assemblies cannot be used on the server side of a Web service. This tool is only for Web service clients and manual serialization scenarios.

If the assembly containing the type to serialize is named MyType.dll, then the associated serialization assembly will be named MyType.XmlSerializers.dll.

Note

The `sgen` tool is not compatible with `init-only` setters. The tool will fail if the target assembly contains any public properties that use this feature.

Examples

The following command creates an assembly named `Data.XmlSerializers.dll` for serializing all the types contained in the assembly named `Data.dll`.

Console

```
sgen Data.dll
```

The `Data.XmlSerializers.dll` assembly can be referenced from code that needs to serialize and deserialize the types in `Data.dll`.

XML Schema Definition Tool (Xsd.exe)

Article • 07/29/2022

The XML Schema Definition (Xsd.exe) tool generates XML schema or common language runtime classes from XDR, XML, and XSD files, or from classes in a runtime assembly.

The XML Schema Definition tool (Xsd.exe) usually can be found in the following path:
C:\Program Files (x86)\Microsoft SDKs\Windows\{version}\bin\NETFX {version} Tools

Syntax

Run the tool from the command line.

Console

```
xsd file.xdr [-outputdir:directory][/parameters:file.xml]
xsd file.xml [-outputdir:directory] [/parameters:file.xml]
xsd file.xsd{/classes | /dataset} [/element:element]
    [/enableLinqDataSet] [/language:language]
    [/namespace:namespace] [-outputdir:directory]
[URI:uri]
    [/parameters:file.xml]
xsd {file.dll | file.exe} [-outputdir:directory] [/type:typename [...]]
[/parameters:file.xml]
```

Tip

For .NET Framework tools to function properly, you must set your `Path`, `Include`, and `Lib` environment variables correctly. Set these environment variables by running `SDKVars.bat`, which is located in the `<SDK>\<version>\Bin` directory. `SDKVars.bat` must be executed in every command shell.

Argument

| Argument | Description |
|-----------------------------|--|
| <code>file.extension</code> | Specifies the input file to convert. You must specify the extension as one of the following: <code>.xdr</code> , <code>.xml</code> , <code>.xsd</code> , <code>.dll</code> , or <code>.exe</code> . If you specify an XDR schema file (<code>.xdr</code> extension), <code>Xsd.exe</code> converts the XDR schema to an XSD schema. The output file has the same name as the XDR schema, but with the <code>.xsd</code> extension. |

| Argument | Description |
|----------|---|
| | If you specify an XML file (.xml extension), Xsd.exe infers a schema from the data in the file and produces an XSD schema. The output file has the same name as the XML file, but with the .xsd extension. |
| | If you specify an XML schema file (.xsd extension), Xsd.exe generates source code for runtime objects that correspond to the XML schema. |
| | If you specify a runtime assembly file (.exe or .dll extension), Xsd.exe generates schemas for one or more types in that assembly. You can use the <code>/type</code> option to specify the types for which to generate schemas. The output schemas are named schema0.xsd, schema1.xsd, and so on. Xsd.exe produces multiple schemas only if the given types specify a namespace using the <code>XMLRoot</code> custom attribute. |

General Options

| Option | Description |
|-------------------------------------|--|
| <code>/h[elp]</code> | Displays command syntax and options for the tool. |
| <code>/o[utputdir]:directory</code> | Specifies the directory for output files. This argument can appear only once. The default is the current directory. |
| <code>/?</code> | Displays command syntax and options for the tool. |
| <code>/p[arameters]:file.xml</code> | Read options for various operation modes from the specified .xml file. The short form is <code>/p:</code> . For more information, see the Remarks section. |

XSD File Options

You must specify only one of the following options for .xsd files.

| Option | Description |
|-------------------------|---|
| <code>/c[lasses]</code> | Generates classes that correspond to the specified schema. To read XML data into the object, use the XmlSerializer.Deserialize method. |
| <code>/d[ataset]</code> | Generates a class derived from DataSet that corresponds to the specified schema. To read XML data into the derived class, use the DataSet.ReadXml method. |

You can also specify any of the following options for .xsd files.

| Option | Description |
|------------------------|---|
| /e[element]:element | Specifies the element in the schema to generate code for. By default all elements are typed. You can specify this argument more than once. |
| /enableDataBinding | Implements the INotifyPropertyChanged interface on all generated types to enable data binding. The short form is <code>/edb</code> . |
| /enableLinqDataSet | (Short form: <code>/eld</code> .) Specifies that the generated DataSet can be queried against using LINQ to DataSet. This option is used when the <code>/dataset</code> option is also specified. For more information, see LINQ to DataSet Overview and Querying Typed DataSets . For general information about using LINQ, see Language-Integrated Query (LINQ) - C# or Language-Integrated Query (LINQ) - Visual Basic . |
| /f[ields] | Generates fields only. By default, properties with backing fields are generated. |
| /l[anguage]:language | Specifies the programming language to use. Choose from <code>cs</code> (C#, which is the default), <code>vb</code> (Visual Basic), <code>js</code> (JScript), or <code>vjs</code> (Visual J#). You can also specify a fully qualified name for a class implementing System.CodeDom.Compiler.CodeDomProvider |
| /n[amespace]:namespace | Specifies the runtime namespace for the generated types. The default namespace is <code>Schemas</code> . |
| /nologo | Suppresses the banner. |
| /order | Generates explicit order identifiers on all particle members. |
| /o[ut]:directoryName | Specifies the output directory to place the files in. The default is the current directory. |
| /u[ri]:uri | Specifies the URI for the elements in the schema to generate code for. This URI, if present, applies to all elements specified with the <code>/element</code> option. |

DLL and EXE File Options

| Option | Description |
|-------------------|---|
| /t[type]:typename | Specifies the name of the type to create a schema for. You can specify multiple type arguments. If <code>typename</code> does not specify a namespace, Xsd.exe matches all types in the assembly with the specified type. If <code>typename</code> specifies a namespace, only that type is matched. If <code>typename</code> ends with an asterisk character (*), the tool matches all types that start with the string preceding the *. If you omit the <code>/type</code> option, Xsd.exe generates schemas for all types in the assembly. |

Remarks

The following table shows the operations that Xsd.exe performs.

| Operation | Description |
|----------------|---|
| XDR to XSD | Generates an XML schema from an XML-Data-Reduced schema file. XDR is an early XML-based schema format. |
| XML to XSD | Generates an XML schema from an XML file. |
| XSD to DataSet | Generates common language runtime DataSet classes from an XSD schema file. The generated classes provide a rich object model for regular XML data. |
| XSD to Classes | Generates runtime classes from an XSD schema file. The generated classes can be used in conjunction with System.Xml.Serialization.XmlSerializer to read and write XML code that follows the schema. |
| Classes to XSD | Generates an XML schema from a type or types in a runtime assembly file. The generated schema defines the XML format used by the XmlSerializer . |

Xsd.exe only allows you to manipulate XML schemas that follow the XML Schema Definition (XSD) language proposed by the World Wide Web Consortium (W3C). For more information on the XML Schema Definition proposal or the XML standard, see <https://w3.org>.

Setting Options with an XML File

By using the `/parameters` switch, you can specify a single XML file that sets various options. The options you can set depend on how you are using the XSD.exe tool. Choices include generating schemas, generating code files, or generating code files that include `DataSet` features. For example, you can set the `<assembly>` element to the name of an executable (.exe) or type library (.dll) file when generating a schema, but not when generating a code file. The following XML shows how to use the `<generateSchemas>` element with a specified executable:

XML

```
<!-- This is in a file named GenerateSchemas.xml. -->
<xsd xmlns='http://microsoft.com/dotnet/tools/xsd/'>
<generateSchemas>
    <assembly>ConsoleApplication1.exe</assembly>
</generateSchemas>
</xsd>
```

If the preceding XML is contained in a file named GenerateSchemas.xml, then use the `/parameters` switch by typing the following at a command prompt and pressing `Enter`:

Console

```
xsd /p:GenerateSchemas.xml
```

On the other hand, if you are generating a schema for a single type found in the assembly, you can use the following XML:

XML

```
<!-- This is in a file named GenerateSchemaFromType.xml. -->
<xsd xmlns='http://microsoft.com/dotnet/tools/xsd/'>
<generateSchemas>
  <type>IDItems</type>
</generateSchemas>
</xsd>
```

But to use preceding code, you must also supply the name of the assembly at the command prompt. Enter the following at a command prompt (presuming the XML file is named GenerateSchemaFromType.xml):

Console

```
xsd /p:GenerateSchemaFromType.xml ConsoleApplication1.exe
```

You must specify only one of the following options for the `<generateSchemas>` element.

| Element | Description |
|-------------------------------|---|
| <code><assembly></code> | Specifies an assembly to generate the schema from. |
| <code><type></code> | Specifies a type found in an assembly to generate a schema for. |
| <code><xml></code> | Specifies an XML file to generate a schema for. |
| <code><xdr></code> | Specifies an XDR file to generate a schema for. |

To generate a code file, use the `<generateClasses>` element. The following example generates a code file. Note that two attributes are also shown that allow you to set the programming language and namespace of the generated file.

XML

```

<xsd xmlns='http://microsoft.com/dotnet/tools/xsd/'>
<generateClasses language='VB'
namespace='Microsoft.Serialization.Examples' />
</xsd>
<!-- You must supply an .xsd file when typing in the command line.-->
<!-- For example: xsd /p:genClasses mySchema.xsd -->

```

Options you can set for the `<generateClasses>` element include the following.

| Element | Description |
|--|---|
| <code><element></code> | Specifies an element in the .xsd file to generate code for. |
| <code><schemalimporterExtensions></code> | Specifies a type derived from the SchemalimporterExtension class. |
| <code><schema></code> | Specifies a XML Schema file to generate code for. Multiple XML Schema files can be specified using multiple <code><schema></code> elements. |

The following table shows the attributes that can also be used with the `<generateClasses>` element.

| Attribute | Description |
|------------------------|--|
| <code>language</code> | Specifies the programming language to use. Choose from <code>cs</code> (C#, the default), <code>VB</code> (Visual Basic), <code>JS</code> (JScript), or <code>VJS</code> (Visual J#). You can also specify a fully qualified name for a class that implements CodeDomProvider . |
| <code>namespace</code> | Specifies the namespace for the generated code. The namespace must conform to CLR standards (for example, no spaces or backslash characters). |
| <code>options</code> | One of the following values: <code>none</code> , <code>properties</code> (generates properties instead of public fields), <code>order</code> , or <code>enableDataBinding</code> (see the <code>/order</code> and <code>/enableDataBinding</code> switches in the preceding XSD File Options section). |

You can also control how `DataSet` code is generated by using the `<generateDataSet>` element. The following XML specifies that the generated code uses `DataSet` structures (such as the `DataTable` class) to create Visual Basic code for a specified element. The generated DataSet structures will support LINQ queries.

XML

```

<xsd xmlns='http://microsoft.com/dotnet/tools/xsd/'>
  <generateDataSet language='VB'
  namespace='Microsoft.Serialization.Examples' enableLinqDataSet='true'>
    </generateDataSet>
  </xsd>

```

Options you can set for the `<generateDataSet>` element include the following.

| Element | Description |
|-----------------------------|--|
| <code><schema></code> | Specifies an XML Schema file to generate code for. Multiple XML Schema files can be specified using multiple <code><schema></code> elements. |

The following table shows the attributes that can be used with the `<generateDataSet>` element.

| Attribute | Description |
|--------------------------------|---|
| <code>enableLinqDataSet</code> | Specifies that the generated DataSet can be queried against using LINQ to DataSet. The default value is false. |
| <code>language</code> | Specifies the programming language to use. Choose from <code>cs</code> (C#, the default), <code>VB</code> (Visual Basic), <code>JS</code> (JScript), or <code>VJS</code> (Visual J#). You can also specify a fully qualified name for a class that implements CodeDomProvider . |
| <code>namespace</code> | Specifies the namespace for the generated code. The namespace must conform to CLR standards (for example, no spaces or backslash characters). |

There are attributes that you can set on the top level `<xsd>` element. These options can be used with any of the child elements (`<generateSchemas>`, `<generateClasses>` or `<generateDataSet>`). The following XML code generates code for an element named "IDItems" in the output directory named "MyOutputDirectory".

| XML |
|---|
| <pre><xsd xmlns='http://microsoft.com/dotnet/tools/xsd/' output='MyOutputDirectory'> <generateClasses> <element>IDItems</element> </generateClasses> </xsd></pre> |

The following table shows the attributes that can also be used with the `<xsd>` element.

| Attribute | Description |
|---------------------|--|
| <code>output</code> | The name of a directory where the generated schema or code file will be placed. |
| <code>nologo</code> | Suppresses the banner. Set to <code>true</code> or <code>false</code> . |
| <code>help</code> | Displays command syntax and options for the tool. Set to <code>true</code> or <code>false</code> . |

Examples

The following command generates an XML schema from `myFile.xdr` and saves it to the current directory.

```
Console
```

```
xsd myFile.xdr
```

The following command generates an XML schema from `myFile.xml` and saves it to the specified directory.

```
Console
```

```
xsd myFile.xml /outputdir:myOutputDir
```

The following command generates a data set that corresponds to the specified schema in the C# language and saves it as `XSDSchemaFile.cs` in the current directory.

```
Console
```

```
xsd /dataset /language:CS XSDSchemaFile.xsd
```

The following command generates XML schemas for all types in the assembly `myAssembly.dll` and saves them as `schema0.xsd` in the current directory.

```
Console
```

```
xsd myAssembly.dll
```

Deserialization risks in use of BinaryFormatter and related types

Article • 04/05/2023

This article applies to the following types:

- [BinaryFormatter](#)
- [SoapFormatter](#)
- [NetDataContractSerializer](#)
- [LosFormatter](#)
- [ObjectStateFormatter](#)

This article applies to the following .NET implementations:

- .NET Framework all versions
- .NET Core 2.1 - 3.1
- .NET 5 and later

⚠ Warning

The **BinaryFormatter** type is dangerous and is *not* recommended for data processing. Applications should stop using `BinaryFormatter` as soon as possible, even if they believe the data they're processing to be trustworthy. `BinaryFormatter` is insecure and can't be made secure.

Deserialization vulnerabilities

Deserialization vulnerabilities are a threat category where request payloads are processed insecurely. An attacker who successfully leverages these vulnerabilities against an app can cause denial of service (DoS), information disclosure, or remote code execution inside the target app. This risk category consistently makes the [OWASP Top 10](#). Targets include apps written in [a variety of languages](#), including C/C++, Java, and C#.

In .NET, the biggest risk target is apps that use the `BinaryFormatter` type to deserialize data. `BinaryFormatter` is widely used throughout the .NET ecosystem because of its power and its ease of use. However, this same power gives attackers the ability to influence control flow within the target app. Successful attacks can result in the attacker being able to run code within the context of the target process.

As a simpler analogy, assume that calling `BinaryFormatter.Deserialize` over a payload is the equivalent of interpreting that payload as a standalone executable and launching it.

BinaryFormatter security vulnerabilities

⚠ Warning

The `BinaryFormatter.Deserialize` method is **never** safe when used with untrusted input. We strongly recommend that consumers instead consider using one of the alternatives outlined later in this article.

`BinaryFormatter` was implemented before deserialization vulnerabilities were a well-understood threat category. As a result, the code does not follow modern best practices. The `Deserialize` method can be used as a vector for attackers to perform DoS attacks against consuming apps. These attacks might render the app unresponsive or result in unexpected process termination. This category of attack cannot be mitigated with a `SerializationBinder` or any other `BinaryFormatter` configuration switch. .NET considers this behavior to be *by design* and won't issue a code update to modify the behavior.

`BinaryFormatter.Deserialize` may be vulnerable to other attack categories, such as information disclosure or remote code execution. Utilizing features such as a custom `SerializationBinder` may be insufficient to properly mitigate these risks. The possibility exists that a novel vulnerability will be discovered for which .NET cannot practically publish a security update. Consumers should assess their individual scenarios and consider their potential exposure to these risks.

We recommend that `BinaryFormatter` consumers perform individual risk assessments on their apps. It is the consumer's sole responsibility to determine whether to utilize `BinaryFormatter`. If you're considering using it, you should risk-assess the security, technical, reputation, legal, and regulatory consequences.

Preferred alternatives

.NET offers several in-box serializers that can handle untrusted data safely:

- `XmlSerializer` and `DataContractSerializer` to serialize object graphs into and from XML. Do not confuse `DataContractSerializer` with `NetDataContractSerializer`.
- `BinaryReader` and `BinaryWriter` for XML and JSON.
- The `System.Text.Json` APIs to serialize object graphs into JSON.

Dangerous alternatives

Avoid the following serializers:

- [SoapFormatter](#)
- [LosFormatter](#)
- [NetDataContractSerializer](#)
- [ObjectStateFormatter](#)

The preceding serializers all perform unrestricted polymorphic deserialization and are dangerous, just like `BinaryFormatter`.

The risks of assuming data to be trustworthy

Frequently, an app developer might believe that they are processing only trusted input. The safe input case is true in some rare circumstances. But it's much more common that a payload crosses a trust boundary without the developer realizing it.

Consider an **on-prem server** where employees use a desktop client from their workstations to interact with the service. This scenario might be seen naively as a "safe" setup where utilizing `BinaryFormatter` is acceptable. However, this scenario presents a vector for malware that gains access to a single employee's machine to be able to spread throughout the enterprise. That malware can leverage the enterprise's use of `BinaryFormatter` to move laterally from the employee's workstation to the backend server. It can then exfiltrate the company's sensitive data. Such data could include trade secrets or customer data.

Consider also an app that uses `BinaryFormatter` to persist save state. This might at first seem to be a safe scenario, as reading and writing data on your own hard drive represents a minor threat. However, sharing documents across email or the internet is common, and most end users wouldn't perceive opening these downloaded files as risky behavior.

This scenario can be leveraged to nefarious effect. If the app is a game, users who share save files unknowingly place themselves at risk. The developers themselves can also be targeted. The attacker might email the developers' tech support, attaching a malicious data file and asking the support staff to open it. This kind of attack could give the attacker a foothold in the enterprise.

Another scenario is where the data file is stored in cloud storage and automatically synced between the user's machines. An attacker who is able to gain access to the cloud storage account can poison the data file. This data file will be automatically synced to

the user's machines. The next time the user opens the data file, the attacker's payload runs. Thus the attacker can leverage a cloud storage account compromise to gain full code execution permissions.

Consider an app that moves from a desktop-install model to a cloud-first model. This scenario includes apps that move from a desktop app or rich client model into a web-based model. Any threat models drawn for the desktop app aren't necessarily applicable to the cloud-based service. The threat model for the desktop app might dismiss a given threat as "not interesting for the client to attack itself." But that same threat might become interesting when it considers a remote user (the client) attacking the cloud service itself.

Note

In general terms, the intent of serialization is to transmit an object into or out of an app. A threat modeling exercise almost always marks this kind of data transfer as crossing a trust boundary.

BinaryFormatter event source

Article • 04/19/2023

Starting with .NET 5, [BinaryFormatter](#) includes a built-in [EventSource](#) that gives you visibility into when an object serialization or deserialization is occurring. Apps can use [EventListener](#)-derived types to listen for these notifications and log them.

This functionality is not a substitute for a [SerializationBinder](#) or an [ISerializationSurrogate](#) and can't be used to modify the data being serialized or deserialized. Rather, this eventing system is intended to provide insight into the types being serialized or deserialized. It can also be used to detect unintended calls into the [BinaryFormatter](#) infrastructure, such as calls originating from third-party library code.

Description of events

The `BinaryFormatter` event source has the well-known name `System.Runtime.Serialization.Formatters.Binary.BinaryFormatterEventSource`. Listeners can subscribe to six events.

SerializationStart event (id = 10)

Raised when `BinaryFormatter.Serialize` has been called and has started the serialization process. This event is paired with the `SerializationEnd` event. The `SerializationStart` event can be called recursively if an object calls `BinaryFormatter.Serialize` within its own serialization routine.

This event doesn't contain a payload.

SerializationEnd event (id = 11)

Raised when `BinaryFormatter.Serialize` has completed its work. Each occurrence of `SerializationEnd` denotes the completion of the last unpaired `SerializationStart` event.

This event doesn't contain a payload.

SerializingObject event (id = 12)

Raised when `BinaryFormatter.Serialize` is in the process of serializing a non-primitive type. The `BinaryFormatter` infrastructure special-cases certain types (such as `string` and `int`) and doesn't raise this event when these types are encountered. This event is raised for user-defined types and other types that `BinaryFormatter` doesn't natively understand.

This event may be raised zero or more times between `SerializationStart` and `SerializationEnd` events.

This event contains a payload with one argument:

- `typeName` (`string`): The assembly-qualified name (see [Type.AssemblyQualifiedName](#)) of the type being serialized.

DeserializationStart event (id = 20)

Raised when `BinaryFormatter.Deserialize` has been called and has started the deserialization process. This event is paired with the `DeserializationEnd` event. The `DeserializationStart` event can be called recursively if an object calls `BinaryFormatter.Deserialize` within its own deserialization routine.

This event doesn't contain a payload.

DeserializationEnd event (id = 21)

Raised when `BinaryFormatter.Deserialize` has completed its work. Each occurrence of `DeserializationEnd` denotes the completion of the last unpaired `DeserializationStart` event.

This event doesn't contain a payload.

DeserializingObject event (id = 22)

Raised when `BinaryFormatter.Deserialize` is in the process of deserializing a non-primitive type. The `BinaryFormatter` infrastructure special-cases certain types (such as `string` and `int`) and doesn't raise this event when these types are encountered. This event is raised for user-defined types and other types that `BinaryFormatter` doesn't natively understand.

This event may be raised zero or more times between `DeserializationStart` and `DeserializationEnd` events.

This event contains a payload with one argument.

- `typeName` (`string`): The assembly-qualified name (see [Type.AssemblyQualifiedName](#)) of the type being deserialized.

[Advanced] Subscribing to a subset of notifications

Listeners who wish to subscribe to only a subset of notifications can choose which keywords to enable.

- `Serialization` = `(EventKeywords)1`: Raises the `SerializationStart`, `SerializationEnd`, and `SerializingObject` events.
- `Deserialization` = `(EventKeywords)2`: Raises the `DeserializationStart`, `DeserializationEnd`, and `DeserializingObject` events.

If no keyword filters are provided during `EventListener` registration, all events are raised.

For more information, see [System.Diagnostics.Tracing.EventKeywords](#).

Sample code

The following code:

- creates an `EventListener`-derived type that writes to `System.Console`,
- subscribes that listener to `BinaryFormatter`-produced notifications,
- serializes and deserializes a simple object graph using `BinaryFormatter`, and
- analyzes the events that have been raised.

C#

```
using System;
using System.Diagnostics.Tracing;
using System.IO;
using System.Runtime.Serialization.Formatters.Binary;

namespace BinaryFormatterEventSample
{
    class Program
    {
        static EventListener? _globalListener = null;

        static void Main(string[] args)
        {
            // First, set up the event listener.
            // Note: We assign it to a static field so that it doesn't get
```

```

GCed.

        // We also provide a callback that subscribes this listener to
all
        // events produced by the well-known BinaryFormatter source.

        _globalListener = new ConsoleEventListener();
        _globalListener.EventSourceCreated += (sender, args) =>
    {
        if (args.EventSource?.Name ==
"System.Runtime.Serialization.Formatters.Binary.BinaryFormatterEventSource")
    {
        ((EventListener?)sender)?
            .EnableEvents(args.EventSource,
EventLevel.LogAlways);
    }
};

// Next, create the Person object and serialize it.

Person originalPerson = new Person()
{
    FirstName = "Logan",
    LastName = "Edwards",
    FavoriteBook = new Book()
    {
        Title = "A Tale of Two Cities",
        Author = "Charles Dickens",
        Price = 10.25m
    }
};

byte[] serializedPerson = SerializePerson(originalPerson);

// Finally, deserialize the Person object.

Person rehydratedPerson = DeserializePerson(serializedPerson);

Console.WriteLine
    ($"Rehydrated person {rehydratedPerson.FirstName}"
{rehydratedPerson.LastName}");
Console.Write
    ($"Favorite book: {rehydratedPerson.FavoriteBook?.Title} ");
Console.Write
    ($"by {rehydratedPerson.FavoriteBook?.Author}, ");
Console.WriteLine
    ($"list price {rehydratedPerson.FavoriteBook?.Price}");
}

private static byte[] SerializePerson(Person p)
{
    MemoryStream memStream = new MemoryStream();
    BinaryFormatter formatter = new BinaryFormatter();
#pragma warning disable SYSLIB0011 // BinaryFormatter.Serialize is obsolete
    formatter.Serialize(memStream, p);
}

```

```
#pragma warning restore SYSLIB0011

        return memStream.ToArray();
    }

    private static Person DeserializePerson(byte[] serializedData)
    {
        MemoryStream memStream = new MemoryStream(serializedData);
        BinaryFormatter formatter = new BinaryFormatter();

#pragma warning disable SYSLIB0011 // Danger: BinaryFormatter.Deserialize is
insecure for untrusted input
        return (Person)formatter.Deserialize(memStream);
#pragma warning restore SYSLIB0011
    }
}

[Serializable]
public class Person
{
    public string? FirstName;
    public string? LastName;
    public Book? FavoriteBook;
}

[Serializable]
public class Book
{
    public string? Title;
    public string? Author;
    public decimal? Price;
}

// A sample EventListener that writes data to System.Console.
public class ConsoleEventListener : EventListener
{
    protected override void OnEventWritten(EventWrittenEventArgs eventData)
    {
        base.OnEventWritten(eventData);

        Console.WriteLine($"Event {eventData.EventName} (id={eventData.EventId}) received.");
        if (eventData.PayloadNames != null)
        {
            for (int i = 0; i < eventData.PayloadNames.Count; i++)
            {
                Console.WriteLine($"{eventData.PayloadNames[i]} = {eventData.Payload?[i]}");
            }
        }
    }
}
```

The preceding code produces output similar to the following example:

Output

```
Event SerializationStart (id=10) received.  
Event SerializingObject (id=12) received.  
typeName = BinaryFormatterEventSample.Person, BinaryFormatterEventSample,  
Version=1.0.0.0, Culture=neutral, PublicKeyToken=null  
Event SerializingObject (id=12) received.  
typeName = BinaryFormatterEventSample.Book, BinaryFormatterEventSample,  
Version=1.0.0.0, Culture=neutral, PublicKeyToken=null  
Event SerializationStop (id=11) received.  
Event DeserializationStart (id=20) received.  
Event DeserializingObject (id=22) received.  
typeName = BinaryFormatterEventSample.Person, BinaryFormatterEventSample,  
Version=1.0.0.0, Culture=neutral, PublicKeyToken=null  
Event DeserializingObject (id=22) received.  
typeName = BinaryFormatterEventSample.Book, BinaryFormatterEventSample,  
Version=1.0.0.0, Culture=neutral, PublicKeyToken=null  
Event DeserializationStop (id=21) received.  
Rehydrated person Logan Edwards  
Favorite book: A Tale of Two Cities by Charles Dickens, list price 10.25
```

In this sample, the console-based `EventListener` logs that serialization starts, instances of `Person` and `Book` are serialized, and then serialization completes. Similarly, once deserialization has started, instances of `Person` and `Book` are deserialized, and then deserialization completes.

The app then prints the values contained in the deserialized `Person` to demonstrate that the object did in fact serialize and deserialize properly.

System.Runtime.Serialization.DataContractAttribute class

Article • 01/08/2024

This article provides supplementary remarks to the reference documentation for this API.

Apply the [DataContractAttribute](#) attribute to types (classes, structures, or enumerations) that are used in serialization and deserialization operations by the [DataContractSerializer](#). If you send or receive messages by using the Windows Communication Foundation (WCF) infrastructure, you should also apply the [DataContractAttribute](#) to any classes that hold and manipulate data sent in messages. For more information about data contracts, see [Using Data Contracts](#).

You must also apply the [DataMemberAttribute](#) to any field, property, or event that holds values you want to serialize. By applying the [DataContractAttribute](#), you explicitly enable the [DataContractSerializer](#) to serialize and deserialize the data.

✖ Caution

You can apply the [DataMemberAttribute](#) to private fields. Be aware that the data returned by the field (even if it is private) is serialized and deserialized, and thus can be viewed or intercepted by a malicious user or process.

For more information about data contracts, see the topics listed in [Using Data Contracts](#).

Data contracts

A *data contract* is an abstract description of a set of fields with a name and data type for each field. The data contract exists outside of any single implementation to allow services on different platforms to interoperate. As long as the data passed between the services conforms to the same contract, all the services can process the data. This processing is also known as a *loosely coupled system*. A data contract is also similar to an interface in that the contract specifies how data must be delivered so that it can be processed by an application. For example, the data contract may call for a data type named "Person" that has two text fields, named "FirstName" and "LastName". To create a data contract, apply the [DataContractAttribute](#) to the class and apply the [DataMemberAttribute](#) to any fields or properties that must be serialized. When serialized, the data conforms to the data contract that is implicitly built into the type.

Note

A data contract differs significantly from an actual interface in its inheritance behavior. Interfaces are inherited by any derived types. When you apply the **DataContractAttribute** to a base class, the derived types do not inherit the attribute or the behavior. However, if a derived type has a data contract, the data members of the base class are serialized. However, you must apply the **DataMemberAttribute** to new members in a derived class to make them serializable.

XML schema documents and the SvcUtil tool

If you are exchanging data with other services, you must describe the data contract. For the current version of the **DataContractSerializer**, an XML schema can be used to define data contracts. (Other forms of metadata/description could be used for the same purpose.) To create an XML schema from your application, use the [ServiceModel Metadata Utility Tool \(Svcutil.exe\)](#) with the **/dconly** command line option. When the input to the tool is an assembly, by default, the tool generates a set of XML schemas that define all the data contract types found in that assembly. Conversely, you can also use the Svcutil.exe tool to create Visual Basic or C# class definitions that conform to the requirements of XML schemas that use constructs that can be expressed by data contracts. In this case, the **/dconly** command line option is not required.

If the input to the Svcutil.exe tool is an XML schema, by default, the tool creates a set of classes. If you examine those classes, you find that the **DataContractAttribute** has been applied. You can use those classes to create a new application to process data that must be exchanged with other services.

You can also run the tool against an endpoint that returns a Web Services Description Language (WSDL) document to automatically generate the code and configuration to create an Windows Communication Foundation (WCF) client. The generated code includes types that are marked with the **DataContractAttribute**.

Reuse existing types

A data contract has two basic requirements: a stable name and a list of members. The stable name consists of the namespace uniform resource identifier (URI) and the local name of the contract. By default, when you apply the **DataContractAttribute** to a class, it uses the class name as the local name and the class's namespace (prefixed with "<http://schemas.datacontract.org/2004/07/>") as the namespace URI. You can override

the defaults by setting the [Name](#) and [Namespace](#) properties. You can also change the namespace by applying the [ContractNamespaceAttribute](#) to the namespace. Use this capability when you have an existing type that processes data exactly as you require but has a different namespace and class name from the data contract. By overriding the default values, you can reuse your existing type and have the serialized data conform to the data contract.

 **Note**

In any code, you can use the word `DataContract` instead of the longer `DataContractAttribute`.

Versioning

A data contract can also accommodate later versions of itself. That is, when a later version of the contract includes extra data, that data is stored and returned to a sender untouched. To do this, implement the [IExtensibleDataObject](#) interface.

For more information about versioning, see [Data Contract Versioning](#).

System.Runtime.Serialization.DataContractSerializer class

Article • 01/08/2024

This article provides supplementary remarks to the reference documentation for this API.

Use the [DataContractSerializer](#) class to serialize and deserialize instances of a type into an XML stream or document. For example, you can create a type named `Person` with properties that contain essential data, such as a name and address. You can then create and manipulate an instance of the `Person` class and write all of its property values in an XML document for later retrieval, or in an XML stream for immediate transport. Most important, the [DataContractSerializer](#) is used to serialize and deserialize data sent in Windows Communication Foundation (WCF) messages. Apply the [DataContractAttribute](#) attribute to classes, and the [DataMemberAttribute](#) attribute to class members to specify properties and fields that are serialized.

For a list of types that can be serialized, see [Types Supported by the Data Contract Serializer](#).

To use the [DataContractSerializer](#), first create an instance of a class and an object appropriate to writing or reading the format; for example, an instance of the [XmlDictionaryWriter](#). Then call the [WriteObject](#) method to persist the data. To retrieve data, create an object appropriate to reading the data format (such as an [XmlDictionaryReader](#) for an XML document) and call the [ReadObject](#) method.

For more information about using the [DataContractSerializer](#), see [Serialization and Deserialization](#).

You can set the type of a data contract serializer using the `<dataContractSerializer>` element in a client application configuration file.

Prepare classes for serialization or deserialization

The [DataContractSerializer](#) is used in combination with the [DataContractAttribute](#) and [DataMemberAttribute](#) classes. To prepare a class for serialization, apply the [DataContractAttribute](#) to the class. For each member of the class that returns data that you want to serialize, apply the [DataMemberAttribute](#). You can serialize fields and

properties, regardless of accessibility: private, protected, internal, protected internal, or public.

For example, your schema specifies a `Customer` with an `ID` property, but you already have an existing application that uses a type named `Person` with a `Name` property. To create a type that conforms to the contract, first apply the [DataContractAttribute](#) to the class. Then apply the [DataMemberAttribute](#) to every field or property that you want to serialize.

 **Note**

You can apply the [DataMemberAttribute](#) to both private and public members.

The final format of the XML need not be text. Instead, the [DataContractSerializer](#) writes the data as an XML infoset, which allows you to write the data to any format recognized by the [XmlReader](#) and [XmlWriter](#). It is recommended that you use the [XmlDictionaryReader](#) and [XmlDictionaryWriter](#) classes to read and write, because both are optimized to work with the [DataContractSerializer](#).

If you are creating a class that has fields or properties that must be populated before the serialization or deserialization occurs, use callback attributes, as described in [Version-Tolerant Serialization Callbacks](#).

Add to the collection of known types

When serializing or deserializing an object, it is required that the type is "known" to the [DataContractSerializer](#). Begin by creating an instance of a class that implements `IEnumerable<T>` (such as `List<T>`) and adding the known types to the collection. Then create an instance of the [DataContractSerializer](#) using one of the overloads that takes the `IEnumerable<T>` (for example, `DataContractSerializer(Type, IEnumerable<Type>)`).

 **Note**

Unlike other primitive types, the `DateTimeOffset` structure is not a known type by default, so it must be manually added to the list of known types (see [Data Contract Known Types](#)).

Forward compatibility

The [DataContractSerializer](#) understands data contracts that have been designed to be compatible with future versions of the contract. Such types implement the [IExtensibleDataObject](#) interface. The interface features the [ExtensionData](#) property that returns an [ExtensionDataObject](#) object. For more information, see [Forward-Compatible Data Contracts](#).

Run under partial trust

When instantiating the target object during deserialization, the [DataContractSerializer](#) does not call the constructor of the target object. If you author a [\[DataContract\]](#) type that is accessible from partial trust (that is, it is public and in an assembly that has the [AllowPartiallyTrustedCallers](#) attribute applied) and that performs some security-related actions, you must be aware that the constructor is not called. In particular, the following techniques do not work:

- If you try to restrict partial trust access by making the constructor internal or private, or by adding a [LinkDemand](#) to the constructor -- neither of these have any effect during deserialization under partial trust.
- If you code the class that assumes the constructor has run, the class may get into an invalid internal state that is exploitable.

System.Runtime.Serialization.IExtensibleDataObject interface

Article • 01/08/2024

This article provides supplementary remarks to the reference documentation for this API.

The [IExtensibleDataObject](#) interface provides a single property that sets or returns a structure used to store data that is external to a data contract. The extra data is stored in an instance of the [ExtensionDataObject](#) class and accessed through the [ExtensionData](#) property. In a roundtrip operation where data is received, processed, and sent back, the extra data is sent back to the original sender intact. This is useful to store data received from future versions of the contract. If you do not implement the interface, any extra data is ignored and discarded during a roundtrip operation.

To use this versioning feature

1. Implement the [IExtensibleDataObject](#) interface in a class.
2. Add the [ExtensionData](#) property to your type.
3. Add a private member of type [ExtensionDataObject](#) to the class.
4. Implement get and set methods for the property using the new private member.
5. Apply the [DataContractAttribute](#) attribute to the class. Set the [Name](#) and [Namespace](#) properties to appropriate values if necessary.

For more information about versioning of types, see [Data Contract Versioning](#). For information about creating forward-compatible data contracts, see [Forward-Compatible Data Contracts](#). For more information about data contracts, see [Using Data Contracts](#).

System.Runtime.Serialization.XsdDataContractExporter class

Article • 01/08/2024

This article provides supplementary remarks to the reference documentation for this API.

Use the [XsdDataContractExporter](#) class when you have created a Web service that incorporates data represented by common language runtime (CLR) types and when you need to export XML schemas for each type to be consumed by other Web services. That is, [XsdDataContractExporter](#) transforms a set of CLR types into XML schemas. (For more information about the types that can be used, see [Types Supported by the Data Contract Serializer](#).) The schemas can then be exposed through a Web Services Description Language (WSDL) document for use by others who need to interoperate with your service.

Conversely, if you are creating a Web service that must interoperate with an existing Web service, use the [XsdDataContractImporter](#) to transform XML schemas and create the CLR types that represent the data in a selected programming language.

The [XsdDataContractExporter](#) generates an [XmlSchemaSet](#) object that contains the collection of schemas. Access the set of schemas through the [Schemas\(\)](#) property.

ⓘ Note

To quickly generate XML schema definition (XSD) files that other Web services can consume, use the [XsdDataContractExporter](#).

Export schemas into an XmlSchemaSet

To create an instance of the [XmlSchemaSet](#) class that contains XML schema files, you should be aware of the following.

The set of types you are exporting are recorded as an internal set of data contracts. Thus, you can call the [CanExport](#) method multiple times to add new types to the schema set without degrading performance because only the new types will be added to the set. During the [Export](#) operation, the existing schemas are compared to the new schemas being added. If there are conflicts, an exception will be thrown. A conflict is usually

detected if two types with the same data contract name but different contracts (different members) are exported by the same [XsdDataContractExporter](#) instance.

Use the exporter

A recommended way of using this class is as follows:

1. Use one of the [CanExport](#) overloads to determine whether the specified type or set of types can be exported. Use one of the overloads that is appropriate to your requirements.
2. Call the corresponding [Export](#) method.
3. Retrieve the schemas from the [Schemas](#) property.

System.CommandLine overview

Article • 04/08/2022

ⓘ Important

`System.CommandLine` is currently in PREVIEW, and this documentation is for version 2.0 beta 4. Some information relates to prerelease product that may be substantially modified before it's released. Microsoft makes no warranties, express or implied, with respect to the information provided here.

The `System.CommandLine` library provides functionality that is commonly needed by command-line apps, such as parsing the command-line input and displaying help text.

Apps that use `System.CommandLine` include the [.NET CLI](#), [additional tools](#), and many [global and local tools](#).

For app developers, the library:

- Lets you focus on writing your app code, since you don't have to write code to parse command-line input or produce a help page.
- Lets you test app code independently of input parsing code.
- Is [trim-friendly](#), making it a good choice for developing a fast, lightweight, AOT-capable CLI app.

Use of the library also benefits app users:

- It ensures that command-line input is parsed consistently according to [POSIX](#) or Windows conventions.
- It automatically supports [tab completion](#) and [response files](#).

NuGet package

The library is available in a NuGet package:

- [System.CommandLine](#)

Next steps

To get started with System.CommandLine, see the following resources:

- [Tutorial: Get started with System.CommandLine](#)

- [Command-line syntax overview](#)

To learn more, see the following resources:

Tutorial: Get started with System.CommandLine

Article • 09/21/2022

ⓘ Important

`System.CommandLine` is currently in PREVIEW, and this documentation is for version 2.0 beta 4. Some information relates to prerelease product that may be substantially modified before it's released. Microsoft makes no warranties, express or implied, with respect to the information provided here.

This tutorial shows how to create a .NET command-line app that uses the [System.CommandLine library](#). You'll begin by creating a simple root command that has one option. Then you'll add to that base, creating a more complex app that contains multiple subcommands and different options for each command.

In this tutorial, you learn how to:

- ✓ Create commands, options, and arguments.
- ✓ Specify default values for options.
- ✓ Assign options and arguments to commands.
- ✓ Assign an option recursively to all subcommands under a command.
- ✓ Work with multiple levels of nested subcommands.
- ✓ Create aliases for commands and options.
- ✓ Work with `string`, `string[]`, `int`, `bool`, `FileInfo` and enum option types.
- ✓ Bind option values to command handler code.
- ✓ Use custom code for parsing and validating options.

Prerequisites

- A code editor, such as [Visual Studio Code](#) with the [C# extension](#).
- The [.NET 6 SDK](#).

Or

- [Visual Studio 2022](#) with the [.NET desktop development](#) workload installed.

Create the app

Create a .NET 6 console app project named "scl".

1. Create a folder named *scl* for the project, and then open a command prompt in the new folder.
2. Run the following command:

```
.NET CLI  
dotnet new console --framework net6.0
```

Install the System.CommandLine package

- Run the following command:

```
.NET CLI  
dotnet add package System.CommandLine --prerelease
```

The `--prerelease` option is necessary because the library is still in beta.

1. Replace the contents of *Program.cs* with the following code:

```
C#  
  
using System.CommandLine;  
  
namespace scl;  
  
class Program  
{  
    static async Task<int> Main(string[] args)  
    {  
        var fileOption = new Option<FileInfo?>()  
        {  
            name: "--file",  
            description: "The file to read and display on the  
console."};  
  
        var rootCommand = new RootCommand("Sample app for  
System.CommandLine");  
        rootCommand.AddOption(fileOption);  
  
        rootCommand.SetHandler((file) =>  
        {  
            ReadFile(file!);  
        },  
        fileOption);  
    }  
}
```

```

        return await rootCommand.InvokeAsync(args);
    }

    static void ReadFile(FileInfo file)
    {
        File.ReadLines(file.FullName).ToList()
            .ForEach(line => Console.WriteLine(line));
    }
}

```

The preceding code:

- Creates an [option](#) named `--file` of type [FileInfo](#) and assigns it to the [root command](#):

C#

```

var fileOption = new Option<FileInfo?>(
    name: "--file",
    description: "The file to read and display on the console.");

var rootCommand = new RootCommand("Sample app for System.CommandLine");
rootCommand.AddOption(fileOption);

```

- Specifies that `ReadFile` is the method that will be called when the root command is invoked:

C#

```

rootCommand.SetHandler((file) =>
{
    ReadFile(file!);
},
fileOption);

```

- Displays the contents of the specified file when the root command is invoked:

C#

```

static void ReadFile(FileInfo file)
{
    File.ReadLines(file.FullName).ToList()
        .ForEach(line => Console.WriteLine(line));
}

```

Test the app

You can use any of the following ways to test while developing a command-line app:

- Run the `dotnet build` command, and then open a command prompt in the `scl/bin/Debug/net6.0` folder to run the executable:

Console

```
dotnet build  
cd bin/Debug/net6.0  
scl --file scl.runtimeconfig.json
```

- Use `dotnet run` and pass option values to the app instead of to the `run` command by including them after `--`, as in the following example:

.NET CLI

```
dotnet run -- --file scl.runtimeconfig.json
```

In .NET 7.0.100 SDK Preview, you can use the `commandLineArgs` of a `launchSettings.json` file by running the command `dotnet run --launch-profile <profilename>`.

- [Publish the project to a folder](#), open a command prompt to that folder, and run the executable:

Console

```
dotnet publish -o publish  
cd ./publish  
scl --file scl.runtimeconfig.json
```

- In Visual Studio 2022, select **Debug > Debug Properties** from the menu, and enter the options and arguments in the **Command line arguments** box. For example:

Then run the app, for example by pressing **Ctrl+F5**.

This tutorial assumes you're using the first of these options.

When you run the app, it displays the contents of the file specified by the `--file` option.

```
Output

{
  "runtimeOptions": {
    "tfm": "net6.0",
    "framework": {
      "name": "Microsoft.NETCore.App",
      "version": "6.0.0"
    }
  }
}
```

Help output

`System.CommandLine` automatically provides help output:

```
Console

scl --help
```

```
Output

Description:
  Sample app for System.CommandLine

Usage:
  scl [options]

Options:
  --file <file>    The file to read and display on the console.
  --version         Show version information
  -?, -h, --help   Show help and usage information
```

Version output

`System.CommandLine` automatically provides version output:

```
Console

scl --version
```

```
Output
```

Add a subcommand and options

In this section, you:

- Create more options.
- Create a subcommand.
- Assign the new options to the new subcommand.

The new options will let you configure the foreground and background text colors and the readout speed. These features will be used to read a collection of quotes that comes from the [Teleprompter console app tutorial](#).

1. Copy the [sampleQuotes.txt](#) file from the GitHub repository for this sample into your project directory. For information on how to download files, see the instructions in [Samples and Tutorials](#).
2. Open the project file and add an `<ItemGroup>` element just before the closing `</Project>` tag:

XML

```
<ItemGroup>
  <Content Include="sampleQuotes.txt">
    <CopyToOutputDirectory>Always</CopyToOutputDirectory>
  </Content>
</ItemGroup>
```

Adding this markup causes the text file to be copied to the `bin/debug/net6.0` folder when you build the app. So when you run the executable in that folder, you can access the file by name without specifying a folder path.

3. In `Program.cs`, after the code that creates the `--file` option, create options to control the readout speed and text colors:

C#

```
var delayOption = new Option<int>(
  name: "--delay",
  description: "Delay between lines, specified as milliseconds per character in a line.",
  getDefaultValue: () => 42);
```

```
var fgcolorOption = new Option<ConsoleColor>(
    name: "--fgcolor",
    description: "Foreground color of text displayed on the console.",
    getDefaultValue: () => ConsoleColor.White);

var lightModeOption = new Option<bool>(
    name: "--light-mode",
    description: "Background color of text displayed on the console:
default is black, light mode is white.");
```

4. After the line that creates the root command, delete the line that adds the `--file` option to it. You're removing it here because you'll add it to a new subcommand.

C#

```
var rootCommand = new RootCommand("Sample app for System.CommandLine");
//rootCommand.AddOption(fileOption);
```

5. After the line that creates the root command, create a `read` subcommand. Add the options to this subcommand, and add the subcommand to the root command.

C#

```
var readCommand = new Command("read", "Read and display the file.")
{
    fileOption,
    delayOption,
    fgcolorOption,
    lightModeOption
};
rootCommand.AddCommand(readCommand);
```

6. Replace the `SetHandler` code with the following `SetHandler` code for the new subcommand:

C#

```
readCommand.SetHandler(async (file, delay, fgcolor, lightMode) =>
{
    await ReadFile(file!, delay, fgcolor, lightMode);
},
fileOption, delayOption, fgcolorOption, lightModeOption);
```

You're no longer calling `SetHandler` on the root command because the root command no longer needs a handler. When a command has subcommands, you

typically have to specify one of the subcommands when invoking a command-line app.

7. Replace the `ReadFile` handler method with the following code:

```
C#  
  
internal static async Task ReadFile(  
    FileInfo file, int delay, ConsoleColor fgColor, bool lightMode)  
{  
    Console.BackgroundColor = lightMode ? ConsoleColor.White :  
    ConsoleColor.Black;  
    Console.ForegroundColor = fgColor;  
    List<string> lines = File.ReadLines(file.FullName).ToList();  
    foreach (string line in lines)  
    {  
        Console.WriteLine(line);  
        await Task.Delay(delay * line.Length);  
    };  
}
```

The app now looks like this:

```
C#  
  
using System.CommandLine;  
  
namespace scl;  
  
class Program  
{  
    static int Main(string[] args)  
    {  
        var fileOption = new Option<FileInfo?>(  
            name: "--file",  
            description: "The file to read and display on the console.");  
  
        var delayOption = new Option<int>(  
            name: "--delay",  
            description: "Delay between lines, specified as milliseconds per  
character in a line.",  
            getDefaultValue: () => 42);  
  
        var fgcolorOption = new Option<ConsoleColor>(  
            name: "--fgcolor",  
            description: "Foreground color of text displayed on the  
console.",  
            getDefaultValue: () => ConsoleColor.White);  
  
        var lightModeOption = new Option<bool>(  
            name: "--light-mode",  
            description: "Background color of text displayed on the console:");  
    }  
}
```

```

default is black, light mode is white.");

    var rootCommand = new RootCommand("Sample app for
System.CommandLine");
    //rootCommand.AddOption(fileOption);

    var readCommand = new Command("read", "Read and display the file.")
    {
        fileOption,
        delayOption,
        fgcolorOption,
        lightModeOption
    };
    rootCommand.AddCommand(readCommand);

    readCommand.SetHandler(async (file, delay, fgcolor, lightMode) =>
    {
        await ReadFile(file!, delay, fgcolor, lightMode);
    },
    fileOption, delayOption, fgcolorOption, lightModeOption);

    return rootCommand.InvokeAsync(args).Result;
}

internal static async Task ReadFile(
    FileInfo file, int delay, ConsoleColor fgColor, bool lightMode)
{
    ConsoleColor.BackgroundColor = lightMode ? ConsoleColor.White :
ConsoleColor.Black;
    ConsoleColor.ForegroundColor = fgColor;
    List<string> lines = File.ReadLines(file.FullName).ToList();
    foreach (string line in lines)
    {
        Console.WriteLine(line);
        await Task.Delay(delay * line.Length);
    };
}
}

```

Test the new subcommand

Now if you try to run the app without specifying the subcommand, you get an error message followed by a help message that specifies the subcommand that is available.

Console

```
scl --file sampleQuotes.txt
```

Output

```
'--file' was not matched. Did you mean one of the following?
--help
Required command was not provided.
Unrecognized command or argument '--file'.
Unrecognized command or argument 'sampleQuotes.txt'.

Description:
    Sample app for System.CommandLine

Usage:
    scl [command] [options]

Options:
    --version      Show version information
    -?, -h, --help Show help and usage information

Commands:
    read  Read and display the file.
```

The help text for subcommand `read` shows that four options are available. It shows valid values for the enum.

Console

```
scl read -h
```

Output

```
Description:
    Read and display the file.

Usage:
    scl read [options]

Options:
    --file <file>                                         The file to
    read and display on the console.
    --delay <delay>                                         Delay between
    lines, specified as milliseconds per
    character in a
    line. [default: 42]
    --fgcolor                                              Foreground
    color of text displayed on the console.
    <Black|Blue|Cyan|DarkBlue|DarkCyan|DarkGray|DarkGreen|Dark
    White|Magenta|DarkRed|DarkYellow|Gray|Green|Magenta|Red|White|Ye
    llow>                                                 [default:
    --light-mode                                           Background
    color of text displayed on the console:
    default is
```

```
black, light mode is white.  
-?, -h, --help  
usage information
```

Show help and

Run subcommand `read` specifying only the `--file` option, and you get the default values for the other three options.

Console

```
scl read --file sampleQuotes.txt
```

The 42 milliseconds per character default delay causes a slow readout speed. You can speed it up by setting `--delay` to a lower number.

Console

```
scl read --file sampleQuotes.txt --delay 0
```

You can use `--fgcolor` and `--light-mode` to set text colors:

Console

```
scl read --file sampleQuotes.txt --fgcolor red --light-mode
```

Provide an invalid value for `--delay` and you get an error message:

Console

```
scl read --file sampleQuotes.txt --delay forty-two
```

Output

```
Cannot parse argument 'forty-two' for option '--int' as expected type  
'System.Int32'.
```

Provide an invalid value for `--file` and you get an exception:

Console

```
scl read --file nofile
```

Output

```
Unhandled exception: System.IO.FileNotFoundException:  
Could not find file 'C:\bin\Debug\net6.0\nofile'.
```

Add subcommands and custom validation

This section creates the final version of the app. When finished, the app will have the following commands and options:

- root command with a global* option named `--file`
 - `quotes` command
 - `read` command with options named `--delay`, `--fgcolor`, and `--light-mode`
 - `add` command with arguments named `quote` and `byline`
 - `delete` command with option named `--search-terms`

* A global option is available to the command it's assigned to and recursively to all its subcommands.

Here's sample command line input that invokes each of the available commands with its options and arguments:

Console

```
scl quotes read --file sampleQuotes.txt --delay 40 --fgcolor red --light-mode  
scl quotes add "Hello world!" "Nancy Davolio"  
scl quotes delete --search-terms David "You can do" Antoine "Perfection is  
achieved"
```

1. In `Program.cs`, replace the code that creates the `--file` option with the following code:

C#

```
var fileOption = new Option<FileInfo?>()  
    name: "--file",  
    description: "An option whose argument is parsed as a FileInfo",  
    isDefault: true,  
    parseArgument: result =>  
    {  
        if (result.Tokens.Count == 0)  
        {  
            return new FileInfo("sampleQuotes.txt");  
  
        }  
        string? filePath = result.Tokens.Single().Value;
```

```
        if (!File.Exists(filePath))
    {
        result.ErrorMessage = "File does not exist";
        return null;
    }
    else
    {
        return new FileInfo(filePath);
    }
});
```

This code uses `ParseArgument<T>` to provide custom parsing, validation, and error handling.

Without this code, missing files are reported with an exception and stack trace.
With this code just the specified error message is displayed.

This code also specifies a default value, which is why it sets `isDefault` to `true`. If you don't set `isDefault` to `true`, the `parseArgument` delegate doesn't get called when no input is provided for `--file`.

2. After the code that creates `lightModeOption`, add options and arguments for the `add` and `delete` commands:

```
C#  
  
var searchTermsOption = new Option<string[]>(
    name: "--search-terms",
    description: "Strings to search for when deleting entries.")
{ IsRequired = true, AllowMultipleArgumentsPerToken = true };  
  
var quoteArgument = new Argument<string>(
    name: "quote",
    description: "Text of quote.");  
  
var bylineArgument = new Argument<string>(
    name: "byline",
    description: "Byline of quote.");
```

The `AllowMultipleArgumentsPerToken` setting lets you omit the `--search-terms` option name when specifying elements in the list after the first one. It makes the following examples of command-line input equivalent:

Console

```
scl quotes delete --search-terms David "You can do"  
scl quotes delete --search-terms David --search-terms "You can do"
```

3. Replace the code that creates the root command and the `read` command with the following code:

```
C#  
  
var rootCommand = new RootCommand("Sample app for System.CommandLine");  
rootCommand.AddGlobalOption(fileOption);  
  
var quotesCommand = new Command("quotes", "Work with a file that  
contains quotes.");  
rootCommand.AddCommand(quotesCommand);  
  
var readCommand = new Command("read", "Read and display the file.")  
{  
    delayOption,  
    fgcolorOption,  
    lightModeOption  
};  
quotesCommand.AddCommand(readCommand);  
  
var deleteCommand = new Command("delete", "Delete lines from the  
file.");  
deleteCommand.AddOption(searchTermsOption);  
quotesCommand.AddCommand(deleteCommand);  
  
var addCommand = new Command("add", "Add an entry to the file.");  
addCommand.AddArgument(quoteArgument);  
addCommand.AddArgument(bylineArgument);  
addCommand.AddAlias("insert");  
quotesCommand.AddCommand(addCommand);
```

This code makes the following changes:

- Removes the `--file` option from the `read` command.
- Adds the `--file` option as a global option to the root command.
- Creates a `quotes` command and adds it to the root command.
- Adds the `read` command to the `quotes` command instead of to the root command.
- Creates `add` and `delete` commands and adds them to the `quotes` command.

The result is the following command hierarchy:

- Root command
 - `quotes`
 - `read`

- o `add`
- o `delete`

The app now implements the recommended pattern where the parent command (`quotes`) specifies an area or group, and its children commands (`read`, `add`, `delete`) are actions.

Global options are applied to the command and recursively to subcommands. Since `--file` is on the root command, it will be available automatically in all subcommands of the app.

4. After the `SetHandler` code, add new `SetHandler` code for the new subcommands:

```
C#
deleteCommand.SetHandler((file, searchTerms) =>
{
    DeleteFromFile(file!, searchTerms);
},
fileOption, searchTermsOption);

addCommand.SetHandler((file, quote, byline) =>
{
    AddToFile(file!, quote, byline);
},
fileOption, quoteArgument, bylineArgument);
```

Subcommand `quotes` doesn't have a handler because it isn't a leaf command. Subcommands `read`, `add`, and `delete` are leaf commands under `quotes`, and `SetHandler` is called for each of them.

5. Add the handlers for `add` and `delete`.

```
C#
internal static void DeleteFromFile(FileInfo file, string[] searchTerms)
{
    Console.WriteLine("Deleting from file");
    File.WriteAllLines(
        file.FullName, File.ReadLines(file.FullName)
            .Where(line => searchTerms.All(s =>
                !line.Contains(s))).ToList());
}

internal static void AddToFile(FileInfo file, string quote, string byline)
{
    Console.WriteLine("Adding to file");
```

```

        using StreamWriter? writer = file.AppendText();
        writer.WriteLine(${Environment.NewLine}${Environment.NewLine}
{quote}");
        writer.WriteLine(${Environment.NewLine}-{byline}");
        writer.Flush();
    }

```

The finished app looks like this:

C#

```

using System.CommandLine;

namespace scl;

class Program
{
    static async Task<int> Main(string[] args)
    {
        var fileOption = new Option<FileInfo?>(
            name: "--file",
            description: "An option whose argument is parsed as a FileInfo",
            isDefault: true,
            parseArgument: result =>
        {
            if (result.Tokens.Count == 0)
            {
                return new FileInfo("sampleQuotes.txt");
            }

            string? filePath = result.Tokens.Single().Value;
            if (!File.Exists(filePath))
            {
                result.ErrorMessage = "File does not exist";
                return null;
            }
            else
            {
                return new FileInfo(filePath);
            }
        });
    }

    var delayOption = new Option<int>(
        name: "--delay",
        description: "Delay between lines, specified as milliseconds per
character in a line.",
        getDefaultValue: () => 42);

    var fgcolorOption = new Option<ConsoleColor>(
        name: "--fgcolor",
        description: "Foreground color of text displayed on the
console.",
        getDefaultValue: () => ConsoleColor.White);

```

```
var lightModeOption = new Option<bool>(
    name: "--light-mode",
    description: "Background color of text displayed on the console:
default is black, light mode is white.");

var searchTermsOption = new Option<string[]>(
    name: "--search-terms",
    description: "Strings to search for when deleting entries.")
{ IsRequired = true, AllowMultipleArgumentsPerToken = true };

var quoteArgument = new Argument<string>(
    name: "quote",
    description: "Text of quote.");

var bylineArgument = new Argument<string>(
    name: "byline",
    description: "Byline of quote.");

var rootCommand = new RootCommand("Sample app for
System.CommandLine");
rootCommand.AddGlobalOption(fileOption);

var quotesCommand = new Command("quotes", "Work with a file that
contains quotes.");
rootCommand.AddCommand(quotesCommand);

var readCommand = new Command("read", "Read and display the file.")
{
    delayOption,
    fgcolorOption,
    lightModeOption
};
quotesCommand.AddCommand(readCommand);

var deleteCommand = new Command("delete", "Delete lines from the
file.");
deleteCommand.AddOption(searchTermsOption);
quotesCommand.AddCommand(deleteCommand);

var addCommand = new Command("add", "Add an entry to the file.");
addCommand.AddArgument(quoteArgument);
addCommand.AddArgument(bylineArgument);
addCommand.AddAlias("insert");
quotesCommand.AddCommand(addCommand);

readCommand.SetHandler(async (file, delay, fgcolor, lightMode) =>
{
    await ReadFile(file!, delay, fgcolor, lightMode);
},
fileOption, delayOption, fgcolorOption, lightModeOption);

deleteCommand.SetHandler((file, searchTerms) =>
{
    DeleteFromFile(file!, searchTerms);
```

```

        },
        fileOption, searchTermsOption);

    addCommand.SetHandler((file, quote, byline) =>
    {
        AddToFile(file!, quote, byline);
    },
    fileOption, quoteArgument, bylineArgument);

    return await rootCommand.InvokeAsync(args);
}

internal static async Task ReadFile(
    FileInfo file, int delay, ConsoleColor fgColor, bool
lightMode)
{
    Console.BackgroundColor = lightMode ? ConsoleColor.White :
ConsoleColor.Black;
    Console.ForegroundColor = fgColor;
    var lines = File.ReadLines(file.FullName).ToList();
    foreach (string line in lines)
    {
        Console.WriteLine(line);
        await Task.Delay(delay * line.Length);
    };
}

internal static void DeleteFromFile(FileInfo file, string[] searchTerms)
{
    Console.WriteLine("Deleting from file");
    File.WriteAllLines(
        file.FullName, File.ReadLines(file.FullName)
        .Where(line => searchTerms.All(s =>
!line.Contains(s))).ToList());
}

internal static void AddToFile(FileInfo file, string quote, string
byline)
{
    Console.WriteLine("Adding to file");
    using StreamWriter? writer = file.AppendText();
    writer.WriteLine($"{Environment.NewLine}{Environment.NewLine}
{quote}");
    writer.WriteLine($"{Environment.NewLine}-{byline}");
    writer.Flush();
}
}

```

Build the project, and then try the following commands.

Submit a nonexistent file to `--file` with the `read` command, and you get an error message instead of an exception and stack trace:

Console

```
scl quotes read --file myfile
```

Output

```
File does not exist
```

Try to run subcommand `quotes` and you get a message directing you to use `read`, `add`, or `delete`:

Console

```
scl quotes
```

Output

```
Required command was not provided.
```

Description:

```
Work with a file that contains quotes.
```

Usage:

```
scl quotes [command] [options]
```

Options:

```
--file <file> An option whose argument is parsed as a FileInfo [default:  
sampleQuotes.txt]  
-?, -h, --help Show help and usage information
```

Commands:

| | |
|------------------------------|-----------------------------|
| read | Read and display the file. |
| delete | Delete lines from the file. |
| add, insert <quote> <byline> | Add an entry to the file. |

Run subcommand `add`, and then look at the end of the text file to see the added text:

Console

```
scl quotes add "Hello world!" "Nancy Davolio"
```

Run subcommand `delete` with search strings from the beginning of the file, and then look at the beginning of the text file to see where text was removed:

Console

```
scl quotes delete --search-terms David "You can do" Antoine "Perfection is achieved"
```

ⓘ Note

If you're running in the `bin/debug/net6.0` folder, that folder is where you'll find the file with changes from the `add` and `delete` commands. The copy of the file in the project folder remains unchanged.

Next steps

In this tutorial, you created a simple command-line app that uses `System.CommandLine`. To learn more about the library, see [System.CommandLine overview](#).

Command-line syntax overview for System.CommandLine

Article • 09/21/2022

ⓘ Important

`System.CommandLine` is currently in PREVIEW, and this documentation is for version 2.0 beta 4. Some information relates to prerelease product that may be substantially modified before it's released. Microsoft makes no warranties, express or implied, with respect to the information provided here.

This article explains the command-line syntax that `System.CommandLine` recognizes. The information will be useful to users as well as developers of .NET command-line apps, including the [.NET CLI](#).

Tokens

`System.CommandLine` parses command-line input into *tokens*, which are strings delimited by spaces. For example, consider the following command line:

.NET CLI

```
dotnet tool install dotnet-suggest --global --verbosity quiet
```

This input is parsed by the `dotnet` application into tokens `tool`, `install`, `dotnet-suggest`, `--global`, `--verbosity`, and `quiet`.

Tokens are interpreted as commands, options, or arguments. The command-line app that is being invoked determines how the tokens after the first one are interpreted. The following table shows how `System.CommandLine` interprets the preceding example:

[+] Expand table

| Token | Parsed as |
|-----------------------------|------------------------------|
| <code>tool</code> | Subcommand |
| <code>install</code> | Subcommand |
| <code>dotnet-suggest</code> | Argument for install command |

| Token | Parsed as |
|-------------|---------------------------------|
| --global | Option for install command |
| --verbosity | Option for install command |
| quiet | Argument for --verbosity option |

A token can contain spaces if it's enclosed in quotation marks (""). Here's an example:

```
Console  
dotnet tool search "ef migrations add"
```

Commands

A *command* in command-line input is a token that specifies an action or defines a group of related actions. For example:

- In `dotnet run`, `run` is a command that specifies an action.
- In `dotnet tool install`, `install` is a command that specifies an action, and `tool` is a command that specifies a group of related commands. There are other tool-related commands, such as `tool uninstall`, `tool list`, and `tool update`.

Root commands

The *root command* is the one that specifies the name of the app's executable. For example, the `dotnet` command specifies the `dotnet.exe` executable.

Subcommands

Most command-line apps support *subcommands*, also known as *verbs*. For example, the `dotnet` command has a `run` subcommand that you invoke by entering `dotnet run`.

Subcommands can have their own subcommands. In `dotnet tool install`, `install` is a subcommand of `tool`.

Options

An option is a named parameter that can be passed to a command. [POSIX ↗](#) CLIs typically prefix the option name with two hyphens (--). The following example shows

two options:

.NET CLI

```
dotnet tool update dotnet-suggest --verbosity quiet --global
^-----^          ^-----^
```

As this example illustrates, the value of the option may be explicit (`quiet` for `--verbosity`) or implicit (nothing follows `--global`). Options that have no value specified are typically Boolean parameters that default to `true` if the option is specified on the command line.

For some Windows command-line apps, you identify an option by using a leading slash (/) with the option name. For example:

Console

```
msbuild /version
^-----^
```

`System.CommandLine` supports both POSIX and Windows prefix conventions. When you [configure an option](#), you specify the option name including the prefix.

Arguments

An argument is a value passed to an option or a command. The following examples show an argument for the `verbosity` option and an argument for the `build` command.

Console

```
dotnet tool update dotnet-suggest --verbosity quiet --global
^---^
```

Console

```
dotnet build myapp.csproj
^-----^
```

Arguments can have default values that apply if no argument is explicitly provided. For example, many options are implicitly Boolean parameters with a default of `true` when the option name is in the command line. The following command-line examples are equivalent:

.NET CLI

```
dotnet tool update dotnet-suggest --global  
dotnet tool update dotnet-suggest --global true
```

Some options have required arguments. For example in the .NET CLI, `--output` requires a folder name argument. If the argument is not provided, the command fails.

Arguments can have expected types, and `System.CommandLine` displays an error message if an argument can't be parsed into the expected type. For example, the following command errors because "silent" isn't one of the valid values for `--verbosity`:

.NET CLI

```
dotnet build --verbosity silent
```

Output

```
Cannot parse argument 'silent' for option '-v' as expected type  
'Microsoft.DotNet.Cli.VerbosityOptions'. Did you mean one of the following?  
Detailed  
Diagnostic  
Minimal  
Normal  
Quiet
```

Arguments also have expectations about how many values can be provided. Examples are provided in the [section on argument arity](#).

Order of options and arguments

You can provide options before arguments or arguments before options on the command line. The following commands are equivalent:

.NET CLI

```
dotnet add package System.CommandLine --prerelease  
dotnet add package --prerelease System.CommandLine
```

Options can be specified in any order. The following commands are equivalent:

.NET CLI

```
dotnet add package System.CommandLine --prerelease --no-restore --source https://api.nuget.org/v3/index.json  
dotnet add package System.CommandLine --source https://api.nuget.org/v3/index.json --no-restore --prerelease
```

When there are multiple arguments, the order does matter. The following commands are not necessarily equivalent:

Console

```
myapp argument1 argument2  
myapp argument2 argument1
```

These commands pass a list with the same values to the command handler code, but they differ in the order of the values, which could lead to different results.

Aliases

In both POSIX and Windows, it's common for some commands and options to have aliases. These are usually short forms that are easier to type. Aliases can also be used for other purposes, such as to [simulate case-insensitivity](#) and to [support alternate spellings of a word](#).

POSIX short forms typically have a single leading hyphen followed by a single character. The following commands are equivalent:

.NET CLI

```
dotnet build --verbosity quiet  
dotnet build -v quiet
```

The [GNU standard](#) recommends automatic aliases. That is, you can enter any part of a long-form command or option name and it will be accepted. This behavior would make the following command lines equivalent:

.NET CLI

```
dotnet publish --output ./publish  
dotnet publish --outpu ./publish  
dotnet publish --outp ./publish  
dotnet publish --out ./publish
```

```
dotnet publish --ou ./publish  
dotnet publish --o ./publish
```

`System.CommandLine` doesn't support automatic aliases.

Case sensitivity

Command and option names and aliases are case-sensitive by default according to POSIX convention, and `System.CommandLine` follows this convention. If you want your CLI to be case insensitive, define aliases for the various casing alternatives. For example, `--additional-probing-path` could have aliases `--Additional-Probing-Path` and `--ADDITIONAL-PROBING-PATH`.

In some command-line tools, a difference in casing specifies a difference in function. For example, `git clean -X` behaves differently than `git clean -x`. The .NET CLI is all lowercase.

Case sensitivity does not apply to argument values for options that are based on enums. Enum names are matched regardless of casing.

The `--` token

POSIX convention interprets the double-dash (`--`) token as an escape mechanism. Everything that follows the double-dash token is interpreted as arguments for the command. This functionality can be used to submit arguments that look like options, since it prevents them from being interpreted as options.

Suppose `myapp` takes a `message` argument, and you want the value of `message` to be `--interactive`. The following command line might give unexpected results.

Console

```
myapp --interactive
```

If `myapp` doesn't have an `--interactive` option, the `--interactive` token is interpreted as an argument. But if the app does have an `--interactive` option, this input will be interpreted as referring to that option.

The following command line uses the double-dash token to set the value of the `message` argument to "`--interactive`":

Console

```
myapp -- --interactive  
^^
```

`System.CommandLine` supports this double-dash functionality.

Option-argument delimiters

`System.CommandLine` lets you use a space, '=' or ':' as the delimiter between an option name and its argument. For example, the following commands are equivalent:

.NET CLI

```
dotnet build -v quiet  
dotnet build -v=quiet  
dotnet build -v:quiet
```

A POSIX convention lets you omit the delimiter when you are specifying a single-character option alias. For example, the following commands are equivalent:

Console

```
myapp -vquiet  
myapp -v quiet
```

`System.CommandLine` supports this syntax by default.

Argument arity

The *arity* of an option or command's argument is the number of values that can be passed if that option or command is specified.

Arity is expressed with a minimum value and a maximum value, as the following table illustrates:

[] [Expand table](#)

| Min | Max | Example validity | Example |
|-----|-----|---------------------------|---------------|
| 0 | 0 | Valid: --file | --file |
| | | Invalid: --file a.json | --file a.json |

| Min | Max | Example validity | Example |
|-----|-----|------------------|-----------------------------|
| | | Invalid: | --file a.json --file b.json |
| 0 | 1 | Valid: | --flag |
| | | Valid: | --flag true |
| | | Valid: | --flag false |
| | | Invalid: | --flag false --flag false |
| 1 | 1 | Valid: | --file a.json |
| | | Invalid: | --file |
| | | Invalid: | --file a.json --file b.json |
| 0 | n | Valid: | --file |
| | | Valid: | --file a.json |
| | | Valid: | --file a.json --file b.json |
| 1 | n | Valid: | --file a.json |
| | | Valid: | --file a.json b.json |
| | | Invalid: | --file |

`System.CommandLine` has an [ArgumentArity](#) struct for defining arity, with the following values:

- [Zero](#) - No values allowed.
- [ZeroOrOne](#) - May have one value, may have no values.
- [ExactlyOne](#) - Must have one value.
- [ZeroOrMore](#) - May have one value, multiple values, or no values.
- [OneOrMore](#) - May have multiple values, must have at least one value.

Arity can often be inferred from the type. For example, an `int` option has arity of `ExactlyOne`, and a `List<int>` option has arity `OneOrMore`.

Option overrides

If the arity maximum is 1, `System.CommandLine` can still be configured to accept multiple instances of an option. In that case, the last instance of a repeated option overwrites any earlier instances. In the following example, the value 2 would be passed to the `myapp` command.

Console

```
myapp --delay 3 --message example --delay 2
```

Multiple arguments

If the arity maximum is more than one, `System.CommandLine` can be configured to accept multiple arguments for one option without repeating the option name.

In the following example, the list passed to the `myapp` command would contain "a", "b", "c", and "d":

Console

```
myapp --list a b c --list d
```

Option bundling

POSIX recommends that you support *bundling* of single-character options, also known as *stacking*. Bundled options are single-character option aliases specified together after a single hyphen prefix. Only the last option can specify an argument. For example, the following command lines are equivalent:

Console

```
git clean -f -d -x  
git clean -fdx
```

If an argument is provided after an option bundle, it applies to the last option in the bundle. The following command lines are equivalent:

Console

```
myapp -a -b -c arg  
myapp -abc arg
```

In both variants in this example, the argument `arg` would apply only to the option `-c`.

Boolean options (flags)

If `true` or `false` is passed for an option having a `bool` argument, it's parsed as expected. But an option whose argument type is `bool` typically doesn't require an argument to be specified. Boolean options, sometimes called "flags", typically have an arity of [ZeroOrOne](#). The presence of the option name on the command line, with no argument following it, results in a default value of `true`. The absence of the option name in command-line input results in a value of `false`. If the `myapp` command prints out the value of a Boolean option named `--interactive`, the following input creates the following output:

```
Console
myapp
myapp --interactive
myapp --interactive false
myapp --interactive true

Output
False
True
False
True
```

The `--help` option

Command-line apps typically provide an option to display a brief description of the available commands, options, and arguments. `System.CommandLine` automatically generates help output. For example:

```
.NET CLI
dotnet list --help

Output
Description:
List references or packages of a .NET project.

Usage:
dotnet [options] list [<PROJECT | SOLUTION>] [command]

Arguments:
<PROJECT | SOLUTION> The project or solution file to operate on. If a
file is not specified, the command will search the current directory for
```

```
one.
```

Options:

```
-?, -h, --help Show command line help.
```

Commands:

```
package List all package references of the project or solution.  
reference List all project-to-project references of the project.
```

App users might be accustomed to different ways to request help on different platforms, so apps built on `System.CommandLine` respond to many ways of requesting help. The following commands are all equivalent:

.NET CLI

```
dotnet --help  
dotnet -h  
dotnet /h  
dotnet -?  
dotnet /?
```

Help output doesn't necessarily show all available commands, arguments, and options. Some of them may be *hidden*, which means they don't show up in help output but they can be specified on the command line.

The `--version` option

Apps built on `System.CommandLine` automatically provide the version number in response to the `--version` option used with the root command. For example:

.NET CLI

```
dotnet --version
```

Output

```
6.0.100
```

Response files

A *response file* is a file that contains a set of `tokens` for a command-line app. Response files are a feature of `System.CommandLine` that is useful in two scenarios:

- To invoke a command-line app by specifying input that is longer than the character limit of the terminal.
- To invoke the same command repeatedly without retyping the whole line.

To use a response file, enter the file name prefixed by an `@` sign wherever in the line you want to insert commands, options, and arguments. The `.rsp` file extension is a common convention, but you can use any file extension.

The following lines are equivalent:

.NET CLI

```
dotnet build --no-restore --output ./build-output/
dotnet @sample1.rsp
dotnet build @sample2.rsp --output ./build-output/
```

Contents of `sample1.rsp`:

Console

```
build
--no-restore
--output
./build-output/
```

Contents of `sample2.rsp`:

Console

```
--no-restore
```

Here are syntax rules that determine how the text in a response file is interpreted:

- Tokens are delimited by spaces. A line that contains *Good morning!* is treated as two tokens, *Good* and *morning!*.
- Multiple tokens enclosed in quotes are interpreted as a single token. A line that contains "Good morning!" is treated as one token, *Good morning!*.
- Any text between a `#` symbol and the end of the line is treated as a comment and ignored.
- Tokens prefixed with `@` can reference additional response files.
- The response file can have multiple lines of text. The lines are concatenated and interpreted as a sequence of tokens.

Directives

`System.CommandLine` introduces a syntactic element called a *directive*. The `[parse]` directive is an example. When you include `[parse]` after the app's name, `System.CommandLine` displays a diagram of the parse result instead of invoking the command-line app:

.NET CLI

```
dotnet [parse] build --no-restore --output ./build-output/  
      ^-----^
```

Output

```
[ dotnet [ build [ --no-restore <True> ] [ --output <./build-output/> ] ] ]
```

The purpose of directives is to provide cross-cutting functionality that can apply across command-line apps. Because directives are syntactically distinct from the app's own syntax, they can provide functionality that applies across apps.

A directive must conform to the following syntax rules:

- It's a token on the command line that comes after the app's name but before any subcommands or options.
- It's enclosed in square brackets.
- It doesn't contain spaces.

An unrecognized directive is ignored without causing a parsing error.

A directive can include an argument, separated from the directive name by a colon.

The following directives are built in:

- `[parse]`
- `[suggest]`

The `[parse]` directive

Both users and developers may find it useful to see how an app will interpret a given input. One of the default features of a `System.CommandLine` app is the `[parse]` directive, which lets you preview the result of parsing command input. For example:

Console

```
myapp [parse] --delay not-an-int --interactive --file filename.txt extra
```

Output

```
![ myapp [ --delay !<not-an-int> ] [ --interactive <True> ] [ --file <filename.txt> ] *[ --fgcolor <White> ] ] ???--> extra
```

In the preceding example:

- The command (`myapp`), its child options, and the arguments to those options are grouped using square brackets.
- For the option result `[--delay !<not-an-int>]`, the `!` indicates a parsing error. The value `not-an-int` for an `int` option can't be parsed to the expected type. The error is also flagged by `!` in front of the command that contains the errored option: `![myapp....`.
- For the option result `*[--fgcolor <White>]`, the option wasn't specified on the command line, so the configured default was used. `white` is the effective value for this option. The asterisk indicates that the value is the default.
- `???-->` points to input that wasn't matched to any of the app's commands or options.

The `[suggest]` directive

The `[suggest]` directive lets you search for commands when you don't know the exact command.

.NET CLI

```
dotnet [suggest] buil
```

Output

```
build  
build-server  
msbuild
```

Design guidance

The following sections present guidance that we recommend you follow when designing a CLI. Think of what your app expects on the command line as similar to what a REST

API server expects in the URL. Consistent rules for REST APIs are what make them readily usable to client app developers. In the same way, users of your command-line apps will have a better experience if the CLI design follows common patterns.

Once you create a CLI it is hard to change, especially if your users have used your CLI in scripts they expect to keep running. The guidelines here were developed after the .NET CLI, and it doesn't always follow these guidelines. We are updating the .NET CLI where we can do it without introducing breaking changes. An example of this work is the new design for `dotnet new` in .NET 7.

Commands and subcommands

If a command has subcommands, the command should function as an area, or a grouping identifier for the subcommands, rather than specify an action. When you invoke the app, you specify the grouping command and one of its subcommands. For example, try to run `dotnet tool`, and you get an error message because the `tool` command only identifies a group of tool-related subcommands, such as `install` and `list`. You can run `dotnet tool install`, but `dotnet tool` by itself would be incomplete.

One of the ways that defining areas helps your users is that it organizes the help output.

Within a CLI there is often an implicit area. For example, in the .NET CLI, the implicit area is the project and in the Docker CLI it is the image. As a result, you can use `dotnet build` without including an area. Consider whether your CLI has an implicit area. If it does, consider whether to allow the user to optionally include or omit it as in `docker build` and `docker image build`. If you optionally allow the implicit area to be typed by your user, you also automatically have help and tab completion for this grouping of commands. Supply the optional use of the implicit group by defining two commands that perform the same operation.

Options as parameters

Options should provide parameters to commands, rather than specifying actions themselves. This is a recommended design principle although it isn't always followed by `System.CommandLine` (`--help` displays help information).

Short-form aliases

In general, we recommend that you minimize the number of short-form option aliases that you define.

In particular, avoid using any of the following aliases differently than their common usage in the .NET CLI and other .NET command-line apps:

- `-i` for `--interactive`.

This option signals to the user that they may be prompted for inputs to questions that the command needs answered. For example, prompting for a username. Your CLI may be used in scripts, so use caution in prompting users that have not specified this switch.

- `-o` for `--output`.

Some commands produce files as the result of their execution. This option should be used to help determine where those files should be located. In cases where a single file is created, this option should be a file path. In cases where many files are created, this option should be a directory path.

- `-v` for `--verbosity`.

Commands often provide output to the user on the console; this option is used to specify the amount of output the user requests. For more information, see [The --verbosity option](#) later in this article.

There are also some aliases with common usage limited to the .NET CLI. You can use these aliases for other options in your apps, but be aware of the possibility of confusion.

- `-c` for `--configuration`

This option often refers to a named Build Configuration, like `Debug` or `Release`. You can use any name you want for a configuration, but most tools are expecting one of those. This setting is often used to configure other properties in a way that makes sense for that configuration—for example, doing less code optimization when building the `Debug` configuration. Consider this option if your command has different modes of operation.

- `-f` for `--framework`

This option is used to select a single [Target Framework Moniker \(TFM\)](#) to execute for, so if your CLI application has differing behavior based on which TFM is chosen, you should support this flag.

- `-p` for `--property`

If your application eventually invokes MSBuild, the user will often need to customize that call in some way. This option allows for MSBuild properties to be

provided on the command line and passed on to the underlying MSBuild call. If your app doesn't use MSBuild but needs a set of key-value pairs, consider using this same option name to take advantage of users' expectations.

- `-r` for `--runtime`

If your application can run on different runtimes, or has runtime-specific logic, consider supporting this option as a way of specifying a [Runtime Identifier](#). If your app supports `--runtime`, consider supporting `--os` and `--arch` also. These options let you specify just the OS or the architecture parts of the RID, leaving the part not specified to be determined from the current platform. For more information, see [dotnet publish](#).

Short names

Make names for commands, options, and arguments as short and easy to spell as possible. For example, if `class` is clear enough don't make the command `classification`.

Lowercase names

Define names in lowercase only, except you can make uppercase aliases to make commands or options case insensitive.

Kebab case names

Use [kebab case](#) to distinguish words. For example, `--additional-probing-path`.

Pluralization

Within an app, be consistent in pluralization. For example, don't mix plural and singular names for options that can have multiple values (maximum arity greater than one):

[+] [Expand table](#)

| Option names | Consistency |
|--|-------------|
| <code>--additional-probing-paths</code> and <code>--sources</code> | ✓ |
| <code>--additional-probing-path</code> and <code>--source</code> | ✓ |
| <code>--additional-probing-paths</code> and <code>--source</code> | ✗ |

| Option names | Consistency |
|---|-------------|
| --additional-probing-path and --sources | ✗ |

Verbs vs. nouns

Use verbs rather than nouns for commands that refer to actions (those without subcommands under them), for example: `dotnet workload remove`, not `dotnet workload removal`. And use nouns rather than verbs for options, for example: `--configuration`, not `--configure`.

The `--verbosity` option

`System.CommandLine` applications typically offer a `--verbosity` option that specifies how much output is sent to the console. Here are the standard five settings:

- `Q[uiet]`
- `M[inimal]`
- `N[ormal]`
- `D[etailed]`
- `Diag[nostic]`

These are the standard names, but existing apps sometimes use `Silent` in place of `Quiet`, and `Trace`, `Debug`, or `Verbose` in place of `Diagnostic`.

Each app defines its own criteria that determine what gets displayed at each level. Typically an app only needs three levels:

- Quiet
- Normal
- Diagnostic

If an app doesn't need five different levels, the option should still define the same five settings. In that case, `Minimal` and `Normal` will produce the same output, and `Detailed` and `Diagnostic` will likewise be the same. This allows your users to just type what they are familiar with, and the best fit will be used.

The expectation for `Quiet` is that no output is displayed on the console. However, if an app offers an interactive mode, the app should do one of the following alternatives:

- Display prompts for input when `--interactive` is specified, even if `--verbosity` is `Quiet`.

- Disallow the use of `--verbosity Quiet` and `--interactive` together.

Otherwise the app will wait for input without telling the user what it's waiting for. It will appear that your application froze and the user will have no idea the application is waiting for input.

If you define aliases, use `-v` for `--verbosity` and make `-v` without an argument an alias for `--verbosity Diagnostic`. Use `-q` for `--verbosity Quiet`.

The .NET CLI and POSIX conventions

The .NET CLI does not consistently follow all POSIX conventions.

Double-dash

Several commands in the .NET CLI have a special implementation of the double-dash token. In the case of `dotnet run`, `dotnet watch`, and `dotnet tool run`, tokens that follow `--` are passed to the app that is being run by the command. For example:

```
.NET CLI  
dotnet run --project ./myapp.csproj -- --message "Hello world!"  
      ^^
```

In this example, the `--project` option is passed to the `dotnet run` command, and the `--message` option with its argument is passed as a command-line option to *myapp* when it runs.

The `--` token is not always required for passing options to an app that you run by using `dotnet run`. Without the double-dash, the `dotnet run` command automatically passes on to the app being run any options that aren't recognized as applying to `dotnet run` itself or to MSBuild. So the following command lines are equivalent because `dotnet run` doesn't recognize the arguments and options:

```
.NET CLI  
dotnet run -- quotes read --delay 0 --fg-color red  
dotnet run quotes read --delay 0 --fg-color red
```

Omission of the option-to-argument delimiter

The .NET CLI doesn't support the POSIX convention that lets you omit the delimiter when you are specifying a single-character option alias.

Multiple arguments without repeating the option name

The .NET CLI doesn't accept multiple arguments for one option without repeating the option name.

Boolean options

In the .NET CLI, some Boolean options result in the same behavior when you pass `false` as when you pass `true`. This behavior results when .NET CLI code that implements the option only checks for the presence or absence of the option, ignoring the value. An example is `--no-restore` for the `dotnet build` command. Pass `no-restore false` and the restore operation will be skipped the same as when you specify `no-restore true` or `no-restore`.

Kebab case

In some cases, the .NET CLI doesn't use kebab case for command, option, or argument names. For example, there is a .NET CLI option that is named `--additionalprobingpath` instead of `--additional-probing-path`.

How to define commands, options, and arguments in System.CommandLine

Article • 05/25/2023

ⓘ Important

`System.CommandLine` is currently in PREVIEW, and this documentation is for version 2.0 beta 4. Some information relates to prerelease product that may be substantially modified before it's released. Microsoft makes no warranties, express or implied, with respect to the information provided here.

This article explains how to define [commands](#), [options](#), and [arguments](#) in command-line apps that are built with the `System.CommandLine` library. To build a complete application that illustrates these techniques, see the tutorial [Get started with System.CommandLine](#).

For guidance on how to design a command-line app's commands, options, and arguments, see [Design guidance](#).

Define a root command

Every command-line app has a [root command](#), which refers to the executable file itself. The simplest case for invoking your code, if you have an app with no subcommands, options, or arguments, would look like this:

C#

```
using System.CommandLine;

class Program
{
    static async Task Main(string[] args)
    {
        var rootCommand = new RootCommand("Sample command-line app");

        rootCommand.SetHandler(() =>
        {
            Console.WriteLine("Hello world!");
        });

        await rootCommand.InvokeAsync(args);
    }
}
```

Define subcommands

Commands can have child commands, known as *subcommands* or *verbs*, and they can nest as many levels as you need. You can add subcommands as shown in the following example:

C#

```
var rootCommand = new RootCommand();
var sub1Command = new Command("sub1", "First-level subcommand");
rootCommand.Add(sub1Command);
var sub1aCommand = new Command("sub1a", "Second level subcommand");
sub1Command.Add(sub1aCommand);
```

The innermost subcommand in this example can be invoked like this:

Console

```
myapp sub1 sub1a
```

Define options

A command handler method typically has parameters, and the values can come from command-line *options*. The following example creates two options and adds them to the root command. The option names include double-hyphen prefixes, which is [typical for POSIX CLIs](#). The command handler code displays the values of those options:

C#

```
var delayOption = new Option<int>
    (name: "--delay",
     description: "An option whose argument is parsed as an int.",
     getDefaultValue: () => 42);
var messageOption = new Option<string>
    ("--message", "An option whose argument is parsed as a string.");

var rootCommand = new RootCommand();
rootCommand.Add(delayOption);
rootCommand.Add(messageOption);

rootCommand.SetHandler((delayOptionValue, messageOptionValue) =>
{
    Console.WriteLine($"--delay = {delayOptionValue}");
    Console.WriteLine($"--message = {messageOptionValue}");
},
delayOption, messageOption);
```

Here's an example of command-line input and the resulting output for the preceding example code:

```
Console
myapp --delay 21 --message "Hello world!"

Output
--delay = 21
--message = Hello world!
```

Global options

To add an option to one command at a time, use the `Add` or `AddOption` method as shown in the preceding example. To add an option to a command and recursively to all of its subcommands, use the `AddGlobalOption` method, as shown in the following example:

```
C#
var delayOption = new Option<int>
    ("--delay", "An option whose argument is parsed as an int.");
var messageOption = new Option<string>
    ("--message", "An option whose argument is parsed as a string.");

var rootCommand = new RootCommand();
rootCommand.AddGlobalOption(delayOption);
rootCommand.Add(messageOption);

var subCommand1 = new Command("sub1", "First level subcommand");
rootCommand.Add(subCommand1);

var subCommand1a = new Command("sub1a", "Second level subcommand");
subCommand1.Add(subCommand1a);

subCommand1a.SetHandler((delayOptionValue) =>
{
    Console.WriteLine($"--delay = {delayOptionValue}");
},
delayOption);

await rootCommand.InvokeAsync(args);
```

The preceding code adds `--delay` as a global option to the root command, and it's available in the handler for `subCommand1a`.

Define arguments

Arguments are defined and added to commands like options. The following example is like the options example, but it defines arguments instead of options:

C#

```
var delayArgument = new Argument<int>
    (name: "delay",
     description: "An argument that is parsed as an int.",
     getDefaultValue: () => 42);
var messageArgument = new Argument<string>
    ("message", "An argument that is parsed as a string.");

var rootCommand = new RootCommand();
rootCommand.Add(delayArgument);
rootCommand.Add(messageArgument);

rootCommand.SetHandler((delayArgumentValue, messageArgumentValue) =>
{
    Console.WriteLine($"<delay> argument = {delayArgumentValue}");
    Console.WriteLine($"<message> argument = {messageArgumentValue}");
},
delayArgument, messageArgument);

await rootCommand.InvokeAsync(args);
```

Here's an example of command-line input and the resulting output for the preceding example code:

Console

```
myapp 42 "Hello world!"
```

Output

```
<delay> argument = 42
<message> argument = Hello world!
```

An argument that is defined without a default value, such as `messageArgument` in the preceding example, is treated as a required argument. An error message is displayed, and the command handler isn't called, if a required argument isn't provided.

Define aliases

Both commands and options support [aliases](#). You can add an alias to an option by calling `AddAlias`:

```
C#  
  
var option = new Option("--framework");  
option.AddAlias("-f");
```

Given this alias, the following command lines are equivalent:

```
Console  
  
myapp -f net6.0  
myapp --framework net6.0
```

Command aliases work the same way.

```
C#  
  
var command = new Command("serialize");  
command.AddAlias("serialise");
```

This code makes the following command lines equivalent:

```
Console  
  
myapp serialize  
myapp serialise
```

We recommend that you minimize the number of option aliases that you define, and avoid defining certain aliases in particular. For more information, see [Short-form aliases](#).

Required options

To make an option required, set its `IsRequired` property to `true`, as shown in the following example:

```
C#  
  
var endpointOption = new Option<Uri>("--endpoint") { IsRequired = true };  
var command = new RootCommand();  
command.Add(endpointOption);  
  
command.SetHandler((uri) =>  
{
```

```
        Console.WriteLine(uri?.GetType());
        Console.WriteLine(uri?.ToString());
    },
    endpointOption);

await command.InvokeAsync(args);
```

The options section of the command help indicates the option is required:

Output

```
Options:
--endpoint <uri> (REQUIRED)
--version           Show version information
-?, -h, --help      Show help and usage information
```

If the command line for this example app doesn't include `--endpoint`, an error message is displayed and the command handler isn't called:

Output

```
Option '--endpoint' is required.
```

If a required option has a default value, the option doesn't have to be specified on the command line. In that case, the default value provides the required option value.

Hidden commands, options, and arguments

You might want to support a command, option, or argument, but avoid making it easy to discover. For example, it might be a deprecated or administrative or preview feature. Use the `IsHidden` property to prevent users from discovering such features by using tab completion or help, as shown in the following example:

C#

```
var endpointOption = new Option<Uri>("--endpoint") { IsHidden = true };
var command = new RootCommand();
command.Add(endpointOption);

command.SetHandler((uri) =>
{
    Console.WriteLine(uri?.GetType());
    Console.WriteLine(uri?.ToString());
},
endpointOption);
```

```
await command.InvokeAsync(args);
```

The options section of this example's command help omits the `--endpoint` option.

Output

Options:

| | |
|-----------------------------|---------------------------------|
| <code>--version</code> | Show version information |
| <code>-?, -h, --help</code> | Show help and usage information |

Set argument arity

You can explicitly set argument [arity](#) by using the `Arity` property, but in most cases that is not necessary. `System.CommandLine` automatically determines the argument arity based on the argument type:

[+] Expand table

| Argument type | Default arity |
|----------------------|---------------------------------------|
| <code>Boolean</code> | <code>ArgumentArity.ZeroOrOne</code> |
| Collection types | <code>ArgumentArity.ZeroOrMore</code> |
| Everything else | <code>ArgumentArity.ExactlyOne</code> |

Multiple arguments

By default, when you call a command, you can repeat an option name to specify multiple arguments for an option that has maximum [arity](#) greater than one.

Console

```
myapp --items one --items two --items three
```

To allow multiple arguments without repeating the option name, set `Option.AllowMultipleArgumentsPerToken` to `true`. This setting lets you enter the following command line.

Console

```
myapp --items one two three
```

The same setting has a different effect if maximum argument arity is 1. It allows you to repeat an option but takes only the last value on the line. In the following example, the value `three` would be passed to the app.

Console

```
myapp --item one --item two --item three
```

List valid argument values

To specify a list of valid values for an option or argument, specify an enum as the option type or use [FromAmong](#), as shown in the following example:

C#

```
var languageOption = new Option<string>(
    "--language",
    "An option that must be one of the values of a static list.")
    .FromAmong(
        "csharp",
        "fsharp",
        "vb",
        "pwsh",
        "sql");
```

Here's an example of command-line input and the resulting output for the preceding example code:

Console

```
myapp --language not-a-language
```

Output

```
Argument 'not-a-language' not recognized. Must be one of:
  'csharp'
  'fsharp'
  'vb'
  'pwsh'
  'sql'
```

The options section of command help shows the valid values:

| Output | |
|--|--|
| Options: | |
| --language <csharp fsharp vb pwsh sql> | An option that must be one of the values of a static list. |
| --version | Show version information |
| -?, -h, --help | Show help and usage information |

Option and argument validation

For information about argument validation and how to customize it, see the following sections in the [Parameter binding](#) article:

How to bind arguments to handlers in System.CommandLine

Article • 05/11/2023

ⓘ Important

`System.CommandLine` is currently in PREVIEW, and this documentation is for version 2.0 beta 4. Some information relates to prerelease product that may be substantially modified before it's released. Microsoft makes no warranties, express or implied, with respect to the information provided here.

The process of parsing arguments and providing them to command handler code is called *parameter binding*. `System.CommandLine` has the ability to bind many argument types built in. For example, integers, enums, and file system objects such as `FileInfo` and `DirectoryInfo` can be bound. Several `System.CommandLine` types can also be bound.

Built-in argument validation

Arguments have expected types and [arity](#). `System.CommandLine` rejects arguments that don't match these expectations.

For example, a parse error is displayed if the argument for an integer option isn't an integer.

Console

```
myapp --delay not-an-int
```

Output

```
Cannot parse argument 'not-an-int' as System.Int32.
```

An arity error is displayed if multiple arguments are passed to an option that has maximum arity of one:

Console

```
myapp --delay-option 1 --delay-option 2
```

Output

```
Option '--delay' expects a single argument but 2 were provided.
```

This behavior can be overridden by setting [Option.AllowMultipleArgumentsPerToken](#) to `true`. In that case you can repeat an option that has maximum arity of one, but only the last value on the line is accepted. In the following example, the value `three` would be passed to the app.

Console

```
myapp --item one --item two --item three
```

Parameter binding up to 8 options and arguments

The following example shows how to bind options to command handler parameters, by calling [SetHandler](#):

C#

```
var delayOption = new Option<int>
    ("--delay", "An option whose argument is parsed as an int.");
var messageOption = new Option<string>
    ("--message", "An option whose argument is parsed as a string.");

var rootCommand = new RootCommand("Parameter binding example");
rootCommand.Add(delayOption);
rootCommand.Add(messageOption);

rootCommand.SetHandler(
    (delayOptionValue, messageOptionValue) =>
{
    DisplayIntAndString(delayOptionValue, messageOptionValue);
},
delayOption, messageOption);

await rootCommand.InvokeAsync(args);
```

C#

```
public static void DisplayIntAndString(int delayOptionValue, string
messageOptionValue)
{
    Console.WriteLine($"--delay = {delayOptionValue}");
```

```
        Console.WriteLine($"--message = {messageOptionValue}");
    }
```

The lambda parameters are variables that represent the values of options and arguments:

C#

```
(delayOptionValue, messageOptionValue) =>
{
    DisplayIntAndString(delayOptionValue, messageOptionValue);
},
```

The variables that follow the lambda represent the option and argument objects that are the sources of the option and argument values:

C#

```
delayOption, messageOption);
```

The options and arguments must be declared in the same order in the lambda and in the parameters that follow the lambda. If the order is not consistent, one of the following scenarios will result:

- If the out-of-order options or arguments are of different types, a run-time exception is thrown. For example, an `int` might appear where a `string` should be in the list of sources.
- If the out-of-order options or arguments are of the same type, the handler silently gets the wrong values in the parameters provided to it. For example, `string` option `x` might appear where `string` option `y` should be in the list of sources. In that case, the variable for the option `y` value gets the option `x` value.

There are overloads of `SetHandler` that support up to 8 parameters, with both synchronous and asynchronous signatures.

Parameter binding more than 8 options and arguments

To handle more than 8 options, or to construct a custom type from multiple options, you can use `InvocationContext` or a custom binder.

Use `InvocationContext`

A `SetHandler` overload provides access to the `InvocationContext` object, and you can use `InvocationContext` to get any number of option and argument values. For examples, see [Set exit codes](#) and [Handle termination](#).

Use a custom binder

A custom binder lets you combine multiple option or argument values into a complex type and pass that into a single handler parameter. Suppose you have a `Person` type:

```
C#  
  
public class Person  
{  
    public string? FirstName { get; set; }  
    public string? LastName { get; set; }  
}
```

Create a class derived from `BinderBase<T>`, where `T` is the type to construct based on command line input:

```
C#  
  
public class PersonBinder : BinderBase<Person>  
{  
    private readonly Option<string> _firstNameOption;  
    private readonly Option<string> _lastNameOption;  
  
    public PersonBinder(Option<string> firstNameOption, Option<string>  
lastNameOption)  
    {  
        _firstNameOption = firstNameOption;  
        _lastNameOption = lastNameOption;  
    }  
  
    protected override Person GetBoundValue(BindingContext bindingContext)  
=>  
    new Person  
    {  
        FirstName =  
bindingContext.ParseResult.GetValueForOption(_firstNameOption),  
        LastName =  
bindingContext.ParseResult.GetValueForOption(_lastNameOption)  
    };  
}
```

With the custom binder, you can get your custom type passed to your handler the same way you get values for options and arguments:

```
C#
```

```
rootCommand.SetHandler((fileOptionValue, person) =>
{
    DoRootCommand(fileOptionValue, person);
},
fileOption, new PersonBinder(firstNameOption, lastNameOption));
```

Here's the complete program that the preceding examples are taken from:

```
C#
```

```
using System.CommandLine;
using System.CommandLine.Binding;

public class Program
{
    internal static async Task Main(string[] args)
    {
        var fileOption = new Option<FileInfo?>(
            name: "--file",
            description: "An option whose argument is parsed as a
FileInfo",
            getDefaultValue: () => new
FileInfo("scl.runtimeconfig.json"));

        var firstNameOption = new Option<string>(
            name: "--first-name",
            description: "Person.FirstName");

        var lastNameOption = new Option<string>(
            name: "--last-name",
            description: "Person.LastName");

        var rootCommand = new RootCommand();
        rootCommand.Add(fileOption);
        rootCommand.Add(firstNameOption);
        rootCommand.Add(lastNameOption);

        rootCommand.SetHandler((fileOptionValue, person) =>
        {
            DoRootCommand(fileOptionValue, person);
},
fileOption, new PersonBinder(firstNameOption, lastNameOption));

        await rootCommand.InvokeAsync(args);
    }

    public static void DoRootCommand(FileInfo? aFile, Person aPerson)
```

```

    {
        Console.WriteLine($"File = {aFile?.FullName}");
        Console.WriteLine($"Person = {aPerson?.FirstName}
{aPerson?.LastName}");
    }

    public class Person
    {
        public string? FirstName { get; set; }
        public string? LastName { get; set; }
    }

    public class PersonBinder : BinderBase<Person>
    {
        private readonly Option<string> _firstNameOption;
        private readonly Option<string> _lastNameOption;

        public PersonBinder(Option<string> firstNameOption, Option<string>
lastNameOption)
        {
            _firstNameOption = firstNameOption;
            _lastNameOption = lastNameOption;
        }

        protected override Person GetBoundValue(BindingContext
bindingContext) =>
            new Person
            {
                FirstName =
bindingContext.ParseResult.GetValueForOption(_firstNameOption),
                LastName =
bindingContext.ParseResult.GetValueForOption(_lastNameOption)
            };
    }
}

```

Set exit codes

There are [Task](#)-returning [Func](#) overloads of [SetHandler](#). If your handler is called from [async](#) code, you can return a [Task<int>](#) from a handler that uses one of these, and use the `int` value to set the process exit code, as in the following example:

C#

```

static async Task<int> Main(string[] args)
{
    var delayOption = new Option<int>("--delay");
    var messageOption = new Option<string>("--message");

    var rootCommand = new RootCommand("Parameter binding example");
    rootCommand.Add(delayOption);

```

```

rootCommand.Add(messageOption);

rootCommand.SetHandler((delayOptionValue, messageOptionValue) =>
{
    Console.WriteLine($"--delay = {delayOptionValue}");
    Console.WriteLine($"--message = {messageOptionValue}");
    return Task.FromResult(100);
},
delayOption, messageOption);

return await rootCommand.InvokeAsync(args);
}

```

However, if the lambda itself needs to be async, you can't return a `Task<int>`. In that case, use `InvocationContext.ExitCode`. You can get the `InvocationContext` instance injected into your lambda by using a `SetHandler` overload that specifies the `InvocationContext` as the sole parameter. This `SetHandler` overload doesn't let you specify `IValueDescriptor<T>` objects, but you can get option and argument values from the `ParseResult` property of `InvocationContext`, as shown in the following example:

C#

```

static async Task<int> Main(string[] args)
{
    var delayOption = new Option<int>("--delay");
    var messageOption = new Option<string>("--message");

    var rootCommand = new RootCommand("Parameter binding example");
    rootCommand.Add(delayOption);
    rootCommand.Add(messageOption);

    rootCommand.SetHandler(async (context) =>
    {
        int delayOptionValue =
context.ParseResult.GetValueForOption(delayOption);
        string? messageOptionValue =
context.ParseResult.GetValueForOption(messageOption);

        Console.WriteLine($"--delay = {delayOptionValue}");
        await Task.Delay(delayOptionValue);
        Console.WriteLine($"--message = {messageOptionValue}");
        context.ExitCode = 100;
    });

    return await rootCommand.InvokeAsync(args);
}

```

If you don't have asynchronous work to do, you can use the `Action` overloads. In that case, set the exit code by using `InvocationContext.ExitCode` the same way you would

with an async lambda.

The exit code defaults to 1. If you don't set it explicitly, its value is set to 0 when your handler exits normally. If an exception is thrown, it keeps the default value.

Supported types

The following examples show code that binds some commonly used types.

Enums

The values of `enum` types are bound by name, and the binding is case insensitive:

```
C#  
  
var colorOption = new Option<ConsoleColor>("--color");  
  
var rootCommand = new RootCommand("Enum binding example");  
rootCommand.Add(colorOption);  
  
rootCommand.SetHandler((colorOptionValue) =>  
    { Console.WriteLine(colorOptionValue); },  
    colorOption);  
  
await rootCommand.InvokeAsync(args);
```

Here's sample command-line input and resulting output from the preceding example:

Console

```
myapp --color red  
myapp --color RED
```

Output

```
Red  
Red
```

Arrays and lists

Many common types that implement [IEnumerable](#) are supported. For example:

```
C#
```

```
var itemsOption = new Option<IEnumerable<string>>("--items")
{ AllowMultipleArgumentsPerToken = true };

var command = new RootCommand("IEnumarable binding example");
command.Add(itemsOption);

command.SetHandler((items) =>
{
    Console.WriteLine(items.GetType());

    foreach (string item in items)
    {
        Console.WriteLine(item);
    }
},
itemsOption);

await command.InvokeAsync(args);
```

Here's sample command-line input and resulting output from the preceding example:

Console

```
--items one --items two --items three
```

Output

```
System.Collections.Generic.List`1[System.String]
one
two
three
```

Because `AllowMultipleArgumentsPerToken` is set to `true`, the following input results in the same output:

Console

```
--items one two three
```

File system types

Command-line applications that work with the file system can use the [FileSystemInfo](#), [FileInfo](#), and [DirectoryInfo](#) types. The following example shows the use of [FileSystemInfo](#):

C#

```
var fileOrDirectoryOption = new Option<FileSystemInfo>("--file-or-directory");

var command = new RootCommand();
command.Add(fileOrDirectoryOption);

command.SetHandler((fileSystemInfo) =>
{
    switch (fileSystemInfo)
    {
        case FileInfo file : 
            Console.WriteLine($"File name: {file.FullName}");
            break;
        case DirectoryInfo directory:
            Console.WriteLine($"Directory name: {directory.FullName}");
            break;
        default:
            Console.WriteLine("Not a valid file or directory name.");
            break;
    }
},
fileOrDirectoryOption);

await command.InvokeAsync(args);
```

With `FileInfo` and `DirectoryInfo` the pattern matching code is not required:

C#

```
var fileOption = new Option<FileInfo>("--file");

var command = new RootCommand();
command.Add(fileOption);

command.SetHandler((file) =>
{
    if (file is not null)
    {
        Console.WriteLine($"File name: {file?.FullName}");
    }
    else
    {
        Console.WriteLine("Not a valid file name.");
    }
},
fileOption);

await command.InvokeAsync(args);
```

Other supported types

Many types that have a constructor that takes a single string parameter can be bound in this way. For example, code that would work with `FileInfo` works with a `Uri` instead.

C#

```
var endpointOption = new Option<Uri>("--endpoint");

var command = new RootCommand();
command.Add(endpointOption);

command.SetHandler((uri) =>
{
    Console.WriteLine($"URL: {uri?.ToString()}");
},
endpointOption);

await command.InvokeAsync(args);
```

Besides the file system types and `Uri`, the following types are supported:

- `bool`
- `byte`
- `DateTime`
- `DateTimeOffset`
- `decimal`
- `double`
- `float`
- `Guid`
- `int`
- `long`
- `sbyte`
- `short`
- `uint`
- `ulong`
- `ushort`

Use `System.CommandLine` objects

There's a `SetHandler` overload that gives you access to the `InvocationContext` object. That object can then be used to access other `System.CommandLine` objects. For example,

you have access to the following objects:

- [InvocationContext](#)
- [CancellationToken](#)
- [IConsole](#)
- [ParseResult](#)

InvocationContext

For examples, see [Set exit codes](#) and [Handle termination](#).

CancellationToken

For information about how to use [CancellationToken](#), see [How to handle termination](#).

IConsole

[IConsole](#) makes testing as well as many extensibility scenarios easier than using `System.Console`. It's available in the [InvocationContext.Console](#) property.

ParseResult

The [ParseResult](#) object is available in the [InvocationContext.ParseResult](#) property. It's a singleton structure that represents the results of parsing the command line input. You can use it to check for the presence of options or arguments on the command line or to get the [ParseResult.UnmatchedTokens](#) property. This property contains a list of the [tokens](#) that were parsed but didn't match any configured command, option, or argument.

The list of unmatched tokens is useful in commands that behave like wrappers. A wrapper command takes a set of [tokens](#) and forwards them to another command or app. The `sudo` command in Linux is an example. It takes the name of a user to impersonate followed by a command to run. For example:

```
Console
```

```
sudo -u admin apt update
```

This command line would run the `apt update` command as the user `admin`.

To implement a wrapper command like this one, set the command property `TreatUnmatchedTokensAsErrors` to `false`. Then the `ParseResult.UnmatchedTokens` property will contain all of the arguments that don't explicitly belong to the command. In the preceding example, `ParseResult.UnmatchedTokens` would contain the `apt` and `update` tokens. Your command handler could then forward the `UnmatchedTokens` to a new shell invocation, for example.

Custom validation and binding

To provide custom validation code, call `AddValidator` on your command, option, or argument, as shown in the following example:

C#

```
var delayOption = new Option<int>("--delay");
delayOption.AddValidator(result =>
{
    if (result.GetValueForOption(delayOption) < 1)
    {
        result.ErrorMessage = "Must be greater than 0";
    }
});
```

If you want to parse as well as validate the input, use a `ParseArgument<T>` delegate, as shown in the following example:

C#

```
var delayOption = new Option<int>(
    name: "--delay",
    description: "An option whose argument is parsed as an int.",
    isDefault: true,
    parseArgument: result =>
{
    if (!result.Tokens.Any())
    {
        return 42;
    }

    if (int.TryParse(result.Tokens.Single().Value, out var delay))
    {
        if (delay < 1)
        {
            result.ErrorMessage = "Must be greater than 0";
        }
        return delay;
    }
    else
```

```

    {
        result.ErrorMessage = "Not an int.";
        return 0; // Ignored.
    }
});

```

The preceding code sets `isDefault` to `true` so that the `parseArgument` delegate will be called even if the user didn't enter a value for this option.

Here are some examples of what you can do with `ParseArgument<T>` that you can't do with `AddValidator`:

- Parsing of custom types, such as the `Person` class in the following example:

C#

```

public class Person
{
    public string? FirstName { get; set; }
    public string? LastName { get; set; }
}

```

C#

```

var personOption = new Option<Person?>(
    name: "--person",
    description: "An option whose argument is parsed as a Person",
    parseArgument: result =>
{
    if (result.Tokens.Count != 2)
    {
        result.ErrorMessage = "--person requires two arguments";
        return null;
    }
    return new Person
    {
        FirstName = result.Tokens.First().Value,
        LastName = result.Tokens.Last().Value
    };
})
{
    Arity = ArgumentArity.OneOrMore,
    AllowMultipleArgumentsPerToken = true
};

```

- Parsing of other kinds of input strings (for example, parse "1,2,3" into `int[]`).
- Dynamic arity. For example, you have two arguments that are defined as string arrays, and you have to handle a sequence of strings in the command line input.

The [ArgumentResult.OnlyTake](#) method enables you to dynamically divide up the input strings between the arguments.

Tab completion for System.CommandLine

Article • 03/11/2022

ⓘ Important

`System.CommandLine` is currently in PREVIEW, and this documentation is for version 2.0 beta 4. Some information relates to prerelease product that may be substantially modified before it's released. Microsoft makes no warranties, express or implied, with respect to the information provided here.

Apps that use `System.CommandLine` have built-in support for tab completion in certain shells. To enable it, the end user has to take a few steps once per shell. Once the user does this, tab completion is automatic for static values in your app, such as enum values or values you define by calling [FromAmong](#). You can also customize the tab completion by getting values dynamically at runtime.

Enable tab completion

On the machine where you'd like to enable tab completion, do the following steps.

For the .NET CLI:

- See [How to enable tab completion](#).

For other command-line apps built on `System.CommandLine`:

- Install the [dotnet-suggest](#) global tool.
- Add the appropriate shim script to your shell profile. You may have to create a shell profile file. The shim script forwards completion requests from your shell to the `dotnet-suggest` tool, which delegates to the appropriate `System.CommandLine`-based app.
 - For `bash`, add the contents of [dotnet-suggest-shim.bash](#) to `~/.bash_profile`.
 - For `zsh`, add the contents of [dotnet-suggest-shim.zsh](#) to `~/.zshrc`.
 - For PowerShell, add the contents of [dotnet-suggest-shim.ps1](#) to your PowerShell profile. You can find the expected path to your PowerShell profile by

running the following command in your console:

```
Console
```

```
echo $profile
```

Once the user's shell is set up, completions will work for all apps that are built by using `System.CommandLine`.

For `cmd.exe` on Windows (the Windows Command Prompt) there is no pluggable tab completion mechanism, so no shim script is available. For other shells, [look for a GitHub issue that is labeled Area-Completions ↗](#). If you don't find an issue, you can [open a new one ↗](#).

Get tab completion values at run-time

The following code shows an app that gets values for tab completion dynamically at runtime. The code gets a list of the next two weeks of dates following the current date. The list is provided to the `--date` option by calling `AddCompletions`:

```
C#
```

```
using System.CommandLine;
using System.CommandLine.Completions;
using System.CommandLine.Parsing;

await new DateCommand().InvokeAsync(args);

class DateCommand : Command
{
    private Argument<string> subjectArgument =
        new ("subject", "The subject of the appointment.");
    private Option<DateTime> dateOption =
        new ("--date", "The day of week to schedule. Should be within one
week.");

    public DateCommand() : base("schedule", "Makes an appointment for
sometime in the next week.")
    {
        this.AddArgument(subjectArgument);
        this.AddOption(dateOption);

        dateOption.AddCompletions((ctx) => {
            var today = System.DateTime.Today;
            var dates = new List<CompletionItem>();
            foreach (var i in Enumerable.Range(1, 7))
            {
                var date = today.AddDays(i);
                dates.Add(new CompletionItem(date.ToString("ddd")));
            }
            return dates;
        });
    }
}
```

```

        dates.Add(new CompletionItem(
            label: date.ToShortDateString(),
            sortText: ${i:2}"));
    }
    return dates;
});

this.SetHandler((subject, date) =>
{
    Console.WriteLine($"Scheduled \'{subject}\' for {date}");
},
subjectArgument, dateOption);
}
}

```

The values shown when the tab key is pressed are provided as `CompletionItem` instances:

C#

```

dates.Add(new CompletionItem(
    label: date.ToShortDateString(),
    sortText: ${i:2}"));

```

The following `CompletionItem` properties are set:

- `Label` is the completion value to be shown.
- `SortText` ensures that the values in the list are presented in the right order. It's set by converting `i` to a two-digit string, so that sorting is based on 01, 02, 03, and so on, through 14. If you don't set this parameter, sorting is based on the `Label`, which in this example is in short date format and won't sort correctly.

There are other `CompletionItem` properties, such as `Documentation` and `Detail`, but they aren't used yet in `System.CommandLine`.

The dynamic tab completion list created by this code also appears in help output:

Output

Description:
Makes an appointment for sometime in the next week.

Usage:
`schedule <subject> [options]`

Arguments:
`<subject>` The subject of the appointment.

```
Options:  
--date  
The day of week to schedule. Should be within one week.  
<2/4/2022|2/5/2022|2/6/2022|2/7/2022|2/8/2022|2/9/2022|2/10/2022>  
--version  
Show version information  
-?, -h, --help
```

How to configure dependency injection in System.CommandLine

Article • 05/11/2023

ⓘ Important

`System.CommandLine` is currently in PREVIEW, and this documentation is for version 2.0 beta 4. Some information relates to prerelease product that may be substantially modified before it's released. Microsoft makes no warranties, express or implied, with respect to the information provided here.

Use a [custom binder](#) to inject custom types into a command handler.

We recommend handler-specific dependency injection (DI) for the following reasons:

- Command-line apps are often short-lived processes, in which startup cost can have a noticeable impact on performance. Optimizing performance is particularly important when tab completions have to be calculated. Command-line apps are unlike Web and GUI apps, which tend to be relatively long-lived processes. Unnecessary startup time is not appropriate for short-lived processes.
- When a command-line app that has multiple subcommands is run, only one of those subcommands will be executed. If an app configures dependencies for the subcommands that don't run, it needlessly degrades performance.

To configure DI, create a class that derives from `BinderBase<T>` where `T` is the interface that you want to inject an instance for. In the `GetBoundValue` method override, get and return the instance you want to inject. The following example injects the default logger implementation for `ILogger`:

C#

```
public class MyCustomBinder : BinderBase<ILogger>
{
    protected override ILogger GetBoundValue(
        BindingContext bindingContext) => GetLogger(bindingContext);

    ILogger GetLogger(BindingContext bindingContext)
    {
        using ILoggerFactory loggerFactory = LoggerFactory.Create(
            builder => builder.AddConsole());
        ILogger logger = loggerFactory.CreateLogger("LoggerCategory");
        return logger;
    }
}
```

```
    }  
}
```

When calling the `SetHandler` method, pass to the lambda an instance of the injected class and pass an instance of your binder class in the list of services:

C#

```
rootCommand.SetHandler(async (fileOptionValue, logger) =>  
{  
    await DoRootCommand(fileOptionValue!, logger);  
},  
fileOption, new MyCustomBinder());
```

The following code is a complete program that contains the preceding examples:

C#

```
using System.CommandLine;  
using System.CommandLine.Binding;  
using Microsoft.Extensions.Logging;  
  
class Program  
{  
    static async Task Main(string[] args)  
    {  
        var fileOption = new Option<FileInfo?>(  
            name: "--file",  
            description: "An option whose argument is parsed as a  
FileInfo");  
  
        var rootCommand = new RootCommand("Dependency Injection sample");  
        rootCommand.Add(fileOption);  
  
        rootCommand.SetHandler(async (fileOptionValue, logger) =>  
        {  
            await DoRootCommand(fileOptionValue!, logger);  
        },  
        fileOption, new MyCustomBinder());  
  
        await rootCommand.InvokeAsync("--file scl.runtimeconfig.json");  
    }  
  
    public static async Task DoRootCommand(FileInfo aFile, ILogger logger)  
    {  
        Console.WriteLine($"File = {aFile?.FullName}");  
        logger.LogCritical("Test message");  
        await Task.Delay(1000);  
    }  
  
    public class MyCustomBinder : BinderBase<ILogger>
```

```
{  
    protected override ILogger GetBoundValue(  
        BindingContext bindingContext) => GetLogger(bindingContext);  
  
    ILogger GetLogger(BindingContext bindingContext)  
    {  
        using ILoggerFactory loggerFactory = LoggerFactory.Create(  
            builder => builder.AddConsole());  
        ILogger logger = loggerFactory.CreateLogger("LoggerCategory");  
        return logger;  
    }  
}
```

How to customize help in apps that are built with the System.Commandline library

Article • 07/21/2022

You can customize help for a specific command, option, or argument, and you can add or replace whole help sections.

The examples in this article work with the following command-line application:

This code requires a `using` directive:

C#

```
using System.CommandLine;
```

C#

```
var fileOption = new Option<FileInfo>(
    "--file",
    description: "The file to print out.",
    getDefaultValue: () => new FileInfo("scl.runtimeconfig.json"));
var lightModeOption = new Option<bool> (
    "--light-mode",
    description: "Determines whether the background color will be black or white");
var foregroundColorOption = new Option<ConsoleColor>(
    "--color",
    description: "Specifies the foreground color of console output",
    getDefaultValue: () => ConsoleColor.White);

var rootCommand = new RootCommand("Read a file")
{
    fileOption,
    lightModeOption,
    foregroundColorOption
};

rootCommand.SetHandler((file, lightMode, color) =>
{
    Console.BackgroundColor = lightMode ? ConsoleColor.White:
    ConsoleColor.Black;
    Console.ForegroundColor = color;
    Console.WriteLine($"--file = {file?.FullName}");
    Console.WriteLine($"File
contents:\n{file?.OpenText().ReadToEnd()}");
},
```

```
    fileOption,  
    lightModeOption,  
    foregroundColorOption);  
  
    await rootCommand.InvokeAsync(args);
```

Without customization, the following help output is produced:

Output

```
Description:  
  Read a file  
  
Usage:  
  scl [options]  
  
Options:  
  --file <file>                                     The file to  
  print out. [default: scl.runtimeconfig.json]  
  --light-mode                                         Determines  
  whether the background color will be black or  
  white  
  --color                                              Specifies the  
  foreground color of console output  
  <Black|Blue|Cyan|DarkBlue|DarkCyan|DarkGray|Dark  [default:  
  White]  
  Magenta|DarkRed|DarkYellow|Gray|Green|Magenta|Red|White|Ye  
  llow>  
  --version                                            Show version  
  information  
  -?, -h, --help                                         Show help and  
  usage information
```

Customize help for a single option or argument

ⓘ Important

`System.CommandLine` is currently in PREVIEW, and this documentation is for version 2.0 beta 4. Some information relates to prerelease product that may be substantially modified before it's released. Microsoft makes no warranties, express or implied, with respect to the information provided here.

To customize the name of an option's argument, use the option's [ArgumentHelpName](#) property. And [HelpBuilder.CustomizeSymbol](#) lets you customize several parts of the help output for a command, option, or argument ([Symbol](#) is the base class for all three types). With [CustomizeSymbol](#), you can specify:

- The first column text.
- The second column text.
- The way a default value is described.

In the sample app, `--light-mode` is explained adequately, but changes to the `--file` and `--color` option descriptions will be helpful. For `--file`, the argument can be identified as a `<FILEPATH>` instead of `<file>`. For the `--color` option, you can shorten the list of available colors in column one, and in column two you can add a warning that some colors won't work with some backgrounds.

To make these changes, delete the `await rootCommand.InvokeAsync(args);` line shown in the preceding code and add in its place the following code:

C#

```
fileOption.ArgumentHelpName = "FILEPATH";

var parser = new CommandLineBuilder(rootCommand)
    .UseDefaults()
    .UseHelp(ctx =>
{
    ctx.HelpBuilder.CustomizeSymbol(foregroundColorOption,
        firstColumnText: "--color <Black, White, Red, or Yellow>",
        secondColumnText: "Specifies the foreground color. " +
            "Choose a color that provides enough contrast " +
            "with the background color. " +
            "For example, a yellow foreground can't be read " +
            "against a light mode background.");
})
.Build();

parser.Invoke(args);
```

The updated code requires additional `using` directives:

C#

```
using System.CommandLine.Builder;
using System.CommandLine.Help;
using System.CommandLine.Parsing;
```

The app now produces the following help output:

Output

```
Description:
  Read a file
```

```

Usage:
  scl [options]

Options:
  --file <FILEPATH>                                The file to print out. [default:
  CustomHelp.runtimeconfig.json]
  --light-mode                                         Determines whether the background
  color will be black or white
  --color <Black, White, Red, or Yellow>   Specifies the foreground color.
  Choose a color that provides enough contrast
                                              with the background color. For
  example, a yellow foreground can't be read
                                              against a light mode background.
  --version                                            Show version information
  -?, -h, --help                                         Show help and usage information

```

This output shows that the `firstColumnText` and `secondColumnText` parameters support word wrapping within their columns.

Add or replace help sections

You can add or replace a whole section of the help output. For example, suppose you want to add some ASCII art to the description section by using the [Spectre.Console](#) NuGet package.

Change the layout by adding a call to `HelpBuilder.CustomizeLayout` in the lambda passed to the `UseHelp` method:

```

C#

fileOption.ArgumentHelpName = "FILEPATH";

var parser = new CommandLineBuilder(rootCommand)
    .UseDefaults()
    .UseHelp(ctx =>
{
    ctx.HelpBuilder.CustomizeSymbol(foregroundColorOption,
        firstColumnText: "--color <Black, White, Red, or Yellow>",
        secondColumnText: "Specifies the foreground color. " +
            "Choose a color that provides enough contrast " +
            "with the background color. " +
            "For example, a yellow foreground can't be read " +
            "against a light mode background.");
}

```

```

    ctx.HelpBuilder.CustomizeLayout(
        _ =>
            HelpBuilder.Default
                .GetLayout()
                .Skip(1) // Skip the default command description
section.
                .Prepend(
                    _ => Spectre.Console.AnsiConsole.Write(
                        new FigletText(rootCommand.Description!)))
            ));
    }
    .Build();

await parser.InvokeAsync(args);

```

The preceding code requires an additional `using` directive:

C#

```
using Spectre.Console;
```

The [System.CommandLine.Help.HelpBuilder.Default](#) class lets you reuse pieces of existing help formatting functionality and compose them into your custom help.

The help output now looks like this:

Output

Usage:

```
scl [options]
```

Options:

```
--file <FILEPATH>
```

The file to print out. [default:

```
CustomHelp.runtimeconfig.json]
```

```
--light-mode
```

Determines whether the background

color will be black or white

```
--color <Black, White, Red, or Yellow>
```

Specifies the foreground color.

Choose a color that provides enough contrast

with the background color. For

example, a yellow foreground can't be read

against a light mode background.

```
--version
```

Show version information

```
-?, -h, --help
```

Show help and usage information

If you want to just use a string as the replacement section text instead of formatting it with `Spectre.Console`, replace the `Prepend` code in the preceding example with the following code:

C#

```
.Prepend(  
    _ => _.Output.WriteLine(""))
```

How to handle termination in System.CommandLine

Article • 06/27/2023

ⓘ Important

`System.CommandLine` is currently in PREVIEW, and this documentation is for version 2.0 beta 4. Some information relates to prerelease product that may be substantially modified before it's released. Microsoft makes no warranties, express or implied, with respect to the information provided here.

To handle termination, inject a [CancellationToken](#) instance into your handler code. This token can then be passed along to async APIs that you call from within your handler, as shown in the following example:

C#

```
static async Task<int> Main(string[] args)
{
    int returnCode = 0;

    var urlOption = new Option<string>("--url", "A URL.");

    var rootCommand = new RootCommand("Handle termination example");
    rootCommand.Add(urlOption);

    rootCommand.SetHandler(async (context) =>
    {
        string? urlOptionValue =
        context.ParseResult.GetValueForOption(urlOption);
        var token = context.GetCancellationToken();
        returnCode = await DoRootCommand(urlOptionValue, token);
    });

    await rootCommand.InvokeAsync(args);

    return returnCode;
}

public static async Task<int> DoRootCommand(
    string? urlOptionValue, CancellationToken cancellationToken)
{
    try
    {
        using (var httpClient = new HttpClient())
        {
```

```
        await httpClient.GetAsync(urlOptionValue, cancellationToken);
    }
    return 0;
}
catch (OperationCanceledException)
{
    Console.Error.WriteLine("The operation was aborted");
    return 1;
}
}
```

The preceding code uses a `SetHandler` overload that gets an `InvocationContext` instance rather than one or more `IValueDescriptor<T>` objects. The `InvocationContext` is used to get the `CancellationToken` and `ParseResult` objects. `ParseResult` can provide argument or option values.

To test the sample code, run the command with a URL that will take a moment to load, and before it finishes loading, press `Ctrl + C`. On macOS press `Command + Period(.)`. For example:

.NET CLI

```
testapp --url https://learn.microsoft.com/aspnet/core/fundamentals/minimal-apis
```

Output

```
The operation was aborted
```

Cancellation actions can also be added directly using the `CancellationToken.Register` method.

For information about an alternative way to set the process exit code, see [Set exit codes](#).

How to use middleware in System.CommandLine

Article • 04/09/2022

ⓘ Important

`System.CommandLine` is currently in PREVIEW, and this documentation is for version 2.0 beta 4. Some information relates to prerelease product that may be substantially modified before it's released. Microsoft makes no warranties, express or implied, with respect to the information provided here.

This article explains how to work with middleware in command-line apps that are built with the `System.CommandLine` library. Use of middleware is an advanced topic that most `System.CommandLine` users won't need to consider.

Introduction to middleware

While each command has a handler that `System.CommandLine` will route to based on input, there's also a mechanism for short-circuiting or altering the input before your application logic is invoked. In between parsing and invocation, there's a chain of responsibility, which you can customize. A number of built-in features of `System.CommandLine` make use of this capability. This is how the `--help` and `--version` options short-circuit calls to your handler.

Each call in the pipeline can take action based on the `ParseResult` and return early, or choose to call the next item in the pipeline. The `ParseResult` can even be replaced during this phase. The last call in the chain is the handler for the specified command.

Add to the middleware pipeline

You can add a call to this pipeline by calling `CommandLineBuilderExtensions.AddMiddleware`. Here's an example of code that enables a custom `directive`. After creating a root command named `rootCommand`, the code as usual adds options, arguments, and handlers. Then the middleware is added:

C#

```

var commandLineBuilder = new CommandLineBuilder(rootCommand);

commandLineBuilder.AddMiddleware(async (context, next) =>
{
    if (context.ParseResult.Directives.Contains("just-say-hi"))
    {
        context.Console.WriteLine("Hi!");
    }
    else
    {
        await next(context);
    }
});

commandLineBuilder.UseDefaults();
var parser = commandLineBuilder.Build();
await parser.InvokeAsync(args);

```

In the preceding code, the middleware writes out "Hi!" if the directive `[just-say-hi]` is found in the parse result. When this happens, the command's normal handler isn't invoked. It isn't invoked because the middleware doesn't call the `next` delegate.

In the example, `context` is `InvocationContext`, a singleton structure that acts as the "root" of the entire command-handling process. This is the most powerful structure in `System.CommandLine`, in terms of capabilities. There are two main uses for it in middleware:

- It provides access to the `BindingContext`, `Parser`, `Console`, and `HelpBuilder` to retrieve dependencies that a middleware requires for its custom logic.
- You can set the `InvocationResult` or `ExitCode` properties in order to terminate command processing in a short-circuiting manner. An example is the `--help` option, which is implemented in this manner.

Here's the complete program, including required `using` directives.

C#

```

using System.CommandLine;
using System.CommandLine.Builder;
using System.CommandLine.Parsing;

class Program
{
    static async Task Main(string[] args)
    {
        var delayOption = new Option<int>("--delay");
        var messageOption = new Option<string>("--message");

```

```

    var rootCommand = new RootCommand("Middleware example");
    rootCommand.Add(delayOption);
    rootCommand.Add(messageOption);

    rootCommand.SetHandler((delayOptionValue, messageOptionValue) =>
    {
        DoRootCommand(delayOptionValue, messageOptionValue);
    },
    delayOption, messageOption);

    var commandLineBuilder = new CommandLineBuilder(rootCommand);

    commandLineBuilder.AddMiddleware(async (context, next) =>
    {
        if (context.ParseResult.Directives.Contains("just-say-hi"))
        {
            context.Console.WriteLine("Hi!");
        }
        else
        {
            await next(context);
        }
    });
}

commandLineBuilder.UseDefaults();
var parser = commandLineBuilder.Build();
await parser.InvokeAsync(args);
}

public static void DoRootCommand(int delay, string message)
{
    Console.WriteLine($"--delay = {delay}");
    Console.WriteLine($"--message = {message}");
}
}

```

Here's an example command line and resulting output from the preceding code:

Console

```
myapp [just-say-hi] --delay 42 --message "Hello world!"
```

Output

```
Hi!
```

File and Stream I/O

Article • 09/15/2021

File and stream I/O (input/output) refers to the transfer of data either to or from a storage medium. In .NET, the `System.IO` namespaces contain types that enable reading and writing, both synchronously and asynchronously, on data streams and files. These namespaces also contain types that perform compression and decompression on files, and types that enable communication through pipes and serial ports.

A file is an ordered and named collection of bytes that has persistent storage. When you work with files, you work with directory paths, disk storage, and file and directory names. In contrast, a stream is a sequence of bytes that you can use to read from and write to a backing store, which can be one of several storage mediums (for example, disks or memory). Just as there are several backing stores other than disks, there are several kinds of streams other than file streams, such as network, memory, and pipe streams.

Files and directories

You can use the types in the `System.IO` namespace to interact with files and directories. For example, you can get and set properties for files and directories, and retrieve collections of files and directories based on search criteria.

For path naming conventions and the ways to express a file path for Windows systems, including with the DOS device syntax supported in .NET Core 1.1 and later and .NET Framework 4.6.2 and later, see [File path formats on Windows systems](#).

Here are some commonly used file and directory classes:

- [File](#) - provides static methods for creating, copying, deleting, moving, and opening files, and helps create a [FileStream](#) object.
- [FileInfo](#) - provides instance methods for creating, copying, deleting, moving, and opening files, and helps create a [FileStream](#) object.
- [Directory](#) - provides static methods for creating, moving, and enumerating through directories and subdirectories.
- [DirectoryInfo](#) - provides instance methods for creating, moving, and enumerating through directories and subdirectories.
- [Path](#) - provides methods and properties for processing directory strings in a cross-platform manner.

You should always provide robust exception handling when calling filesystem methods. For more information, see [Handling I/O errors](#).

In addition to using these classes, Visual Basic users can use the methods and properties provided by the [Microsoft.VisualBasic.FileIO.FileSystem](#) class for file I/O.

See [How to: Copy Directories](#), [How to: Create a Directory Listing](#), and [How to: Enumerate Directories and Files](#).

Streams

The abstract base class [Stream](#) supports reading and writing bytes. All classes that represent streams inherit from the [Stream](#) class. The [Stream](#) class and its derived classes provide a common view of data sources and repositories, and isolate the programmer from the specific details of the operating system and underlying devices.

Streams involve three fundamental operations:

- Reading - transferring data from a stream into a data structure, such as an array of bytes.
- Writing - transferring data to a stream from a data source.
- Seeking - querying and modifying the current position within a stream.

Depending on the underlying data source or repository, a stream might support only some of these capabilities. For example, the [PipeStream](#) class does not support seeking. The [CanRead](#), [CanWrite](#), and [CanSeek](#) properties of a stream specify the operations that the stream supports.

Here are some commonly used stream classes:

- [FileStream](#) – for reading and writing to a file.
- [IsolatedStorageFileStream](#) – for reading and writing to a file in isolated storage.
- [MemoryStream](#) – for reading and writing to memory as the backing store.
- [BufferedStream](#) – for improving performance of read and write operations.
- [NetworkStream](#) – for reading and writing over network sockets.
- [PipeStream](#) – for reading and writing over anonymous and named pipes.
- [CryptoStream](#) – for linking data streams to cryptographic transformations.

For an example of working with streams asynchronously, see [Asynchronous File I/O](#).

Readers and writers

The [System.IO](#) namespace also provides types for reading encoded characters from streams and writing them to streams. Typically, streams are designed for byte input and output. The reader and writer types handle the conversion of the encoded characters to and from bytes so the stream can complete the operation. Each reader and writer class is associated with a stream, which can be retrieved through the class's `BaseStream` property.

Here are some commonly used reader and writer classes:

- [BinaryReader](#) and [BinaryWriter](#) – for reading and writing primitive data types as binary values.
- [StreamReader](#) and [StreamWriter](#) – for reading and writing characters by using an encoding value to convert the characters to and from bytes.
- [StringReader](#) and [StringWriter](#) – for reading and writing characters to and from strings.
- [TextReader](#) and [TextWriter](#) – serve as the abstract base classes for other readers and writers that read and write characters and strings, but not binary data.

See [How to: Read Text from a File](#), [How to: Write Text to a File](#), [How to: Read Characters from a String](#), and [How to: Write Characters to a String](#).

Asynchronous I/O operations

Reading or writing a large amount of data can be resource-intensive. You should perform these tasks asynchronously if your application needs to remain responsive to the user. With synchronous I/O operations, the UI thread is blocked until the resource-intensive operation has completed. Use asynchronous I/O operations when developing Windows 8.x Store apps to prevent creating the impression that your app has stopped working.

The asynchronous members contain `Async` in their names, such as the [CopyToAsync](#), [FlushAsync](#), [ReadAsync](#), and [WriteAsync](#) methods. You use these methods with the `async` and `await` keywords.

For more information, see [Asynchronous File I/O](#).

Compression

Compression refers to the process of reducing the size of a file for storage.

Decompression is the process of extracting the contents of a compressed file so they are in a usable format. The [System.IO.Compression](#) namespace contains types for compressing and decompressing files and streams.

The following classes are frequently used when compressing and decompressing files and streams:

- [ZipArchive](#) – for creating and retrieving entries in the zip archive.
- [ZipArchiveEntry](#) – for representing a compressed file.
- [ZipFile](#) – for creating, extracting, and opening a compressed package.
- [ZipFileExtensions](#) – for creating and extracting entries in a compressed package.
- [DeflateStream](#) – for compressing and decompressing streams using the Deflate algorithm.
- [GZipStream](#) – for compressing and decompressing streams in gzip data format.

See [How to: Compress and Extract Files](#).

Isolated storage

Isolated storage is a data storage mechanism that provides isolation and safety by defining standardized ways of associating code with saved data. The storage provides a virtual file system that is isolated by user, assembly, and (optionally) domain. Isolated storage is particularly useful when your application does not have permission to access user files. You can save settings or files for your application in a manner that is controlled by the computer's security policy.

Isolated storage is not available for Windows 8.x Store apps; instead, use application data classes in the [Windows.Storage](#) namespace. For more information, see [Application data](#).

The following classes are frequently used when implementing isolated storage:

- [IsolatedStorage](#) – provides the base class for isolated storage implementations.
- [IsolatedStorageFile](#) – provides an isolated storage area that contains files and directories.

- [IsolatedStorageFileStream](#) - exposes a file within isolated storage.

See [Isolated Storage](#).

I/O operations in Windows Store apps

.NET for Windows 8.x Store apps contains many of the types for reading from and writing to streams; however, this set does not include all the .NET I/O types.

Some important differences to note when using I/O operations in Windows 8.x Store apps:

- Types specifically related to file operations, such as [File](#), [FileInfo](#), [Directory](#) and [DirectoryInfo](#), are not included in the .NET for Windows 8.x Store apps. Instead, use the types in the [Windows.Storage](#) namespace of the Windows Runtime, such as [StorageFile](#) and [StorageFolder](#).
- Isolated storage is not available; instead, use [application data](#).
- Use asynchronous methods, such as [ReadAsync](#) and [WriteAsync](#), to prevent blocking the UI thread.
- The path-based compression types [ZipFile](#) and [ZipFileExtensions](#) are not available. Instead, use the types in the [Windows.Storage.Compression](#) namespace.

You can convert between .NET Framework streams and Windows Runtime streams, if necessary. For more information, see [How to: Convert Between .NET Framework Streams and Windows Runtime Streams](#) or [WindowsRuntimeStreamExtensions](#).

For more information about I/O operations in a Windows 8.x Store app, see [Quickstart: Reading and writing files](#).

I/O and security

When you use the classes in the [System.IO](#) namespace, you must follow operating system security requirements such as access control lists (ACLs) to control access to files and directories. This requirement is in addition to any [FileIOPermission](#) requirements.

You can manage ACLs programmatically. For more information, see [How to: Add or Remove Access Control List Entries](#).

Default security policies prevent Internet or intranet applications from accessing files on the user's computer. Therefore, do not use the I/O classes that require a path to a

physical file when writing code that will be downloaded over the internet or intranet. Instead, use [isolated storage](#) for .NET applications.

A security check is performed only when the stream is constructed. Therefore, do not open a stream and then pass it to less-trusted code or application domains.

File path formats on Windows systems

Article • 12/14/2022

Members of many of the types in the [System.IO](#) namespace include a `path` parameter that lets you specify an absolute or relative path to a file system resource. This path is then passed to [Windows file system APIs](#). This topic discusses the formats for file paths that you can use on Windows systems.

Traditional DOS paths

A standard DOS path can consist of three components:

- A volume or drive letter followed by the volume separator (`:`).
- A directory name. The [directory separator character](#) separates subdirectories within the nested directory hierarchy.
- An optional filename. The [directory separator character](#) separates the file path and the filename.

If all three components are present, the path is absolute. If no volume or drive letter is specified and the directory name begins with the [directory separator character](#), the path is relative from the root of the current drive. Otherwise, the path is relative to the current directory. The following table shows some possible directory and file paths.

| Path | Description |
|---|---|
| <code>C:\Documents\Newsletters\Summer2018.pdf</code> | An absolute file path from the root of drive <code>C:</code> . |
| <code>\Program Files\Custom Utilities\StringFinder.exe</code> | A relative path from the root of the current drive. |
| <code>2018\January.xlsx</code> | A relative path to a file in a subdirectory of the current directory. |
| <code>..\Publications\TravelBrochure.pdf</code> | A relative path to a file in a directory starting from the current directory. |
| <code>C:\Projects\apilibrary\apilibrary.sln</code> | An absolute path to a file from the root of drive <code>C:</code> . |
| <code>C:Projects\apilibrary\apilibrary.sln</code> | A relative path from the current directory of the <code>C:</code> drive. |

Important

Note the difference between the last two paths. Both specify the optional volume specifier (`C:` in both cases), but the first begins with the root of the specified volume, whereas the second does not. As result, the first is an absolute path from the root directory of drive `C:`, whereas the second is a relative path from the current directory of drive `C:`. Use of the second form when the first is intended is a common source of bugs that involve Windows file paths.

You can determine whether a file path is fully qualified (that is, if the path is independent of the current directory and does not change when the current directory changes) by calling the [Path.IsPathFullyQualified](#) method. Note that such a path can include relative directory segments (`.` and `..`) and still be fully qualified if the resolved path always points to the same location.

The following example illustrates the difference between absolute and relative paths. It assumes that the directory `D:\FY2018\` exists, and that you haven't set any current directory for `D:\` from the command prompt before running the example.

C#

```
using System;
using System.Diagnostics;
using System.IO;
using System.Reflection;

public class Example
{
    public static void Main(string[] args)
    {
        Console.WriteLine($"Current directory is
'{Environment.CurrentDirectory}'");
        Console.WriteLine("Setting current directory to 'C:\\'");

        Directory.SetCurrentDirectory(@"C:\\");
        string path = Path.GetFullPath(@"D:\\FY2018");
        Console.WriteLine($"'D:\\FY2018' resolves to {path}");
        path = Path.GetFullPath(@"D:FY2018");
        Console.WriteLine($"'D:FY2018' resolves to {path}");

        Console.WriteLine("Setting current directory to 'D:\\\\Docs'");
        Directory.SetCurrentDirectory(@"D:\\Docs");

        path = Path.GetFullPath(@"D:\\FY2018");
        Console.WriteLine($"'D:\\FY2018' resolves to {path}");
        path = Path.GetFullPath(@"D:FY2018");

        // This will be "D:\\Docs\\FY2018" as it happens to match the drive of
        // the current directory
        Console.WriteLine($"'D:FY2018' resolves to {path}");
```

```

Console.WriteLine("Setting current directory to 'C:\\\'");
Directory.SetCurrentDirectory(@"C:\\");

path = Path.GetFullPath(@"D:\\FY2018");
Console.WriteLine($"'D:\\FY2018' resolves to {path}");

// This will be either "D:\\FY2018" or "D:\\FY2018\\FY2018" in the
// subprocess. In the sub process,
// the command prompt set the current directory before launch of our
application, which
// sets a hidden environment variable that is considered.
path = Path.GetFullPath(@"D:\\FY2018");
Console.WriteLine($"'D:\\FY2018' resolves to {path}");

if (args.Length < 1)
{
    Console.WriteLine(@"Launching again, after setting current
directory to D:\\FY2018");
    Uri currentExe = new
Uri(Assembly.GetExecutingAssembly().GetName().CodeBase, UriKind.Absolute);
    string commandLine = $"{"/C cd D:\\FY2018 & \"}
{currentExe.LocalPath}\\ stop";
    ProcessStartInfo psi = new ProcessStartInfo("cmd", commandLine); ;
    Process.Start(psi).WaitForExit();

    Console.WriteLine("Sub process returned:");
    path = Path.GetFullPath(@"D:\\FY2018");
    Console.WriteLine($"'D:\\FY2018' resolves to {path}");
    path = Path.GetFullPath(@"D:\\FY2018");
    Console.WriteLine($"'D:\\FY2018' resolves to {path}");
}
Console.WriteLine("Press any key to continue... ");
Console.ReadKey();
}

}

// The example displays the following output:
//      Current directory is 'C:\\Programs\\file-paths'
//      Setting current directory to 'C:\\'
//      'D:\\FY2018' resolves to D:\\FY2018
//      'D:\\FY2018' resolves to d:\\FY2018
//      Setting current directory to 'D:\\Docs'
//      'D:\\FY2018' resolves to D:\\FY2018
//      'D:\\FY2018' resolves to D:\\Docs\\FY2018
//      Setting current directory to 'C:\\'
//      'D:\\FY2018' resolves to D:\\FY2018
//      'D:\\FY2018' resolves to d:\\FY2018
//      Launching again, after setting current directory to D:\\FY2018
//      Sub process returned:
//      'D:\\FY2018' resolves to D:\\FY2018
//      'D:\\FY2018' resolves to d:\\FY2018
// The subprocess displays the following output:
//      Current directory is 'C:\\'
//      Setting current directory to 'C:\\'
//      'D:\\FY2018' resolves to D:\\FY2018

```

```
//      'D:FY2018' resolves to D:\FY2018\FY2018
//      Setting current directory to 'D:\Docs'
//      'D:\FY2018' resolves to D:\FY2018
//      'D:FY2018' resolves to D:\Docs\FY2018
//      Setting current directory to 'C:\'
//      'D:\FY2018' resolves to D:\FY2018
//      'D:FY2018' resolves to D:\FY2018\FY2018
```

UNC paths

Universal naming convention (UNC) paths, which are used to access network resources, have the following format:

- A server or host name, which is prefaced by `\\"`. The server name can be a NetBIOS machine name or an IP/FQDN address (IPv4 as well as v6 are supported).
- A share name, which is separated from the host name by `\`. Together, the server and share name make up the volume.
- A directory name. The [directory separator character](#) separates subdirectories within the nested directory hierarchy.
- An optional filename. The [directory separator character](#) separates the file path and the filename.

The following are some examples of UNC paths:

| Path | Description |
|--|---|
| <code>\system07\C\$\</code> | The root directory of the <code>c:</code> drive on <code>system07</code> . |
| <code>\Server2\Share\Test\Foo.txt</code> | The <code>Foo.txt</code> file in the <code>Test</code> directory of the <code>\Server2\Share</code> volume. |

UNC paths must always be fully qualified. They can include relative directory segments (`.` and `..`), but these must be part of a fully qualified path. You can use relative paths only by mapping a UNC path to a drive letter.

DOS device paths

The Windows operating system has a unified object model that points to all resources, including files. These object paths are accessible from the console window and are exposed to the Win32 layer through a special folder of symbolic links that legacy DOS and UNC paths are mapped to. This special folder is accessed via the DOS device path syntax, which is one of:

```
\.\.\C:\Test\Foo.txt \?\C:\Test\Foo.txt
```

In addition to identifying a drive by its drive letter, you can identify a volume by using its volume GUID. This takes the form:

```
\.\.\Volume{b75e2c83-0000-0000-0000-602f00000000}\Test\Foo.txt \?\Volume{b75e2c83-0000-0000-0000-602f00000000}\Test\Foo.txt
```

ⓘ Note

DOS device path syntax is supported on .NET implementations running on Windows starting with .NET Core 1.1 and .NET Framework 4.6.2.

The DOS device path consists of the following components:

- The device path specifier (`\.\.` or `\?\`), which identifies the path as a DOS device path.

ⓘ Note

The `\?\` is supported in all versions of .NET Core and .NET 5+ and in .NET Framework starting with version 4.6.2.

- A symbolic link to the "real" device object (C: in the case of a drive name, or `Volume{b75e2c83-0000-0000-0000-602f00000000}` in the case of a volume GUID).

The first segment of the DOS device path after the device path specifier identifies the volume or drive. (For example, `\?\C:\` and `\.\.\BootPartition\.`)

There is a specific link for UNC's that is called, not surprisingly, `UNC`. For example:

```
\.\.\UNC\Server\Share\Test\Foo.txt \?\UNC\Server\Share\Test\Foo.txt
```

For device UNC's, the server/share portion forms the volume. For example, in `\?\server1\utilities\filecomparer\`, the server/share portion is `server1\utilities`. This is significant when calling a method such as `Path.GetFullPath(String, String)` with relative directory segments; it is never possible to navigate past the volume.

DOS device paths are fully qualified by definition and cannot begin with a relative directory segment (`.` or `..`). Current directories never enter into their usage.

Example: Ways to refer to the same file

The following example illustrates some of the ways in which you can refer to a file when using the APIs in the `System.IO` namespace. The example instantiates a `FileInfo` object and uses its `Name` and `Length` properties to display the filename and the length of the file.

C#

```
using System;
using System.IO;

class Program
{
    static void Main()
    {
        string[] filenames = {
            @"c:\temp\test-file.txt",
            @"\127.0.0.1\c$\temp\test-file.txt",
            @"\LOCALHOST\c$\temp\test-file.txt",
            @"\.\c:\temp\test-file.txt",
            @"\?\c:\temp\test-file.txt",
            @"\UNC\LOCALHOST\c$\temp\test-file.txt",
            @"\127.0.0.1\c$\temp\test-file.txt" };

        foreach (var filename in filenames)
        {
            FileInfo fi = new FileInfo(filename);
            Console.WriteLine($"file {fi.Name}: {fi.Length:N0} bytes");
        }
    }
}

// The example displays output like the following:
//     file test-file.txt: 22 bytes
//     file test-file.txt: 22 bytes
//     file test-file.txt: 22 bytes
//     file test-file.txt: 22 bytes
//     file test-file.txt: 22 bytes
//     file test-file.txt: 22 bytes
//     file test-file.txt: 22 bytes
```

Path normalization

Almost all paths passed to Windows APIs are normalized. During normalization, Windows performs the following steps:

- Identifies the path.
- Applies the current directory to partially qualified (relative) paths.
- Canonicalizes component and directory separators.

- Evaluates relative directory components (`.` for the current directory and `..` for the parent directory).
- Trims certain characters.

This normalization happens implicitly, but you can do it explicitly by calling the [Path.GetFullPath](#) method, which wraps a call to the [GetFullPathName\(\) function](#). You can also call the Windows [GetFullPathName\(\) function](#) directly using P/Invoke.

Identify the path

The first step in path normalization is identifying the type of path. Paths fall into one of a few categories:

- They are device paths; that is, they begin with two separators and a question mark or period (`\?\?` or `\?\.`).
- They are UNC paths; that is, they begin with two separators without a question mark or period.
- They are fully qualified DOS paths; that is, they begin with a drive letter, a volume separator, and a component separator (`C:\`).
- They designate a legacy device (`CON`, `LPT1`).
- They are relative to the root of the current drive; that is, they begin with a single component separator (`\`).
- They are relative to the current directory of a specified drive; that is, they begin with a drive letter, a volume separator, and no component separator (`C:\`).
- They are relative to the current directory; that is, they begin with anything else (`temp\testfile.txt`).

The type of the path determines whether or not a current directory is applied in some way. It also determines what the "root" of the path is.

Handle legacy devices

If the path is a legacy DOS device such as `CON`, `COM1`, or `LPT1`, it is converted into a device path by prepending `\?\.\` and returned.

A path that begins with a legacy device name is always interpreted as a legacy device by the [Path.GetFullPath\(String\)](#) method. For example, the DOS device path for `CON.TXT` is `\?\.\CON`, and the DOS device path for `COM1.TXT\file1.txt` is `\?\.\COM1`.

Apply the current directory

If a path isn't fully qualified, Windows applies the current directory to it. UNC paths and device paths do not have the current directory applied. Neither does a full drive with separator `C:\`.

If the path starts with a single component separator, the drive from the current directory is applied. For example, if the file path is `\utilities` and the current directory is `C:\temp\`, normalization produces `C:\utilities`.

If the path starts with a drive letter, volume separator, and no component separator, the last current directory set from the command shell for the specified drive is applied. If the last current directory was not set, the drive alone is applied. For example, if the file path is `D:sources`, the current directory is `C:\Documents\`, and the last current directory on drive D: was `D:\sources\`, the result is `D:\sources\sources`. These "drive relative" paths are a common source of program and script logic errors. Assuming that a path beginning with a letter and a colon isn't relative is obviously not correct.

If the path starts with something other than a separator, the current drive and current directory are applied. For example, if the path is `filecompare` and the current directory is `C:\utilities\`, the result is `C:\utilities\filecompare\`.

Important

Relative paths are dangerous in multithreaded applications (that is, most applications) because the current directory is a per-process setting. Any thread can change the current directory at any time. Starting with .NET Core 2.1, you can call the [Path.GetFullPath\(String, String\)](#) method to get an absolute path from a relative path and the base path (the current directory) that you want to resolve it against.

Canonicalize separators

All forward slashes (`/`) are converted into the standard Windows separator, the back slash (`\`). If they are present, a series of slashes that follow the first two slashes are collapsed into a single slash.

Evaluate relative components

As the path is processed, any components or segments that are composed of a single or a double period (`.` or `..`) are evaluated:

- For a single period, the current segment is removed, since it refers to the current directory.
- For a double period, the current segment and the parent segment are removed, since the double period refers to the parent directory.

Parent directories are only removed if they aren't past the root of the path. The root of the path depends on the type of path. It is the drive (`c:\`) for DOS paths, the server/share for UNC's (`\Server\Share`), and the device path prefix for device paths (`\?\` or `\\.\).`

Trim characters

Along with the runs of separators and relative segments removed earlier, some additional characters are removed during normalization:

- If a segment ends in a single period, that period is removed. (A segment of a single or double period is normalized in the previous step. A segment of three or more periods is not normalized and is actually a valid file/directory name.)
- If the path doesn't end in a separator, all trailing periods and spaces (U+0020) are removed. If the last segment is simply a single or double period, it falls under the relative components rule above.

This rule means that you can create a directory name with a trailing space by adding a trailing separator after the space.

Important

You should **never** create a directory or filename with a trailing space. Trailing spaces can make it difficult or impossible to access a directory, and applications commonly fail when attempting to handle directories or files whose names include trailing spaces.

Skip normalization

Normally, any path passed to a Windows API is (effectively) passed to the [GetFullPathName function](#) and normalized. There is one important exception: a device path that begins with a question mark instead of a period. Unless the path starts exactly with `\?\` (note the use of the canonical backslash), it is normalized.

Why would you want to skip normalization? There are three major reasons:

1. To get access to paths that are normally unavailable but are legal. A file or directory called `hidden.`, for example, is impossible to access in any other way.
2. To improve performance by skipping normalization if you've already normalized.
3. On .NET Framework only, to skip the `MAX_PATH` check for path length to allow for paths that are greater than 259 characters. Most APIs allow this, with some exceptions.

ⓘ Note

.NET Core and .NET 5+ handles long paths implicitly and does not perform a `MAX_PATH` check. The `MAX_PATH` check applies only to .NET Framework.

Skipping normalization and max path checks is the only difference between the two device path syntaxes; they are otherwise identical. Be careful with skipping normalization, since you can easily create paths that are difficult for "normal" applications to deal with.

Paths that start with `\?\` are still normalized if you explicitly pass them to the [GetFullPathName function](#).

You can pass paths of more than `MAX_PATH` characters to [GetFullPathName](#) without `\?\`. It supports arbitrary length paths up to the maximum string size that Windows can handle.

Case and the Windows file system

A peculiarity of the Windows file system that non-Windows users and developers find confusing is that path and directory names are case-insensitive. That is, directory and file names reflect the casing of the strings used when they are created. For example, the method call

C#

```
Directory.CreateDirectory("TeStDiReCtOrY");
```

creates a directory named `TeStDiReCtOrY`. If you rename a directory or file to change its case, the directory or file name reflects the case of the string used when you rename it. For example, the following code renames a file named `test.txt` to `Test.txt`:

C#

```
using System.IO;

class Example
{
    static void Main()
    {
        var fi = new FileInfo(@".\test.txt");
        fi.MoveTo(@".\Test.txt");
    }
}
```

However, directory and file name comparisons are case-insensitive. If you search for a file named "test.txt", .NET file system APIs ignore case in the comparison. "Test.txt", "TEST.TXT", "test.TXT", and any other combination of uppercase and lowercase letters will match "test.txt".

Common I/O Tasks

Article • 09/15/2021

The [System.IO](#) namespace provides several classes that allow for various actions, such as reading and writing, to be performed on files, directories, and streams. For more information, see [File and Stream I/O](#).

Common File Tasks

| To do this... | See the example in this topic... |
|------------------------------|--|
| Create a text file | File.CreateText method FileInfo.CreateText method File.Create method FileInfo.Create method |
| Write to a text file | How to: Write Text to a File How to: Write a Text File (C++/CLI) |
| Read from a text file | How to: Read Text from a File |
| Append text to a file | How to: Open and Append to a Log File File.AppendText method FileInfo.AppendText method |
| Rename or move a file | File.Move method FileInfo.MoveTo method |
| Delete a file | File.Delete method FileInfo.Delete method |
| Copy a file | File.Copy method FileInfo.CopyTo method |
| Get the size of a file | FileInfo.Length property |
| Get the attributes of a file | File.GetAttributes method |

| To do this... | See the example in this topic... |
|--|---|
| Set the attributes of a file | File.SetAttributes method |
| Determine whether a file exists | File.Exists method |
| Read from a binary file | How to: Read and Write to a Newly Created Data File |
| Write to a binary file | How to: Read and Write to a Newly Created Data File |
| Retrieve a file name extension | Path.GetExtension method |
| Retrieve the fully qualified path of a file | Path.GetFullPath method |
| Retrieve the file name and extension from a path | Path.GetFileName method |
| Change the extension of a file | Path.ChangeExtension method |

Common Directory Tasks

| To do this... | See the example in this topic... |
|--|---|
| Access a file in a special folder such as My Documents | How to: Write Text to a File |
| Create a directory | Directory.CreateDirectory method |
| | FileInfo.Directory property |
| Create a subdirectory | DirectoryInfo.CreateSubdirectory method |
| Rename or move a directory | Directory.Move method |
| | DirectoryInfo.MoveTo method |
| Copy a directory | How to: Copy Directories |
| Delete a directory | Directory.Delete method |
| | DirectoryInfo.Delete method |
| See the files and subdirectories in a directory | How to: Enumerate Directories and Files |
| Find the size of a directory | System.IO.Directory class |
| Determine whether a directory exists | Directory.Exists method |

How to: Copy directories

Article • 12/14/2022

This article demonstrates how to use I/O classes to synchronously copy the contents of a directory to another location.

For an example of asynchronous file copy, see [Asynchronous file I/O](#).

This example copies subdirectories by setting the `recursive` parameter of the `CopyDirectory` method to `true`. The `CopyDirectory` method recursively copies subdirectories by calling itself on each subdirectory until there are no more to copy.

Example

C#

```
using System.IO;

CopyDirectory(@".\", @".\copytest", true);

static void CopyDirectory(string sourceDir, string destinationDir, bool
recursive)
{
    // Get information about the source directory
    var dir = new DirectoryInfo(sourceDir);

    // Check if the source directory exists
    if (!dir.Exists)
        throw new DirectoryNotFoundException($"Source directory not found:
{dir.FullName}");

    // Cache directories before we start copying
    DirectoryInfo[] dirs = dir.GetDirectories();

    // Create the destination directory
    Directory.CreateDirectory(destinationDir);

    // Get the files in the source directory and copy to the destination
    // directory
    foreach (FileInfo file in dir.GetFiles())
    {
        string targetFilePath = Path.Combine(destinationDir, file.Name);
        file.CopyTo(targetFilePath);
    }

    // If recursive and copying subdirectories, recursively call this method
    if (recursive)
    {
```

```
        foreach ( DirectoryInfo subDir in dirs )
    {
        string newDestinationDir = Path.Combine(destinationDir,
subDir.Name);
        CopyDirectory(subDir.FullName, newDestinationDir, true);
    }
}
```

How to: Enumerate directories and files

Article • 09/15/2021

Enumerable collections provide better performance than arrays when you work with large collections of directories and files. To enumerate directories and files, use methods that return an enumerable collection of directory or file names, or their [DirectoryInfo](#), [FileInfo](#), or [FileSystemInfo](#) objects.

If you want to search and return only the names of directories or files, use the enumeration methods of the [Directory](#) class. If you want to search and return other properties of directories or files, use the [DirectoryInfo](#) and [FileSystemInfo](#) classes.

You can use enumerable collections from these methods as the [IEnumerable<T>](#) parameter for constructors of collection classes like [List<T>](#).

The following table summarizes the methods that return enumerable collections of files and directories:

| To search and return | Use method |
|--|--|
| Directory names | Directory.EnumerateDirectories |
| Directory information (DirectoryInfo) | DirectoryInfo.EnumerateDirectories |
| File names | Directory.EnumerateFiles |
| File information (FileInfo) | DirectoryInfo.EnumerateFiles |
| File system entry names | Directory.EnumerateFileSystemEntries |
| File system entry information (FileSystemInfo) | DirectoryInfo.EnumerateFileSystemInfos |
| Directory and file names | Directory.EnumerateFileSystemEntries |

ⓘ Note

Although you can immediately enumerate all the files in the subdirectories of a parent directory by using the [AllDirectories](#) option of the optional [SearchOption](#) enumeration, [UnauthorizedAccessException](#) errors may make the enumeration incomplete. You can catch these exceptions by first enumerating directories and then enumerating files.

Examples: Use the [Directory](#) class

The following example uses the [Directory.EnumerateDirectories\(String\)](#) method to get a list of the top-level directory names in a specified path.

```
C#  
  
using System;  
using System.Collections.Generic;  
using System.IO;  
  
class Program  
{  
    private static void Main(string[] args)  
    {  
        try  
        {  
            // Set a variable to the My Documents path.  
            string docPath =  
                Environment.GetFolderPath(Environment.SpecialFolder.MyDocuments);  
  
            List<string> dirs = new List<string>  
(Directory.EnumerateDirectories(docPath));  
  
            foreach (var dir in dirs)  
            {  
                Console.WriteLine($"  
{dir.Substring(dir.LastIndexOf(Path.DirectorySeparatorChar) + 1)}");  
            }  
            Console.WriteLine($"{dirs.Count} directories found.");  
        }  
        catch (UnauthorizedAccessException ex)  
        {  
            Console.WriteLine(ex.Message);  
        }  
        catch (PathTooLongException ex)  
        {  
            Console.WriteLine(ex.Message);  
        }  
    }  
}
```

The following example uses the [Directory.EnumerateFiles\(String, String, SearchOption\)](#) method to recursively enumerate all file names in a directory and subdirectories that match a certain pattern. It then reads each line of each file and displays the lines that contain a specified string, with their filenames and paths.

```
C#  
  
using System;  
using System.IO;  
using System.Linq;
```

```

class Program
{
    static void Main(string[] args)
    {
        try
        {
            // Set a variable to the My Documents path.
            string docPath =
                Environment.GetFolderPath(Environment.SpecialFolder.MyDocuments);

            var files = from file in Directory.EnumerateFiles(docPath,
                "*.txt", SearchOption.AllDirectories)
                from line in File.ReadLines(file)
                where line.Contains("Microsoft")
                select new
                {
                    File = file,
                    Line = line
                };

            foreach (var f in files)
            {
                Console.WriteLine($"{f.File}\t{f.Line}");
            }
            Console.WriteLine($"{files.Count()} files found.");
        }
        catch (UnauthorizedAccessException uAEx)
        {
            Console.WriteLine(uAEx.Message);
        }
        catch (PathTooLongException pathEx)
        {
            Console.WriteLine(pathEx.Message);
        }
    }
}

```

Examples: Use the DirectoryInfo class

The following example uses the [DirectoryInfo.EnumerateDirectories](#) method to list a collection of top-level directories whose [CreationTimeUtc](#) is earlier than a certain [DateTime](#) value.

C#

```

using System;
using System.IO;

namespace EnumDir
{

```

```

class Program
{
    static void Main(string[] args)
    {
        // Set a variable to the Documents path.
        string docPath =
Environment.GetFolderPath(Environment.SpecialFolder.MyDocuments);

        DirectoryInfo dirPrograms = new DirectoryInfo(docPath);
        DateTime StartOf2009 = new DateTime(2009, 01, 01);

        var dirs = from dir in dirPrograms.EnumerateDirectories()
                   where dir.CreationTimeUtc > StartOf2009
                   select new
        {
            ProgDir = dir,
        };

        foreach (var di in dirs)
        {
            Console.WriteLine($"{di.ProgDir.Name}");
        }
    }
}
// </Snippet1>

```

The following example uses the [DirectoryInfo.EnumerateFiles](#) method to list all files whose [Length](#) exceeds 10MB. This example first enumerates the top-level directories, to catch possible unauthorized access exceptions, and then enumerates the files.

C#

```

using System;
using System.IO;

class Program
{
    static void Main(string[] args)
    {
        // Set a variable to the My Documents path.
        string docPath =
Environment.GetFolderPath(Environment.SpecialFolder.MyDocuments);

        DirectoryInfo diTop = new DirectoryInfo(docPath);

        try
        {
            foreach (var fi in diTop.EnumerateFiles())
            {
                try
                {

```

```
// Display each file over 10 MB;
if (fi.Length > 10000000)
{
    Console.WriteLine(${fi.FullName}\t\t{fi.Length.ToString("N0")}");
}
catch (UnauthorizedAccessException unAuthTop)
{
    Console.WriteLine(${unAuthTop.Message});
}
}

foreach (var di in diTop.EnumerateDirectories("*"))
{
    try
    {
        foreach (var fi in di.EnumerateFiles("*",
SearchOption.AllDirectories))
        {
            try
            {
                // Display each file over 10 MB;
                if (fi.Length > 10000000)
                {
                    Console.WriteLine(${fi.FullName}\t\t{fi.Length.ToString("N0")});
                }
            }
            catch (UnauthorizedAccessException unAuthFile)
            {
                Console.WriteLine(${unAuthFile:
{unAuthFile.Message}});
            }
        }
    }
    catch (UnauthorizedAccessException unAuthSubDir)
    {
        Console.WriteLine(${unAuthSubDir:
{unAuthSubDir.Message}});
    }
}
}

catch (FileNotFoundException dirNotFound)
{
    Console.WriteLine(${dirNotFound.Message});
}
catch (UnauthorizedAccessException unAuthDir)
{
    Console.WriteLine(${unAuthDir: {unAuthDir.Message}});
}
catch (PathTooLongException longPath)
{
    Console.WriteLine(${longPath.Message});
}
```

```
    }  
}
```

How to: Read and write to a newly created data file

Article • 09/15/2021

The [System.IO.BinaryWriter](#) and [System.IO.BinaryReader](#) classes are used for writing and reading data other than character strings. The following example shows how to create an empty file stream, write data to it, and read data from it.

The example creates a data file called *Test.data* in the current directory, creates the associated [BinaryWriter](#) and [BinaryReader](#) objects, and uses the [BinaryWriter](#) object to write the integers 0 through 10 to *Test.data*, which leaves the file pointer at the end of the file. The [BinaryReader](#) object then sets the file pointer back to the origin and reads out the specified content.

ⓘ Note

If *Test.data* already exists in the current directory, an [IOException](#) exception is thrown. Use the file mode option [FileMode.Create](#) rather than [FileMode.CreateNew](#) to always create a new file without throwing an exception.

Example

C#

```
using System;
using System.IO;

class MyStream
{
    private const string FILE_NAME = "Test.data";

    public static void Main()
    {
        if (File.Exists(FILE_NAME))
        {
            Console.WriteLine($"{FILE_NAME} already exists!");
            return;
        }

        using (FileStream fs = new FileStream(FILE_NAME,
FileMode.CreateNew))
        {
            using (BinaryWriter w = new BinaryWriter(fs))

```

```

    {
        for (int i = 0; i < 11; i++)
        {
            w.Write(i);
        }
    }

    using (FileStream fs = new FileStream(FILE_NAME, FileMode.Open,
FileAccess.Read))
    {
        using (BinaryReader r = new BinaryReader(fs))
        {
            for (int i = 0; i < 11; i++)
            {
                Console.WriteLine(r.ReadInt32());
            }
        }
    }
}

// The example creates a file named "Test.data" and writes the integers 0
// through 10 to it in binary format.
// It then writes the contents of Test.data to the console with each integer
// on a separate line.

How to: Open and append to a log file

Article • 09/15/2021

[StreamWriter](#) and [StreamReader](#) write characters to and read characters from streams. The following code example opens the *log.txt* file for input, or creates it if it doesn't exist, and appends log information to the end of the file. The example then writes the contents of the file to standard output for display.

As an alternative to this example, you could store the information as a single string or string array, and use the [File.WriteAllText](#) or [File.WriteAllLines](#) method to achieve the same functionality.

ⓘ Note

Visual Basic users may choose to use the methods and properties provided by the [Log](#) class or [FileSystem](#) class for creating or writing to log files.

Example

C#

```
using System;
using System.IO;

class DirAppend
{
    public static void Main()
    {
        using (StreamWriter w = File.AppendText("log.txt"))
        {
            Log("Test1", w);
            Log("Test2", w);
        }

        using (StreamReader r = File.OpenText("log.txt"))
        {
            DumpLog(r);
        }
    }

    public static void Log(string logMessage, TextWriter w)
    {
        w.WriteLine("\r\nLog Entry : ");
        w.WriteLine($"{DateTime.Now.ToString("yyyy-MM-dd HH:mm:ss.fff")}");
        w.WriteLine($"{DateTime.Now.ToString("HH:mm:ss.fff")}");
        w.WriteLine(" :");
    }
}
```

```

        w.WriteLine($" :{logMessage}");
        w.WriteLine ("-----");
    }

    public static void DumpLog(StreamReader r)
    {
        string line;
        while ((line = r.ReadLine()) != null)
        {
            Console.WriteLine(line);
        }
    }
}

// The example creates a file named "log.txt" and writes the following lines
// to it,
// or appends them to the existing "log.txt" file:

// Log Entry : <current long time string> <current long date string>
// :
// :Test1
// ----

// Log Entry : <current long time string> <current long date string>
// :
// :Test2
// ----

// It then writes the contents of "log.txt" to the console.

How to: Write text to a file

Article • 12/14/2022

This article shows different ways to write text to a file for a .NET app.

The following classes and methods are typically used to write text to a file:

- [StreamWriter](#) contains methods to write to a file synchronously ([Write](#) and [WriteLine](#)) or asynchronously ([WriteAsync](#) and [WriteLineAsync](#)).
- [File](#) provides static methods to write text to a file such as [WriteAllLines](#) and [WriteAllText](#), or to append text to a file such as [AppendAllLines](#), [AppendAllText](#), and [AppendText](#).
- [Path](#) is for strings that have file or directory path information. It contains the [Combine](#) method and in .NET Core 2.1 and later, the [Join](#) and [TryJoin](#) methods. These methods let you concatenate strings for building a file or directory path.

ⓘ Note

The following examples show only the minimum amount of code needed. A real-world app usually provides more robust error checking and exception handling.

Example: Synchronously write text with StreamWriter

The following example shows how to use the [StreamWriter](#) class to synchronously write text to a new file one line at a time. Because the [StreamWriter](#) object is declared and instantiated in a `using` statement, the [Dispose](#) method is invoked, which automatically flushes and closes the stream.

C#

```
using System;
using System.IO;

class Program
{
    static void Main(string[] args)
    {

        // Create a string array with the lines of text
        string[] lines = { "First line", "Second line", "Third line" };
    }
}
```

```

// Set a variable to the Documents path.
string docPath =
    Environment.GetFolderPath(Environment.SpecialFolder.MyDocuments);

// Write the string array to a new file named "WriteLines.txt".
using (StreamWriter outputFile = new
StreamWriter(Path.Combine(docPath, "WriteLines.txt")))
{
    foreach (string line in lines)
        outputFile.WriteLine(line);
}
}

// The example creates a file named "WriteLines.txt" with the following
contents:
// First line
// Second line
// Third line

```

Example: Synchronously append text with StreamWriter

The following example shows how to use the [StreamWriter](#) class to synchronously append text to the text file created in the first example:

C#

```

using System;
using System.IO;

class Program
{
    static void Main(string[] args)
    {

        // Set a variable to the Documents path.
        string docPath =
Environment.GetFolderPath(Environment.SpecialFolder.MyDocuments);

        // Append text to an existing file named "WriteLines.txt".
        using (StreamWriter outputFile = new
StreamWriter(Path.Combine(docPath, "WriteLines.txt"), true))
        {
            outputFile.WriteLine("Fourth Line");
        }
    }
}

```

```
// The example adds the following line to the contents of "WriteLines.txt":  
// Fourth Line
```

Example: Asynchronously write text with StreamWriter

The following example shows how to asynchronously write text to a new file using the [StreamWriter](#) class. To invoke the [WriteAsync](#) method, the method call must be within an `async` method.

C#

```
using System;  
using System.IO;  
using System.Threading.Tasks;  
  
class Program  
{  
    static async Task Main()  
    {  
        // Set a variable to the Documents path.  
        string docPath =  
Environment.GetFolderPath(Environment.SpecialFolder.MyDocuments);  
  
        // Write the specified text asynchronously to a new file named  
        // "WriteTextAsync.txt".  
        using (StreamWriter outputFile = new  
StreamWriter(Path.Combine(docPath, "WriteTextAsync.txt")))  
        {  
            await outputFile.WriteAsync("This is a sentence.");  
        }  
    }  
    // The example creates a file named "WriteTextAsync.txt" with the following  
    // contents:  
    // This is a sentence.
```

Example: Write and append text with the File class

The following example shows how to write text to a new file and append new lines of text to the same file using the [File](#) class. The [WriteAllText](#) and [AppendAllLines](#) methods open and close the file automatically. If the path you provide to the [WriteAllText](#) method already exists, the file is overwritten.

C#

```
using System;
using System.IO;

class Program
{
    static void Main(string[] args)
    {
        // Create a string with a line of text.
        string text = "First line" + Environment.NewLine;

        // Set a variable to the Documents path.
        string docPath =
Environment.GetFolderPath(Environment.SpecialFolder.MyDocuments);

        // Write the text to a new file named "WriteFile.txt".
        File.WriteAllText(Path.Combine(docPath, "WriteFile.txt"), text);

        // Create a string array with the additional lines of text
        string[] lines = { "New line 1", "New line 2" };

        // Append new lines of text to the file
        File.AppendAllLines(Path.Combine(docPath, "WriteFile.txt"), lines);
    }
}

// The example creates a file named "WriteFile.txt" with the contents:
// First line
// And then appends the following contents:
// New line 1
// New line 2
```

How to: Read text from a file

Article • 10/04/2022

The following examples show how to read text synchronously and asynchronously from a text file using .NET for desktop apps. In both examples, when you create the instance of the [StreamReader](#) class, you provide the relative or absolute path to the file.

ⓘ Note

These code examples don't apply to Universal Windows (UWP) apps because the Windows runtime provides different stream types for reading and writing to files. For an example that shows how to read text from a file in a UWP app, see [Quickstart: Reading and writing files](#). For examples that show how to convert between .NET Framework streams and Windows Runtime streams, see [How to: Convert between .NET Framework streams and Windows Runtime streams](#).

Example: Synchronous read in a console app

The following example shows a synchronous read operation within a console app. This example opens the text file using a stream reader, copies the contents to a string, and outputs the string to the console.

ⓘ Important

The example assumes that a file named *TestFile.txt* already exists in the same folder as the app.

C#

```
using System;
using System.IO;

class Program
{
    public static void Main()
    {
        try
        {
            // Open the text file using a stream reader.
            using (var sr = new StreamReader("TestFile.txt"))
            {
                // Read the stream as a string, and write the string to the
                // console.
                string contents = sr.ReadToEnd();
                Console.WriteLine(contents);
            }
        }
    }
}
```

```
        Console.WriteLine(sr.ReadToEnd());
    }
}
catch (IOException e)
{
    Console.WriteLine("The file could not be read:");
    Console.WriteLine(e.Message);
}
}
}
```

Example: Asynchronous read in a WPF app

The following example shows an asynchronous read operation in a Windows Presentation Foundation (WPF) app.

ⓘ Important

The example assumes that a file named *TestFile.txt* already exists in the same folder as the app.

C#

```
using System.IO;
using System.Windows;

namespace TextFiles;

/// <summary>
/// Interaction logic for MainWindow.xaml
/// </summary>
public partial class MainWindow : Window
{
    public MainWindow() => InitializeComponent();

    private async void MainWindow_Loaded(object sender, RoutedEventArgs e)
    {
        try
        {
            using (var sr = new StreamReader("TestFile.txt"))
            {
                ResultBlock.Text = await sr.ReadToEndAsync();
            }
        }
        catch (FileNotFoundException ex)
        {
            ResultBlock.Text = ex.Message;
        }
    }
}
```

```
    }  
}
```

How to: Read characters from a string

Article • 09/15/2021

The following code examples show how to read characters synchronously or asynchronously from a string.

Example: Read characters synchronously

This example reads 13 characters synchronously from a string, stores them in an array, and displays them. The example then reads the rest of the characters in the string, stores them in the array starting at the sixth element, and displays the contents of the array.

C#

```
using System;
using System.IO;

public class CharsFromStr
{
    public static void Main()
    {
        string str = "Some number of characters";
        char[] b = new char[str.Length];

        using (StringReader sr = new StringReader(str))
        {
            // Read 13 characters from the string into the array.
            sr.Read(b, 0, 13);
            Console.WriteLine(b);

            // Read the rest of the string starting at the current string
            position.
            // Put in the array starting at the 6th array member.
            sr.Read(b, 5, str.Length - 13);
            Console.WriteLine(b);
        }
    }
}

// The example has the following output:
//
// Some number o
// Some f characters
```

Example: Read characters asynchronously

The next example is the code behind a WPF app. On window load, the example asynchronously reads all characters from a [TextBox](#) control and stores them in an array. It then asynchronously writes each letter or white-space character to a separate line of a [TextBlock](#) control.

C#

```
using System;
using System.Text;
using System.Windows;
using System.IO;

namespace StringReaderWriter
{
    /// <summary>
    /// Interaction logic for MainWindow.xaml
    /// </summary>
    public partial class MainWindow : Window
    {
        public MainWindow()
        {
            InitializeComponent();
        }

        private async void Window_Loaded(object sender, RoutedEventArgs e)
        {
            char[] charsRead = new char[UserInput.Text.Length];
            using (StringReader reader = new StringReader(UserInput.Text))
            {
                await reader.ReadAsync(charsRead, 0, UserInput.Text.Length);
            }

            StringBuilder reformattedText = new StringBuilder();
            using (StringWriter writer = new StringWriter(reformattedText))
            {
                foreach (char c in charsRead)
                {
                    if (char.IsLetter(c) || char.IsWhiteSpace(c))
                    {
                        await writer.WriteLineAsync(char.ToLower(c));
                    }
                }
            }
            Result.Text = reformattedText.ToString();
        }
    }
}
```

How to: Write characters to a string

Article • 09/15/2021

The following code examples write characters synchronously or asynchronously from a character array into a string.

Example: Write characters synchronously in a console app

The following example uses a [StringWriter](#) to write five characters synchronously to a [StringBuilder](#) object.

C#

```
using System;
using System.IO;
using System.Text;

public class CharsToStr
{
    public static void Main()
    {
        StringBuilder sb = new StringBuilder("Start with a string and add
from ");
        char[] b = { 'c', 'h', 'a', 'r', '.', ' ', 'B', 'u', 't', ' ', 'n',
'o', 't', ' ', 'a', 'l', 'l' };

        using (StringWriter sw = new StringWriter(sb))
        {
            // Write five characters from the array into the StringBuilder.
            sw.Write(b, 0, 5);
            Console.WriteLine(sb);
        }
    }
}

// The example has the following output:
//
// Start with a string and add from char.
```

Example: Write characters asynchronously in a WPF app

The next example is the code behind a WPF app. On window load, the example asynchronously reads all characters from a [TextBox](#) control and stores them in an array. It then asynchronously writes each letter or white-space character to a separate line of a [TextBlock](#) control.

C#

```
using System;
using System.Text;
using System.Windows;
using System.IO;

namespace StringReaderWriter
{
    /// <summary>
    /// Interaction logic for MainWindow.xaml
    /// </summary>
    public partial class MainWindow : Window
    {
        public MainWindow()
        {
            InitializeComponent();
        }

        private async void Window_Loaded(object sender, RoutedEventArgs e)
        {
            char[] charsRead = new char[UserInput.Text.Length];
            using (StringReader reader = new StringReader(UserInput.Text))
            {
                await reader.ReadAsync(charsRead, 0, UserInput.Text.Length);
            }

            StringBuilder reformattedText = new StringBuilder();
            using (StringWriter writer = new StringWriter(reformattedText))
            {
                foreach (char c in charsRead)
                {
                    if (char.IsLetter(c) || char.IsWhiteSpace(c))
                    {
                        await writer.WriteLineAsync(char.ToLower(c));
                    }
                }
            }
            Result.Text = reformattedText.ToString();
        }
    }
}
```

How to: Add or remove Access Control List entries (.NET Framework only)

Article • 09/15/2021

To add or remove Access Control List (ACL) entries to or from a file or directory, get the [FileSecurity](#) or [DirectorySecurity](#) object from the file or directory. Modify the object, and then apply it back to the file or directory.

Add or remove an ACL entry from a file

1. Call the [File.GetAccessControl](#) method to get a [FileSecurity](#) object that contains the current ACL entries of a file.
2. Add or remove ACL entries from the [FileSecurity](#) object returned from step 1.
3. To apply the changes, pass the [FileSecurity](#) object to the [File.SetAccessControl](#) method.

Add or remove an ACL entry from a directory

1. Call the [Directory.GetAccessControl](#) method to get a [DirectorySecurity](#) object that contains the current ACL entries of a directory.
2. Add or remove ACL entries from the [DirectorySecurity](#) object returned from step 1.
3. To apply the changes, pass the [DirectorySecurity](#) object to the [Directory.SetAccessControl](#) method.

Example

You must use a valid user or group account to run this example. The example uses a [File](#) object. Use the same procedure for the [FileInfo](#), [Directory](#), and [DirectoryInfo](#) classes.

C#

```
using System;
using System.IO;
using System.Security.AccessControl;

namespace FileSystemExample
{
    class FileExample
```

```
{  
    public static void Main()  
    {  
        try  
        {  
            string fileName = "test.xml";  
  
            Console.WriteLine("Adding access control entry for "  
                + fileName);  
  
            // Add the access control entry to the file.  
            AddFileSecurity(fileName, @"DomainName\AccountName",  
                FileSystemRights.ReadData, AccessControlType.Allow);  
  
            Console.WriteLine("Removing access control entry from "  
                + fileName);  
  
            // Remove the access control entry from the file.  
            RemoveFileSecurity(fileName, @"DomainName\AccountName",  
                FileSystemRights.ReadData, AccessControlType.Allow);  
  
            Console.WriteLine("Done.");  
        }  
        catch (Exception e)  
        {  
            Console.WriteLine(e);  
        }  
    }  
  
    // Adds an ACL entry on the specified file for the specified  
    account.  
    public static void AddFileSecurity(string fileName, string account,  
        FileSystemRights rights, AccessControlType controlType)  
    {  
  
        // Get a FileSecurity object that represents the  
        // current security settings.  
        FileSecurity fSecurity = File.GetAccessControl(fileName);  
  
        // Add the FileSystemAccessRule to the security settings.  
        fSecurity.AddAccessRule(new FileSystemAccessRule(account,  
            rights, controlType));  
  
        // Set the new access settings.  
        File.SetAccessControl(fileName, fSecurity);  
    }  
  
    // Removes an ACL entry on the specified file for the specified  
    account.  
    public static void RemoveFileSecurity(string fileName, string  
account,  
        FileSystemRights rights, AccessControlType controlType)  
    {  
  
        // Get a FileSecurity object that represents the
```

```
// current security settings.  
FileSecurity fSecurity = File.GetAccessControl(fileName);  
  
// Remove the FileSystemAccessRule from the security settings.  
fSecurity.RemoveAccessRule(new FileSystemAccessRule(account,  
    rights, controlType));  
  
// Set the new access settings.  
File.SetAccessControl(fileName, fSecurity);  
}  
}  
}
```

How to: Compress and extract files

Article • 08/12/2022

The [System.IO.Compression](#) namespace contains the following classes for compressing and decompressing files and streams. You also can use these types to read and modify the contents of a compressed file:

- [ZipFile](#)
- [ZipArchive](#)
- [ZipArchiveEntry](#)
- [DeflateStream](#)
- [GZipStream](#)

The following examples show some of the operations you can perform with compressed files. These examples require the following NuGet packages to be added to your project:

- [System.IO.Compression](#) ↗
- [System.IO.Compression.ZipFile](#) ↗

If you're using .NET Framework, add references to these two libraries to your project:

- `System.IO.Compression`
- `System.IO.Compression.FileSystem`

Example 1: Create and extract a .zip file

The following example shows how to create and extract a compressed `.zip` file by using the [ZipFile](#) class. The example compresses the contents of a folder into a new `.zip` file, and then extracts the file to a new folder.

To run the sample, create a *start* folder in your program folder and populate it with files to zip.

C#

```
using System;
using System.IO.Compression;

class Program
{
    static void Main(string[] args)
    {
        string startPath = @".\start";
        string zipPath = @".\result.zip";
```

```
        string extractPath = @".\extract";

        ZipFile.CreateDirectory(startPath, zipPath);

        ZipFile.ExtractToDirectory(zipPath, extractPath);
    }
}
```

Example 2: Extract specific file extensions

The following example iterates through the contents of an existing `.zip` file and extracts files with a `.txt` extension. It uses the [ZipArchive](#) class to access the `.zip` file, and the [ZipArchiveEntry](#) class to inspect the individual entries. The extension method [ExtractToFile](#) for the [ZipArchiveEntry](#) object is available in the [System.IO.Compression.ZipFileExtensions](#) class.

To run the sample, place a `.zip` file called `result.zip` in your program folder. When prompted, provide a folder name to extract to.

ⓘ Important

When unzipping files, you must look for malicious file paths, which can escape from the directory you unzip into. This is known as a path traversal attack. The following example demonstrates how to check for malicious file paths and provides a safe way to unzip.

C#

```
using System;
using System.IO;
using System.IO.Compression;

class Program
{
    static void Main(string[] args)
    {
        string zipPath = @".\result.zip";

        Console.WriteLine("Provide path where to extract the zip file:");
        string extractPath = Console.ReadLine();

        // Normalizes the path.
        extractPath = Path.GetFullPath(extractPath);

        // Ensures that the last character on the extraction path
        // is the directory separator char.
```

```

        // Without this, a malicious zip file could try to traverse outside
        // of the expected
        // extraction path.
        if (!extractPath.EndsWith(Path.DirectorySeparatorChar.ToString(),
StringComparison.OrdinalIgnoreCase))
            extractPath += Path.DirectorySeparatorChar;

        using (ZipArchive archive = ZipFile.OpenRead(zipPath))
        {
            foreach (ZipArchiveEntry entry in archive.Entries)
            {
                if (entry.FullName.EndsWith(".txt",
StringComparison.OrdinalIgnoreCase))
                {
                    // Gets the full path to ensure that relative segments
                    // are removed.
                    string destinationPath =
Path.GetFullPath(Path.Combine(extractPath, entry.FullName));

                    // Ordinal match is safest, case-sensitive volumes can
                    // be mounted within volumes that
                    // are case-insensitive.
                    if (destinationPath.StartsWith(extractPath,
StringComparison.OrdinalIgnoreCase))
                        entry.ExtractToFile(destinationPath);
                }
            }
        }
    }
}

```

Example 3: Add a file to an existing .zip file

The following example uses the [ZipArchive](#) class to access an existing .zip file, and adds a file to it. The new file gets compressed when you add it to the existing .zip file.

C#

```

using System;
using System.IO;
using System.IO.Compression;

namespace ConsoleApplication
{
    class Program
    {
        static void Main(string[] args)
        {
            using (FileStream zipToOpen = new
FileStream(@"c:\users\exampleuser\release.zip", FileMode.Open))
            {

```

```

        using (ZipArchive archive = new ZipArchive(zipToOpen,
ZipArchiveMode.Update))
        {
            ZipArchiveEntry readmeEntry =
archive.CreateEntry("Readme.txt");
            using (StreamWriter writer = new
StreamWriter(readmeEntry.Open()))
            {
                writer.WriteLine("Information about this
package.");
                writer.WriteLine("=====");
            }
        }
    }
}

```

Example 4: Compress and decompress .gz files

You can also use the [GZipStream](#) and [DeflateStream](#) classes to compress and decompress data. They use the same compression algorithm. You can decompress [GZipStream](#) objects that are written to a .gz file by using many common tools. The following example shows how to compress and decompress a directory of files by using the [GZipStream](#) class:

C#

```

using System;
using System.IO;
using System.IO.Compression;

public class Program
{
    private static string directoryPath = @"..\temp";
    public static void Main()
    {
        DirectoryInfo directorySelected = new DirectoryInfo(directoryPath);
        Compress(directorySelected);

        foreach (FileInfo fileToDecompress in
directorySelected.GetFiles("*.gz"))
        {
            Decompress(fileToDecompress);
        }
    }

    public static void Compress(DirectoryInfo directorySelected)
    {
        foreach (FileInfo fileToCompress in directorySelected.GetFiles())
        {
            fileToCompress.Compress();
        }
    }

    public static void Decompress(FileInfo fileToDecompress)
    {
        fileToDecompress.Decompress();
    }
}

```

```

    {
        using (FileStream originalFileStream =
fileToCompress.OpenRead())
        {
            if ((File.GetAttributes(fileToCompress.FullName) &
                FileAttributes.Hidden) != FileAttributes.Hidden &
fileToCompress.Extension != ".gz")
            {
                using (FileStream compressedFileStream =
File.Create(fileToCompress.FullName + ".gz"))
                {
                    using (GZipStream compressionStream = new
GZipStream(compressedFileStream,
                        CompressionMode.Compress))
                    {
                        originalFileStream.CopyTo(compressionStream);
                    }
                }
                FileInfo info = new FileInfo(directoryPath +
Path.DirectorySeparatorChar + fileToCompress.Name + ".gz");
                Console.WriteLine($"Compressed {fileToCompress.Name}
from {fileToCompress.Length.ToString()} to {info.Length.ToString()}
bytes.");
            }
        }
    }

    public static void Decompress(FileInfo fileToDecompress)
{
    using (FileStream originalFileStream = fileToDecompress.OpenRead())
    {
        string currentFileName = fileToDecompress.FullName;
        string newFileName =
currentFileName.Remove(currentFileName.Length -
fileToDecompress.Extension.Length);

        using (FileStream decompressedFileStream =
File.Create(newFileName))
        {
            using (GZipStream decompressionStream = new
GZipStream(originalFileStream, CompressionMode.Decompress))
            {
                decompressionStream.CopyTo(decompressedFileStream);
                Console.WriteLine($"Decompressed:
{fileToDecompress.Name}");
            }
        }
    }
}
}

```

Compose streams

Article • 09/15/2021

A *backing store* is a storage medium, such as a disk or memory. Each different backing store implements its own stream as an implementation of the [Stream](#) class.

Each stream type reads and writes bytes from and to its given backing store. Streams that connect to backing stores are called *base streams*. Base streams have constructors with the parameters necessary to connect the stream to the backing store. For example, [FileStream](#) has constructors that specify a path parameter, which specifies how the file will be shared by processes.

The design of the [System.IO](#) classes provides simplified stream composition. You can attach base streams to one or more pass-through streams that provide the functionality you want. You can attach a reader or writer to the end of the chain, so the preferred types can be read or written easily.

The following code examples create a [FileStream](#) around the existing *MyFile.txt* in order to buffer *MyFile.txt*. Note that [FileStreams](#) are buffered by default.

ⓘ Important

The examples assume that a file named *MyFile.txt* already exists in the same folder as the app.

Example: Use StreamReader

The following example creates a [StreamReader](#) to read characters from the [FileStream](#), which is passed to the [StreamReader](#) as its constructor argument.

[StreamReader.ReadLine](#) then reads until [StreamReader.Peek](#) finds no more characters.

C#

```
using System;
using System.IO;

public class CompBuf
{
    private const string FILE_NAME = "MyFile.txt";

    public static void Main()
    {
        if (!File.Exists(FILE_NAME))

```

```
        {
            Console.WriteLine($"{FILE_NAME} does not exist!");
            return;
        }
        // Create an instance of StreamReader characters from the file.
        using (StreamReader sr = new StreamReader(FILE_NAME))
        {
            string input;
            // While not at the end of the file, read lines from the file.
            while (sr.Peek() > -1)
            {
                input = sr.ReadLine();
                Console.WriteLine(input);
            }
        }
    }
}
```

Example: Use BinaryReader

The following example creates a [BinaryReader](#) to read bytes from the [FileStream](#), which is passed to the [BinaryReader](#) as its constructor argument. [ReadByte](#) then reads until [PeekChar](#) finds no more bytes.

C#

```
using System;
using System.IO;

public class ReadBuf
{
    private const string FILE_NAME = "MyFile.txt";

    public static void Main()
    {
        if (!File.Exists(FILE_NAME))
        {
            Console.WriteLine($"{FILE_NAME} does not exist.");
            return;
        }
        using (FileStream f = new FileStream(FILE_NAME, FileMode.Open,
FileAccess.Read, FileShare.Read))
        {
            // Create an instance of BinaryReader that can
            // read bytes from the FileStream.
            using (BinaryReader br = new BinaryReader(f))
            {
                byte input;
                // While not at the end of the file, read lines from the
file.
                while (br.PeekChar() > -1)
```

```
        input = br.ReadByte();
        Console.WriteLine(input);
    }
}
}
```

How to: Convert between .NET Framework and Windows Runtime streams (Windows only)

Article • 03/28/2023

.NET Framework for UWP apps is a subset of the full .NET Framework. Because of security and other requirements for UWP apps, you can't use the full set of .NET Framework APIs to open and read files. For more information, see [.NET for UWP apps overview](#). However, you may want to use .NET Framework APIs for other stream manipulation operations. To manipulate these streams, you can convert between a .NET Framework stream type, such as [MemoryStream](#) or [FileStream](#), and a Windows Runtime stream, such as [IInputStream](#), [IOOutputStream](#), or [IRandomAccessStream](#).

The [System.IO.WindowsRuntimeStreamExtensions](#) class contains methods that make these conversions easy. However, underlying differences between .NET Framework and Windows Runtime streams affect the results of using these methods, as described in the following sections:

Convert from a Windows Runtime to a .NET Framework stream

To convert from a Windows Runtime stream to a .NET Framework stream, use one of the following [System.IO.WindowsRuntimeStreamExtensions](#) methods:

- [WindowsRuntimeStreamExtensionsAsStream](#) converts a random-access stream in the Windows Runtime to a managed stream in .NET for UWP apps.
- [WindowsRuntimeStreamExtensionsAsStreamForWrite](#) converts an output stream in the Windows Runtime to a managed stream in .NET for UWP apps.
- [WindowsRuntimeStreamExtensionsAsStreamForRead](#) converts an input stream in the Windows Runtime to a managed stream in .NET for UWP apps.

The Windows Runtime offers stream types that support reading only, writing only, or reading and writing. These capabilities are maintained when you convert a Windows Runtime stream to a .NET Framework stream. Furthermore, if you convert a Windows Runtime stream to a .NET Framework stream and back, you get the original Windows Runtime instance back.

It's best practice to use the conversion method that matches the capabilities of the Windows Runtime stream you want to convert. However, since [IRandomAccessStream](#) is readable and writeable (it implements both [IOutputStream](#) and [IInputStream](#)), the conversion methods maintain the capabilities of the original stream. For example, using [WindowsRuntimeStreamExtensions.AsStreamForRead](#) to convert an [IRandomAccessStream](#) doesn't limit the converted .NET Framework stream to being readable. It's also writable.

Example: Convert Windows Runtime random-access to .NET Framework stream

To convert from a Windows Runtime random-access stream to a .NET Framework stream, use the [WindowsRuntimeStreamExtensionsAsStream](#) method.

The following code example prompts you to select a file, opens it with Windows Runtime APIs, and then converts it to a .NET Framework stream. It reads the stream and outputs it to a text block. You would typically manipulate the stream with .NET Framework APIs before outputting the results.

C#

```
// Create a file picker.
FileOpenPicker picker = new FileOpenPicker();
picker.SuggestedStartLocation = PickerLocationId.DocumentsLibrary;
picker.ViewMode = PickerViewMode.List;
picker.FileTypeFilter.Add(".txt");

// Show picker, enabling user to pick one file.
StorageFile result = await picker.PickSingleFileAsync();
if (result != null)
{
    try
    {
        // Retrieve the stream. This method returns a
        IRandomAccessStreamWithContentType.
        var stream = await result.OpenReadAsync();

        // Convert the stream to a .NET stream using AsStream, pass to a
        // StreamReader and read the stream.
        using (StreamReader sr = new StreamReader(streamAsStream()))
        {
            TextBlock1.Text = sr.ReadToEnd();
        }
    }
    catch (Exception ex)
    {
        // ...
    }
}
```

```
    }  
}
```

Convert from a .NET Framework to a Windows Runtime stream

To convert from a .NET Framework stream to a Windows Runtime stream, use one of the following [System.IO.WindowsRuntimeStreamExtensions](#) methods:

- [WindowsRuntimeStreamExtensions.AsInputStream](#) converts a managed stream in .NET for UWP apps to an input stream in the Windows Runtime.
- [WindowsRuntimeStreamExtensions.AsOutputStream](#) converts a managed stream in .NET for UWP apps to an output stream in the Windows Runtime.
- [WindowsRuntimeStreamExtensions.AsRandomAccessStream](#) converts a managed stream in .NET for UWP apps to a random-access stream that the Windows Runtime can use for reading or writing.

When you convert a .NET Framework stream to a Windows Runtime stream, the capabilities of the converted stream depend on the original stream. For example, if the original stream supports both reading and writing, and you call [WindowsRuntimeStreamExtensions.AsInputStream](#) to convert the stream, the returned type is an `IRandomAccessStream`. `IRandomAccessStream` implements `IInputStream` and `IOutputStream`, and supports reading and writing.

.NET Framework streams don't support cloning, even after conversion. If you convert a .NET Framework stream to a Windows Runtime stream and call [GetInputStreamAt](#) or [GetOutputStreamAt](#), which call [CloneStream](#), or if you call [CloneStream](#) directly, an exception occurs.

Example: Convert .NET Framework to Windows Runtime random-access stream

To convert from a .NET Framework stream to a Windows Runtime random-access stream, use the [AsRandomAccessStream](#) method, as shown in the following example:

 **Important**

Make sure that the .NET Framework stream you are using supports seeking, or copy it to a stream that does. You can use the `Stream.CanSeek` property to determine this.

C#

```
// Create an HttpClient and access an image as a stream.  
var client = new HttpClient();  
Stream stream = await client.GetStreamAsync("https://learn.microsoft.com/en-us/dotnet/images/hub/featured-1.png");  
// Create a .NET memory stream.  
var memStream = new MemoryStream();  
// Convert the stream to the memory stream, because a memory stream supports seeking.  
await stream.CopyToAsync(memStream);  
// Set the start position.  
memStream.Position = 0;  
// Create a new bitmap image.  
var bitmap = new BitmapImage();  
// Set the bitmap source to the stream, which is converted to a IRandomAccessStream.  
bitmap.SetSource(memStream.AsRandomAccessStream());  
// Set the image control source to the bitmap.  
Image1.Source = bitmap;
```

Asynchronous File I/O

Article • 02/13/2023

Asynchronous operations enable you to perform resource-intensive I/O operations without blocking the main thread. This performance consideration is particularly important in a Windows 8.x Store app or desktop app where a time-consuming stream operation can block the UI thread and make your app appear as if it is not working.

Starting with .NET Framework 4.5, the I/O types include `async` methods to simplify asynchronous operations. An `async` method contains `Async` in its name, such as [ReadAsync](#), [WriteAsync](#), [CopyToAsync](#), [FlushAsync](#), [ReadLineAsync](#), and [ReadToEndAsync](#). These `async` methods are implemented on stream classes, such as [Stream](#), [FileStream](#), and [MemoryStream](#), and on classes that are used for reading from or writing to streams, such [TextReader](#) and [TextWriter](#).

In .NET Framework 4 and earlier versions, you have to use methods such as [BeginRead](#) and [EndRead](#) to implement asynchronous I/O operations. These methods are still available in current .NET versions to support legacy code; however, the `async` methods help you implement asynchronous I/O operations more easily.

C# and Visual Basic each have two keywords for asynchronous programming:

- `Async` (Visual Basic) or `async` (C#) modifier, which is used to mark a method that contains an asynchronous operation.
- `Await` (Visual Basic) or `await` (C#) operator, which is applied to the result of an `async` method.

To implement asynchronous I/O operations, use these keywords in conjunction with the `async` methods, as shown in the following examples. For more information, see [Asynchronous programming with async and await \(C#\)](#) or [Asynchronous Programming with Async and Await \(Visual Basic\)](#).

The following example demonstrates how to use two [FileStream](#) objects to copy files asynchronously from one directory to another. Notice that the [Click](#) event handler for the [Button](#) control is marked with the `async` modifier because it calls an asynchronous method.

C#

```
using System;
using System.Threading.Tasks;
using System.Windows;
```

```

using System.IO;

namespace WpfApplication
{
    public partial class MainWindow : Window
    {
        public MainWindow()
        {
            InitializeComponent();
        }

        private async void Button_Click(object sender, RoutedEventArgs e)
        {
            string startDirectory = @"c:\Users\exampleuser\start";
            string endDirectory = @"c:\Users\exampleuser\end";

            foreach (string filename in
Directory.EnumerateFiles(startDirectory))
            {
                using (FileStream sourceStream = File.Open(filename,
 FileMode.Open))
                {
                    using (FileStream destinationStream =
File.Create(Path.Combine(endDirectory, Path.GetFileName(filename))))
                    {
                        await sourceStream.CopyToAsync(destinationStream);
                    }
                }
            }
        }
    }
}

```

The next example is similar to the previous one but uses [StreamReader](#) and [StreamWriter](#) objects to read and write the contents of a text file asynchronously.

C#

```

private async void Button_Click(object sender, RoutedEventArgs e)
{
    string UserDirectory = @"c:\Users\exampleuser\";

    using (StreamReader SourceReader = File.OpenText(UserDirectory +
"BigFile.txt"))
    {
        using (StreamWriter DestinationWriter =
File.CreateText(UserDirectory + "CopiedFile.txt"))
        {
            await CopyFilesAsync(SourceReader, DestinationWriter);
        }
    }
}

```

```
public async Task CopyFilesAsync(StreamReader Source, StreamWriter Destination)
{
    char[] buffer = new char[0x1000];
    int numRead;
    while ((numRead = await Source.ReadAsync(buffer, 0, buffer.Length)) != 0)
    {
        await Destination.WriteAsync(buffer, 0, numRead);
    }
}
```

The next example shows the code-behind file and the XAML file that are used to open a file as a [Stream](#) in a Windows 8.x Store app, and read its contents by using an instance of the [StreamReader](#) class. It uses asynchronous methods to open the file as a stream and to read its contents.

C#

```
using System;
using System.IO;
using System.Text;
using Windows.Storage.Pickers;
using Windows.Storage;
using Windows.UI.Xaml;
using Windows.UI.Xaml.Controls;

namespace ExampleApplication
{
    public sealed partial class BlankPage : Page
    {
        public BlankPage()
        {
            this.InitializeComponent();
        }

        private async void Button_Click_1(object sender, RoutedEventArgs e)
        {
            StringBuilder contents = new StringBuilder();
            string nextLine;
            int lineCounter = 1;

            var openPicker = new FileOpenPicker();
            openPicker.SuggestedStartLocation =
PickerLocationId.DocumentsLibrary;
            openPicker.FileTypeFilter.Add(".txt");
            StorageFile selectedFile = await
openPicker.PickSingleFileAsync();

            using (StreamReader reader = new StreamReader(await
selectedFile.OpenStreamForReadAsync()))
            {
```

```

        while ((nextLine = await reader.ReadLineAsync()) != null)
        {
            contents.AppendFormat("{0}. ", lineCounter);
            contents.Append(nextLine);
            contents.AppendLine();
            lineCounter++;
            if (lineCounter > 3)
            {
                contents.AppendLine("Only first 3 lines shown.");
                break;
            }
        }
        DisplayContentsBlock.Text = contents.ToString();
    }
}

```

XAML

```

<Page
    x:Class="ExampleApplication.BlankPage"
    xmlns="http://schemas.microsoft.com/winfx/2006/xaml/presentation"
    xmlns:x="http://schemas.microsoft.com/winfx/2006/xaml"
    xmlns:local="using:ExampleApplication"
    xmlns:d="http://schemas.microsoft.com/expression/blend/2008"
    xmlns:mc="http://schemas.openxmlformats.org/markup-compatibility/2006"
    mc:Ignorable="d">

    <StackPanel Background="{StaticResource ApplicationPageBackgroundBrush}"
    VerticalAlignment="Center" HorizontalAlignment="Center">
        <TextBlock Text="Display lines from a file."></TextBlock>
        <Button Content="Load File" Click="Button_Click_1"></Button>
        <TextBlock Name="DisplayContentsBlock"></TextBlock>
    </StackPanel>
</Page>

```

Handling I/O errors in .NET

Article • 09/15/2021

In addition to the exceptions that can be thrown in any method call (such as an [OutOfMemoryException](#) when a system is stressed or an [NullReferenceException](#) due to programmer error), .NET file system methods can throw the following exceptions:

- [System.IO.IOException](#), the base class of all [System.IO](#) exception types. It is thrown for errors whose return codes from the operating system don't directly map to any other exception type.
- [System.IO.FileNotFoundException](#).
- [System.IO.DirectoryNotFoundException](#).
- [DriveNotFoundException](#).
- [System.IO.PathTooLongException](#).
- [System.OperationCanceledException](#).
- [System.UnauthorizedAccessException](#).
- [System.ArgumentException](#), which is thrown for invalid path characters on .NET Framework and on .NET Core 2.0 and previous versions.
- [System.NotSupportedException](#), which is thrown for invalid colons in .NET Framework.
- [System.Security.SecurityException](#), which is thrown for applications running in limited trust that lack the necessary permissions on .NET Framework only. (Full trust is the default on .NET Framework.)

Mapping error codes to exceptions

Because the file system is an operating system resource, I/O methods in both .NET Core and .NET Framework wrap calls to the underlying operating system. When an I/O error occurs in code executed by the operating system, the operating system returns error information to the .NET I/O method. The method then translates the error information, typically in the form of an error code, into a .NET exception type. In most cases, it does this by directly translating the error code into its corresponding exception type; it does not perform any special mapping of the error based on the context of the method call.

For example, on the Windows operating system, a method call that returns an error code of `ERROR_FILE_NOT_FOUND` (or 0x02) maps to a [FileNotFoundException](#), and an error code of `ERROR_PATH_NOT_FOUND` (or 0x03) maps to a [DirectoryNotFoundException](#).

However, the precise conditions under which the operating system returns particular error codes is often undocumented or poorly documented. As a result, unexpected

exceptions can occur. For example, because you are working with a directory rather than a file, you would expect that providing an invalid directory path to the [DirectoryInfo](#) constructor throws a [DirectoryNotFoundException](#). However, it may also throw a [FileNotFoundException](#).

Exception handling in I/O operations

Because of this reliance on the operating system, identical exception conditions (such as the directory not found error in our example) can result in an I/O method throwing any one of the entire class of I/O exceptions. This means that, when calling I/O APIs, your code should be prepared to handle most or all of these exceptions, as shown in the following table:

| Exception type | .NET Core/.NET 5+ | .NET Framework |
|---|---------------------------|--------------------|
| IOException | Yes | Yes |
| FileNotFoundException | Yes | Yes |
| DirectoryNotFoundException | Yes | Yes |
| DriveNotFoundException | Yes | Yes |
| PathTooLongException | Yes | Yes |
| OperationCanceledException | Yes | Yes |
| UnauthorizedAccessException | Yes | Yes |
| ArgumentException | .NET Core 2.0 and earlier | Yes |
| NotSupportedException | No | Yes |
| SecurityException | No | Limited trust only |

Handling IOException

As the base class for exceptions in the [System.IO](#) namespace, [IOException](#) is also thrown for any error code that does not map to a predefined exception type. This means that it can be thrown by any I/O operation.

Important

Because [IOException](#) is the base class of the other exception types in the [System.IO](#) namespace, you should handle in a `catch` block after you've handled the

other I/O-related exceptions.

In addition, starting with .NET Core 2.1, validation checks for path correctness (for example, to ensure that invalid characters are not present in a path) have been removed, and the runtime throws an exception mapped from an operating system error code rather than from its own validation code. The most likely exception to be thrown in this case is an [IOException](#), although any other exception type could also be thrown.

Note that, in your exception handling code, you should always handle the [IOException](#) last. Otherwise, because it is the base class of all other IO exceptions, the catch blocks of derived classes will not be evaluated.

In the case of an [IOException](#), you can get additional error information from the [IOException.HResult](#) property. To convert the HResult value to a Win32 error code, you strip out the upper 16 bits of the 32-bit value. The following table lists error codes that may be wrapped in an [IOException](#).

| HResult | Constant | Description |
|-------------------------|----------|---|
| ERROR_SHARING_VIOLATION | 32 | The file name is missing, or the file or directory is in use. |
| ERROR_FILE_EXISTS | 80 | The file already exists. |
| ERROR_INVALID_PARAMETER | 87 | An argument supplied to the method is invalid. |
| ERROR_ALREADY_EXISTS | 183 | The file or directory already exists. |

You can handle these using a `when` clause in a catch statement, as the following example shows.

C#

```
using System;
using System.IO;
using System.Text;

class Program
{
    static void Main()
    {
        var sw = OpenStream(@".\textfile.txt");
        if (sw is null)
            return;
        sw.WriteLine("This is the first line.");
        sw.WriteLine("This is the second line.");
        sw.Close();
    }
}
```

```
static StreamWriter? OpenStream(string path)
{
    if (path is null)
    {
        Console.WriteLine("You did not supply a file path.");
        return null;
    }

    try
    {
        var fs = new FileStream(path, FileMode.CreateNew);
        return new StreamWriter(fs);
    }
    catch (FileNotFoundException)
    {
        Console.WriteLine("The file or directory cannot be found.");
    }
    catch (DirectoryNotFoundException)
    {
        Console.WriteLine("The file or directory cannot be found.");
    }
    catch (DriveNotFoundException)
    {
        Console.WriteLine("The drive specified in 'path' is invalid.");
    }
    catch (PathTooLongException)
    {
        Console.WriteLine("'path' exceeds the maximum supported path
length.");
    }
    catch (UnauthorizedAccessException)
    {
        Console.WriteLine("You do not have permission to create this
file.");
    }
    catch (IOException e) when ((e.HResult & 0x0000FFFF) == 32)
    {
        Console.WriteLine("There is a sharing violation.");
    }
    catch (IOException e) when ((e.HResult & 0x0000FFFF) == 80)
    {
        Console.WriteLine("The file already exists.");
    }
    catch (IOException e)
    {
        Console.WriteLine($"An exception occurred:\nError code: " +
                      $"{e.HResult & 0x0000FFFF}\nMessage:
{e.Message}");
    }
    return null;
}
```

Isolated storage

Article • 10/11/2022

For desktop apps, isolated storage is a data storage mechanism that provides isolation and safety by defining standardized ways of associating code with saved data.

Standardization provides other benefits as well. Administrators can use tools designed to manipulate isolated storage to configure file storage space, set security policies, and delete unused data. With isolated storage, your code no longer needs unique paths to specify safe locations in the file system, and data is protected from other applications that only have isolated storage access. Hard-coded information that indicates where an application's storage area is located is unnecessary.

ⓘ Important

Isolated storage is not available for Windows 8.x Store apps. Instead, use the application data classes in the `Windows.Storage` namespaces included in the Windows Runtime API to store local data and files. For more information, see [Application data](#) in the Windows Dev Center.

Data Compartments and Stores

When an application stores data in a file, the file name and storage location must be carefully chosen to minimize the possibility that the storage location will be known to another application and, therefore, vulnerable to corruption. Without a standard system in place to manage these problems, improvising techniques that minimize storage conflicts can be complex, and the results can be unreliable.

With isolated storage, data is always isolated by user and by assembly. Credentials such as the origin or the strong name of the assembly determine assembly identity. Data can also be isolated by application domain, using similar credentials.

When you use isolated storage, your application saves data to a unique data compartment that is associated with some aspect of the code's identity, such as its publisher or signature. The data compartment is an abstraction, not a specific storage location; it consists of one or more isolated storage files, called stores, which contain the actual directory locations where data is stored. For example, an application might have a data compartment associated with it, and a directory in the file system would implement the store that actually preserves the data for that application. The data saved in the store can be any kind of data, from user preference information to application state. For

the developer, the location of the data compartment is transparent. Stores usually reside on the client, but a server application could use isolated stores to store information by impersonating the user on whose behalf it is functioning. Isolated storage can also store information on a server with a user's roaming profile so that the information will travel with the roaming user.

Quotas for Isolated Storage

A quota is a limit on the amount of isolated storage that can be used. The quota includes bytes of file space as well as the overhead associated with the directory and other information in the store. Isolated storage uses permission quotas, which are storage limits that are set by using [IsolatedStoragePermission](#) objects. If you try to write data that exceeds the quota, an [IsolatedStorageException](#) exception is thrown. Security policy, which can be modified using the .NET Framework Configuration Tool (Mscorcfg.msc), determines which permissions are granted to code. Code that has been granted [IsolatedStoragePermission](#) is restricted to using no more storage than the [UserQuota](#) property allows. However, because code can bypass permission quotas by presenting different user identities, permission quotas serve as guidelines for how code should behave rather than as a firm limit on code behavior.

Quotas are not enforced on roaming stores. Because of this, a slightly higher level of permission is required for code to use them. The enumeration values [AssemblyIsolationByRoamingUser](#) and [DomainIsolationByRoamingUser](#) specify a permission to use isolated storage for a roaming user.

Secure Access

Using isolated storage enables partially trusted applications to store data in a manner that is controlled by the computer's security policy. This is especially useful for downloaded components that a user might want to run cautiously. Security policy rarely grants this kind of code permission when you access the file system by using standard I/O mechanisms. However, by default, code running from the local computer, a local network, or the Internet is granted the right to use isolated storage.

Administrators can limit how much isolated storage an application or a user has available, based on an appropriate trust level. In addition, administrators can remove a user's persisted data completely. To create or access isolated storage, code must be granted the appropriate [IsolatedStorageFilePermission](#) permission.

To access isolated storage, code must have all necessary native platform operating system rights. The access control lists (ACLs) that control which users have the rights to

use the file system must be satisfied. .NET applications already have operating system rights to access isolated storage unless they perform (platform-specific) impersonation. In this case, the application is responsible for ensuring that the impersonated user identity has the proper operating system rights to access isolated storage. This access provides a convenient way for code that is run or downloaded from the web to read and write to a storage area related to a particular user.

To control access to isolated storage, the common language runtime uses [IsolatedStorageFilePermission](#) objects. Each object has properties that specify the following values:

- Allowed usage, which indicates the type of access that is allowed. The values are members of the [IsolatedStorageContainment](#) enumeration. For more information about these values, see the table in the next section.
- Storage quota, as discussed in the preceding section.

The runtime demands [IsolatedStorageFilePermission](#) permission when code first attempts to open a store. It decides whether to grant this permission, based on how much the code is trusted. If the permission is granted, the allowed usage and storage quota values are determined by security policy and by the code's request for [IsolatedStorageFilePermission](#). Security policy is set by using the .NET Framework Configuration Tool (Mscorcfg.msc). All callers in the call stack are checked to ensure that each caller has at least the appropriate allowed usage. The runtime also checks the quota imposed on the code that opened or created the store in which the file is to be saved. If these conditions are satisfied, permission is granted. The quota is checked again every time a file is written to the store.

Application code is not required to request permission because the common language runtime will grant whatever [IsolatedStorageFilePermission](#) is appropriate based on security policy. However, there are good reasons to request specific permissions that your application needs, including [IsolatedStorageFilePermission](#).

Allowed Usage and Security Risks

The allowed usage specified by [IsolatedStorageFilePermission](#) determines the degree to which code will be allowed to create and use isolated storage. The following table shows how the allowed usage specified in the permission corresponds to types of isolation and summarizes the security risks associated with each allowed usage.

| Allowed usage | Isolation types | Security impact |
|---|---|---|
| None | No isolated storage use is allowed. | There is no security impact. |
| DomainIsolationByUser | Isolation by user, domain, and assembly. Each assembly has a separate substore within the domain. Stores that use this permission are also implicitly isolated by computer. | This permission level leaves resources open to unauthorized overuse, although enforced quotas make it more difficult. This is called a denial of service attack. |
| DomainIsolationByRoamingUser | Same as DomainIsolationByUser , but store is saved to a location that will roam if roaming user profiles are enabled and quotas are not enforced. | Because quotas must be disabled, storage resources are more vulnerable to a denial of service attack. |
| AssemblyIsolationByUser | Isolation by user and assembly. Stores that use this permission are also implicitly isolated by computer. | Quotas are enforced at this level to help prevent a denial of service attack. The same assembly in another domain can access this store, opening the possibility that information could be leaked between applications. |
| AssemblyIsolationByRoamingUser | Same as AssemblyIsolationByUser , but store is saved to a location that will roam if roaming user profiles are enabled and quotas are not enforced. | Same as in AssemblyIsolationByUser , but without quotas, the risk of a denial of service attack increases. |
| AdministerIsolatedStorageByUser | Isolation by user. Typically, only administrative or debugging tools use this level of permission. | Access with this permission allows code to view or delete any of a user's isolated storage files or directories (regardless of assembly isolation). Risks include, but are not limited to, leaking information and data loss. |
| UnrestrictedIsolatedStorage | Isolation by all users, domains, and assemblies. Typically, only administrative | This permission creates the potential for a total compromise of all isolated stores for all users. |

| Allowed usage | Isolation types | Security impact |
|---------------|--|-----------------|
| | or debugging tools use this level of permission. | |

Safety of isolated storage components with regard to untrusted data

This section applies to the following frameworks:

- .NET Framework (all versions)
- .NET Core 2.1+
- .NET 5+

.NET Framework and .NET Core offer isolated storage as a mechanism to persist data for a user, an application, or a component. This is a legacy component primarily designed for now-deprecated Code Access Security scenarios.

Various isolated storage APIs and tools can be used to read data across trust boundaries. For example, reading data from a machine-wide scope can aggregate data from other, possibly less-trusted user accounts on the machine. Components or applications that read from machine-wide isolated storage scopes should be aware of the consequences of reading this data.

Security-sensitive APIs that can read from the machine-wide scope

Components or applications that call any of the following APIs read from the machine-wide scope:

- [IsolatedStorageFile.GetEnumerator](#), passing a scope that includes the `IsolatedStorageScope.Machine` flag
- [IsolatedStorageFile.GetMachineStoreForApplication](#)
- [IsolatedStorageFile.GetMachineStoreForAssembly](#)
- [IsolatedStorageFile.GetMachineStoreForDomain](#)
- [IsolatedStorageFile.GetStore](#), passing a scope that includes the `IsolatedStorageScope.Machine` flag
- [IsolatedStorageFile.Remove](#), passing a scope that includes the `IsolatedStorageScope.Machine` flag

The [isolated storage tool](#) `storeadm.exe` is impacted if called with the `/machine` switch, as shown in the following code:

txt

```
storeadm.exe /machine [any-other-switches]
```

The isolated storage tool is provided as part of Visual Studio and the .NET Framework SDK.

If the application doesn't involve calls to the preceding APIs, or if the workflow doesn't involve calling `storeadm.exe` in this manner, this document doesn't apply.

Impact in multi-user environments

As mentioned previously, the security impact from these APIs results from data written from one trust environment is read from a different trust environment. Isolated storage generally uses one of three locations to read and write data:

1. `%LOCALAPPDATA%\IsolatedStorage\`: For example, `C:\Users\<username>\AppData\Local\IsolatedStorage\`, for `User` scope.
2. `%APPDATA%\IsolatedStorage\`: For example, `C:\Users\<username>\AppData\Roaming\IsolatedStorage\`, for `User|Roaming` scope.
3. `%PROGRAMDATA%\IsolatedStorage\`: For example, `C:\ProgramData\IsolatedStorage\`, for `Machine` scope.

The first two locations are isolated per-user. Windows ensures that different user accounts on the same machine cannot access each other's user profile folders. Two different user accounts who use the `User` or `User|Roaming` stores will not see each other's data and cannot interfere with each other's data.

The third location is shared across all user accounts on the machine. Different accounts can read from and write to this location, and they're able to see each other's data.

The preceding paths may differ based on the version of Windows in use.

Now consider a multi-user system with two registered users *Mallory* and *Bob*. Mallory has the ability to access her user profile directory `C:\Users\Mallory\`, and she can access the shared machine-wide storage location `C:\ProgramData\IsolatedStorage\`. She cannot access Bob's user profile directory `C:\Users\Bob\`.

If Mallory wishes to attack Bob, she might write data to the machine-wide storage location, then attempt to influence Bob into reading from the machine-wide store. When Bob runs an app that reads from this store, that app will operate on the data Mallory placed there, but from within the context of Bob's user account. The remainder

of this document contemplates various attack vectors and what steps apps can do to minimize their risk to these attacks.

ⓘ Note

In order for such an attack to take place, Mallory requires:

- A user account on the machine.
- The ability to place a file into a known location on the file system.
- Knowledge that Bob will at some point run an app that attempts to read this data.

These are not threat vectors that apply to standard single-user desktop environments like home PCs or single-employee enterprise workstations.

Elevation of privilege

An **elevation of privilege** attack occurs when Bob's app reads Mallory's file and automatically tries to take some action based on the contents of that payload. Consider an app that reads the contents of a startup script from the machine-wide store and passes those contents to `Process.Start`. If Mallory can place a malicious script inside the machine-wide store, when Bob launches his app:

- His app parses and launches Mallory's malicious script *under the context of Bob's user profile*.
- Mallory gains access to Bob's account on the local machine.

Denial of service

A **denial of service** attack occurs when Bob's app reads Mallory's file and crashes or otherwise stops functioning correctly. Consider again the app mentioned previously, which attempts to parse a startup script from the machine-wide store. If Mallory can place a file with malformed contents inside the machine-wide store, she might:

- Cause Bob's app to throw an exception early in the startup path.
- Prevent the app from launching successfully because of the exception.

She has then denied Bob the ability to launch the app under his own user account.

Information disclosure

An **information disclosure** attack occurs when Mallory can trick Bob into disclosing the contents of a file that Mallory does not normally have access to. Consider that Bob has a secret file `C:\Users\Bob\secret.txt` that Mallory wants to read. She knows the path to this file, but she cannot read it because Windows forbids her from gaining access to Bob's user profile directory.

Instead, Mallory places a hard link into the machine-wide store. This is a special kind of file that itself does not contain any contents, rather, it points to another file on disk.

Attempting to read the hard link file will instead read the contents of the file targeted by the link. After creating the hard link, Mallory still cannot read the file contents because she does not have access to the target (`c:\Users\Bob\secret.txt`) of the link. However, Bob *does* have access to this file.

When Bob's app reads from the machine-wide store, it now inadvertently reads the contents of his `secret.txt` file, just as if the file itself had been present in the machine-wide store. When Bob's app exits, if it attempts to resave the file to the machine-wide store, it will end up placing an actual copy of the file in the `*C:\ProgramData\IsolatedStorage*` directory. Since this directory is readable by any user on the machine, Mallory can now read the contents of the file.

Best practices to defend against these attacks

Important: If your environment has multiple mutually untrusted users, **do not** call the API `IsolatedStorageFile.GetEnumerator(IsolatedStorageScope.Machine)` or invoke the tool `storeadm.exe /machine /list`. Both of these assume that they're operating on trusted data. If an attacker can seed a malicious payload in the machine-wide store, that payload can lead to an elevation of privilege attack under the context of the user who runs these commands.

If operating in a multi-user environment, reconsider use of isolated storage features that target the *Machine* scope. If an app must read data from a machine-wide location, prefer to read the data from a location that's writable only by admin accounts. The `%PROGRAMFILES%` directory and the `HKLM` registry hive are examples of locations that are writable by only administrators and readable by everyone. Data read from those locations is therefore considered trustworthy.

If an app must use the *Machine* scope in a multi-user environment, validate the contents of any file that you read from the machine-wide store. If the app is deserializing object graphs from these files, consider using safer serializers like `XmlSerializer` instead of dangerous serializers like `BinaryFormatter` or `NetDataContractSerializer`. Use caution

with deeply nested object graphs or object graphs that perform resource allocation based on the file contents.

Isolated Storage Locations

Sometimes it is helpful to verify a change to isolated storage by using the file system of the operating system. You might also want to know the location of isolated storage files. This location is different depending on the operating system. The following table shows the root locations where isolated storage is created on a few common operating systems. Look for Microsoft\IsolatedStorage directories under this root location. You must change folder settings to show hidden files and folders in order to see isolated storage in the file system.

| Operating system | Location in file system |
|--|---|
| Windows 2000, Windows XP, Windows Server 2003 (upgrade from Windows NT 4.0) | <p>Roaming-enabled stores = <SYSTEMROOT>\Profiles\<user>\Application Data</p> <p>Nonroaming stores = <SYSTEMROOT>\Profiles\<user>\Local Settings\Application Data</p> |
| Windows 2000 - clean installation (and upgrades from Windows 98 and Windows NT 3.51) | <p>Roaming-enabled stores = <SYSTEMDRIVE>\Documents and Settings\<user>\Application Data</p> <p>Nonroaming stores = <SYSTEMDRIVE>\Documents and Settings\<user>\Local Settings\Application Data</p> |
| Windows XP, Windows Server 2003 - clean installation (and upgrades from Windows 2000 and Windows 98) | <p>Roaming-enabled stores = <SYSTEMDRIVE>\Documents and Settings\<user>\Application Data</p> <p>Nonroaming stores = <SYSTEMDRIVE>\Documents and Settings\<user>\Local Settings\Application Data</p> |
| Windows 8, Windows 7, Windows Server 2008, Windows Vista | Roaming-enabled stores = |

| Operating system | Location in file system |
|------------------|---|
| | <SYSTEMDRIVE>\Users\ <user>\AppData\Roaming |
| | Nonroaming stores = <SYSTEMDRIVE>\Users\<user>\AppData\Local |

Creating, Enumerating, and Deleting Isolated Storage

.NET provides three classes in the [System.IO.IsolatedStorage](#) namespace to help you perform tasks that involve isolated storage:

- [IsolatedStorageFile](#), derives from [System.IO.IsolatedStorage.IsolatedStorage](#) and provides basic management of stored assembly and application files. An instance of the [IsolatedStorageFile](#) class represents a single store located in the file system.
- [IsolatedStorageFileStream](#) derives from [System.IO.FileStream](#) and provides access to the files in a store.
- [IsolatedStorageScope](#) is an enumeration that enables you to create and select a store with the appropriate isolation type.

The isolated storage classes enable you to create, enumerate, and delete isolated storage. The methods for performing these tasks are available through the [IsolatedStorageFile](#) object. Some operations require you to have the [IsolatedStorageFilePermission](#) permission that represents the right to administer isolated storage; you might also need to have operating system rights to access the file or directory.

For a series of examples that demonstrate common isolated storage tasks, see the how-to topics listed in [Related Topics](#).

Scenarios for Isolated Storage

Isolated storage is useful in many situations, including these four scenarios:

- Downloaded controls. Managed code controls downloaded from the Internet are not allowed to write to the hard drive through normal I/O classes, but they can use isolated storage to persist users' settings and application states.

- Shared component storage. Components that are shared between applications can use isolated storage to provide controlled access to data stores.
- Server storage. Server applications can use isolated storage to provide individual stores for a large number of users making requests to the application. Because isolated storage is always segregated by user, the server must impersonate the user making the request. In this case, data is isolated based on the identity of the principal, which is the same identity the application uses to distinguish between its users.
- Roaming. Applications can also use isolated storage with roaming user profiles. This allows a user's isolated stores to roam with the profile.

Do not use isolated storage in the following situations:

- To store high-value secrets, such as unencrypted keys or passwords, because isolated storage is not protected from highly trusted code, from unmanaged code, or from trusted users of the computer.
- To store code.
- To store configuration and deployment settings, which administrators control. (User preferences are not considered to be configuration settings because administrators do not control them.)

Many applications use a database to store and isolate data, in which case one or more rows in a database might represent storage for a specific user. You might choose to use isolated storage instead of a database when the number of users is small, when the overhead of using a database is significant, or when no database facility exists. Also, when the application requires storage that is more flexible and complex than what a row in a database provides, isolated storage can provide a viable alternative.

Types of isolation

Article • 09/15/2021

Access to isolated storage is always restricted to the user who created it. To implement this type of isolation, the common language runtime uses the same notion of user identity that the operating system recognizes, which is the identity associated with the process in which the code is running when the store is opened. This identity is an authenticated user identity, but impersonation can cause the identity of the current user to change dynamically.

Access to isolated storage is also restricted according to the identity associated with the application's domain and assembly, or with the assembly alone. The runtime obtains these identities in the following ways:

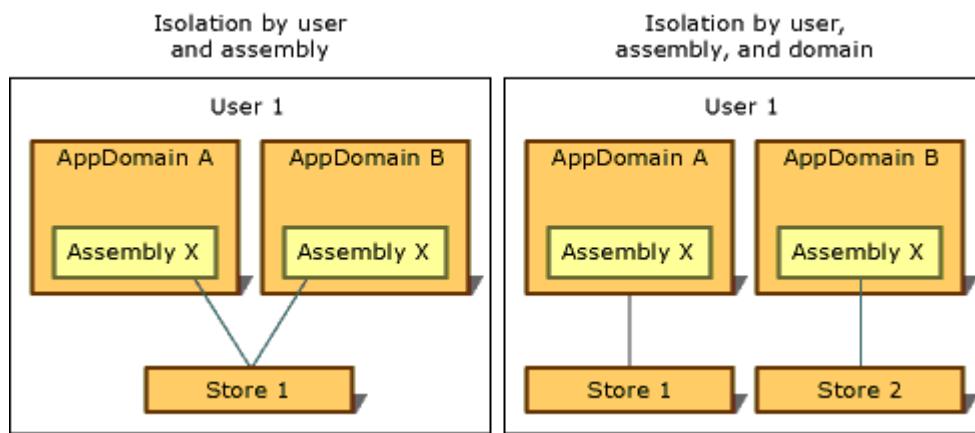

- Domain identity represents the evidence of the application, which in the case of a web application might be the full URL. For shell-hosted code, the domain identity might be based on the application directory path. For example, if the executable runs from the path C:\Office\MyApp.exe, the domain identity would be C:\Office\MyApp.exe.
- Assembly identity is the evidence of the assembly. This might come from a cryptographic digital signature, which can be the assembly's [strong name](#), the software publisher of the assembly, or its URL identity. If an assembly has both a strong name and a software publisher identity, then the software publisher identity is used. If the assembly comes from the Internet and is unsigned, the URL identity is used. For more information about assemblies and strong names, see [Programming with Assemblies](#).
- Roaming stores move with a user that has a roaming user profile. Files are written to a network directory and are downloaded to any computer the user logs into. For more information about roaming user profiles, see [IsolatedStorageScope.Roaming](#).

By combining the concepts of user, domain, and assembly identity, isolated storage can isolate data in the following ways, each of which has its own usage scenarios:

- [Isolation by user and assembly](#)
- [Isolation by user, domain, and assembly](#)

Either of these isolations can be combined with a roaming user profile. For more information, see the section [Isolated Storage and Roaming](#).

The following illustration demonstrates how stores are isolated in different scopes:

Except for roaming stores, isolated storage is always implicitly isolated by computer because it uses the storage facilities that are local to a given computer.

ⓘ Important

Isolated storage is not available for Windows 8.x Store apps. Instead, use the application data classes in the `Windows.Storage` namespaces included in the Windows Runtime API to store local data and files. For more information, see [Application data](#) in the Windows Dev Center.

Isolation by User and Assembly

When the assembly that uses the data store needs to be accessible from any application's domain, isolation by user and assembly is appropriate. Typically, in this situation, isolated storage is used to store data that applies across multiple applications and is not tied to any particular application, such as the user's name or license information. To access storage isolated by user and assembly, code must be trusted to transfer information between applications. Typically, isolation by user and assembly is allowed on intranets but not on the Internet. Calling the static `IsolatedStorageFile.GetStore` method and passing in a user and an assembly `IsolatedStorageScope` returns storage with this kind of isolation.

The following code example retrieves a store that is isolated by user and assembly. The store can be accessed through the `isoFile` object.

C#

```
IsolatedStorageFile isoFile =
    IsolatedStorageFile.GetStore(IsolatedStorageScope.User |
    IsolatedStorageScope.Assembly, null, null);
```

For an example that uses the evidence parameters, see [GetStore\(IsolatedStorageScope, Evidence, Type, Evidence, Type\)](#).

The [GetUserStoreForAssembly](#) method is available as a shortcut, as shown in the following code example. This shortcut cannot be used to open stores that are capable of roaming; use [GetStore](#) in such cases.

```
C#
```

```
IsolatedStorageFile isoFile = IsolatedStorageFile.GetUserStoreForAssembly();
```

Isolation by User, Domain, and Assembly

If your application uses a third-party assembly that requires a private data store, you can use isolated storage to store the private data. Isolation by user, domain, and assembly ensures that only code in a given assembly can access the data, and only when the assembly is used by the application that was running when the assembly created the store, and only when the user for whom the store was created runs the application. Isolation by user, domain, and assembly keeps the third-party assembly from leaking data to other applications. This isolation type should be your default choice if you know that you want to use isolated storage but are not sure which type of isolation to use. Calling the static [GetStore](#) method of [IsolatedStorageFile](#) and passing in a user, domain, and assembly [IsolatedStorageScope](#) returns storage with this kind of isolation.

The following code example retrieves a store isolated by user, domain, and assembly. The store can be accessed through the `isoFile` object.

```
C#
```

```
IsolatedStorageFile isoFile =
    IsolatedStorageFile.GetStore(IsolatedStorageScope.User |
        IsolatedStorageScope.Domain |
        IsolatedStorageScope.Assembly, null, null);
```

Another method is available as a shortcut, as shown in the following code example. This shortcut cannot be used to open stores that are capable of roaming; use [GetStore](#) in such cases.

```
C#
```

```
IsolatedStorageFile isoFile = IsolatedStorageFile.GetUserStoreForDomain();
```

Isolated Storage and Roaming

Roaming user profiles are a Windows feature that enables a user to set up an identity on a network and use that identity to log into any network computer, carrying over all personalized settings. An assembly that uses isolated storage can specify that the user's isolated storage should move with the roaming user profile. Roaming can be used in conjunction with isolation by user and assembly or with isolation by user, domain, and assembly. If a roaming scope is not used, stores will not roam even if a roaming user profile is used.

The following code example retrieves a roaming store isolated by user and assembly. The store can be accessed through the `isoFile` object.

C#

```
IsolatedStorageFile isoFile =
    IsolatedStorageFile.GetStore(IsolatedStorageScope.User |
        IsolatedStorageScope.Assembly |
        IsolatedStorageScope.Roaming, null, null);
```

A domain scope can be added to create a roaming store isolated by user, domain, and application. The following code example demonstrates this.

C#

```
IsolatedStorageFile isoFile =
    IsolatedStorageFile.GetStore(IsolatedStorageScope.User |
        IsolatedStorageScope.Assembly | IsolatedStorageScope.Domain |
        IsolatedStorageScope.Roaming, null, null);
```

How to: Obtain Stores for Isolated Storage

Article • 09/15/2021

An isolated store exposes a virtual file system within a data compartment. The [IsolatedStorageFile](#) class supplies a number of methods for interacting with an isolated store. To create and retrieve stores, [IsolatedStorageFile](#) provides three static methods:

- [GetUserStoreForAssembly](#) returns storage that is isolated by user and assembly.
- [GetUserStoreForDomain](#) returns storage that is isolated by domain and assembly.

Both methods retrieve a store that belongs to the code from which they are called.

- The static method [GetStore](#) returns an isolated store that is specified by passing in a combination of scope parameters.

The following code returns a store that is isolated by user, assembly, and domain.

C#

```
IsolatedStorageFile isoStore =  
    IsolatedStorageFile.GetStore(IsolatedStorageScope.User |  
        IsolatedStorageScope.Assembly | IsolatedStorageScope.Domain, null,  
        null);
```

You can use the [GetStore](#) method to specify that a store should roam with a roaming user profile. For details on how to set this up, see [Types of Isolation](#).

Isolated stores obtained from within different assemblies are, by default, different stores. You can access the store of a different assembly or domain by passing in the assembly or domain evidence in the parameters of the [GetStore](#) method. This requires permission to access isolated storage by application domain identity. For more information, see the [GetStore](#) method overloads.

The [GetUserStoreForAssembly](#), [GetUserStoreForDomain](#), and [GetStore](#) methods return an [IsolatedStorageFile](#) object. To help you decide which isolation type is most appropriate for your situation, see [Types of Isolation](#). When you have an isolated storage file object, you can use the isolated storage methods to read, write, create, and delete files and directories.

There is no mechanism that prevents code from passing an [IsolatedStorageFile](#) object to code that does not have sufficient access to get the store itself. Domain and assembly

identities and isolated storage permissions are checked only when a reference to an [IsolatedStorage](#) object is obtained, typically in the [GetUserStoreForAssembly](#), [GetUserStoreForDomain](#), or [GetStore](#) method. Protecting references to [IsolatedStorageFile](#) objects is, therefore, the responsibility of the code that uses these references.

Example

The following code provides a simple example of a class obtaining a store that is isolated by user and assembly. The code can be changed to retrieve a store that is isolated by user, domain, and assembly by adding [IsolatedStorageScope.Domain](#) to the arguments that the [GetStore](#) method passes.

After you run the code, you can confirm that a store was created by typing [StoreAdm /LIST](#) at the command line. This runs the [Isolated Storage tool \(Storeadm.exe\)](#) and lists all the current isolated stores for the user.

C#

```
using System;
using System.IO.IsolatedStorage;

public class ObtainingAStore
{
    public static void Main()
    {
        // Get a new isolated store for this assembly and put it into an
        // isolated store object.

        IsolatedStorageFile isoStore =
IsolatedStorageFile.GetStore(IsolatedStorageScope.User |
    IsolatedStorageScope.Assembly, null, null);
    }
}
```

How to: Enumerate Stores for Isolated Storage

Article • 09/15/2021

You can enumerate all isolated stores for the current user by using the [IsolatedStorageFile.GetEnumerator](#) static method. This method takes an [IsolatedStorageScope](#) value and returns an [IsolatedStorageFile](#) enumerator. To enumerate stores, you must have the [IsolatedStorageFilePermission](#) permission that specifies the [AdministerIsolatedStorageByUser](#) value. If you call the [GetEnumerator](#) method with the [User](#) value, it returns an array of [IsolatedStorageFile](#) objects that are defined for the current user.

Example

The following code example obtains a store that is isolated by user and assembly, creates a few files, and retrieves those files by using the [GetEnumerator](#) method.

C#

```
using System;
using System.IO;
using System.IO.IsolatedStorage;
using System.Collections;

public class EnumeratingStores
{
    public static void Main()
    {
        using (IsolatedStorageFile isoStore =
IsolatedStorageFile.GetStore(IsolatedStorageScope.User |
IsolatedStorageScope.Assembly, null, null))
        {
            isoStore.CreateFile("TestFileA.Txt");
            isoStore.CreateFile("TestFileB.Txt");
            isoStore.CreateFile("TestFileC.Txt");
            isoStore.CreateFile("TestFileD.Txt");
        }

        IEnumerator allFiles =
IsolatedStorageFile.GetEnumerator(IsolatedStorageScope.User);
        long totalsize = 0;

        while (allFiles.MoveNext())
        {
            IsolatedStorageFile storeFile =
(IsolatedStorageFile)allFiles.Current;
```

```
        totalsize += (long)storeFile.UsedSize;  
    }  
  
    Console.WriteLine("The total size = " + totalsize);  
}  
}
```

How to: Delete Stores in Isolated Storage

Article • 09/15/2021

The [IsolatedStorageFile](#) class supplies two methods for deleting isolated storage files:

- The instance method [Remove\(\)](#) does not take any arguments and deletes the store that calls it. No permissions are required for this operation. Any code that can access the store can delete any or all the data inside it.
- The static method [Remove\(IsolatedStorageScope\)](#) takes the [User](#) enumeration value, and deletes all the stores for the user who is running the code. This operation requires [IsolatedStorageFilePermission](#) permission for the [AdministerIsolatedStorageByUser](#) value.

Example

The following code example demonstrates the use of the static and instance [Remove](#) methods. The class obtains two stores; one is isolated for user and assembly and the other is isolated for user, domain, and assembly. The user, domain, and assembly store is then deleted by calling the [Remove\(\)](#) method of the isolated storage file `isoStore1`. Then, all remaining stores for the user are deleted by calling the static method [Remove\(IsolatedStorageScope\)](#).

C#

```
using System;
using System.IO.IsolatedStorage;

public class DeletingStores
{
    public static void Main()
    {
        // Get a new isolated store for this user, domain, and assembly.
        // Put the store into an IsolatedStorageFile object.

        IsolatedStorageFile isoStore1 =
IsolatedStorageFile.GetStore(IsolatedStorageScope.User |
    IsolatedStorageScope.Domain | IsolatedStorageScope.Assembly,
null, null);
        Console.WriteLine("A store isolated by user, assembly, and domain
has been obtained.");

        // Get a new isolated store for user and assembly.
```

```
// Put that store into a different IsolatedStorageFile object.

IsolatedStorageFile isoStore2 =
IsolatedStorageFile.GetStore(IsolatedStorageScope.User |
    IsolatedStorageScope.Assembly, null, null);
Console.WriteLine("A store isolated by user and assembly has been
obtained.");

// The Remove method deletes a specific store, in this case the
// isoStore1 file.

isoStore1.Remove();
Console.WriteLine("The user, domain, and assembly isolated store has
been deleted.");

// This static method deletes all the isolated stores for this user.

IsolatedStorageFile.Remove(IsolatedStorageScope.User);
Console.WriteLine("All isolated stores for this user have been
deleted.");
} // End of Main.
}
```

How to: Anticipate Out-of-Space Conditions with Isolated Storage

Article • 09/15/2021

Code that uses isolated storage is constrained by a [quota](#) that specifies the maximum size for the data compartment in which isolated storage files and directories exist. The quota is defined by security policy and is configurable by administrators. If the maximum allowed size is exceeded when you try to write data, an [IsolatedStorageException](#) exception is thrown and the operation fails. This helps prevent malicious denial-of-service attacks that could cause the application to refuse requests because data storage is filled.

To help you determine whether a given write attempt is likely to fail for this reason, the [IsolatedStorage](#) class provides three read-only properties: [AvailableFreeSpace](#), [UsedSize](#), and [Quota](#). You can use these properties to determine whether writing to the store will cause the maximum allowed size of the store to be exceeded. Keep in mind that isolated storage can be accessed concurrently; therefore, when you compute the amount of remaining storage, the storage space could be consumed by the time you try to write to the store. However, you can use the maximum size of the store to help determine whether the upper limit on available storage is about to be reached.

The [Quota](#) property depends on evidence from the assembly to work properly. For this reason, you should retrieve this property only on [IsolatedStorageFile](#) objects that were created by using the [GetUserStoreForAssembly](#), [GetUserStoreForDomain](#), or [GetStore](#) method. [IsolatedStorageFile](#) objects that were created in any other way (for example, objects that were returned from the [GetEnumerator](#) method) will not return an accurate maximum size.

Example

The following code example obtains an isolated store, creates a few files, and retrieves the [AvailableFreeSpace](#) property. The remaining space is reported in bytes.

C#

```
using System;
using System.IO;
using System.IO.IsolatedStorage;

public class CheckingSpace
{
```

```
public static void Main()
{
    // Get an isolated store for this assembly and put it into an
    // IsolatedStorageFile object.
    IsolatedStorageFile isoStore =
IsolatedStorageFile.GetStore(IsolatedStorageScope.User |
    IsolatedStorageScope.Assembly, null, null);

    // Create a few placeholder files in the isolated store.
    new IsolatedStorageFileStream("InTheRoot.txt", FileMode.Create,
isoStore);
    new IsolatedStorageFileStream("Another.txt", FileMode.Create,
isoStore);
    new IsolatedStorageFileStream("AThird.txt", FileMode.Create,
isoStore);
    new IsolatedStorageFileStream("AFourth.txt", FileMode.Create,
isoStore);
    new IsolatedStorageFileStream("AFifth.txt", FileMode.Create,
isoStore);

    Console.WriteLine(isoStore.AvailableFreeSpace + " bytes of space
remain in this isolated store.");
} // End of Main.
}
```

How to: Create Files and Directories in Isolated Storage

Article • 09/15/2021

After you've obtained an isolated store, you can create directories and files for storing data. Within a store, file and directory names are specified with respect to the root of the virtual file system.

To create a directory, use the [IsolatedStorageFile.CreateDirectory](#) instance method. If you specify a subdirectory of a directory that doesn't exist, both directories are created. If you specify a directory that already exists, the method returns without creating a directory, and no exception is thrown. However, if you specify a directory name that contains invalid characters, an [IsolatedStorageException](#) exception is thrown.

To create a file, use the [IsolatedStorageFile.CreateFile](#) method.

In the Windows operating system, isolated storage file and directory names are case-insensitive. That is, if you create a file named `ThisFile.txt`, and then create another file named `THISFILE.TXT`, only one file is created. The file name keeps its original casing for display purposes.

Isolated storage file creation will throw an [IsolatedStorageException](#) if the path contains a directory that does not exist.

Example

The following code example illustrates how to create files and directories in an isolated store.

C#

```
using System;
using System.IO;
using System.IO.IsolatedStorage;

public class CreatingFilesDirectories
{
    public static void Main()
    {
        using (IsolatedStorageFile isoStore =
IsolatedStorageFile.GetStore(IsolatedStorageScope.User |
IsolatedStorageScope.Domain | IsolatedStorageScope.Assembly, null, null))
        {
            isoStore.CreateDirectory("TopLevelDirectory");
```

```
isoStore.CreateDirectory("TopLevelDirectory/SecondLevel");

isoStore.CreateDirectory("AnotherTopLevelDirectory/InsideDirectory");
Console.WriteLine("Created directories.");

isoStore.CreateFile("InTheRoot.txt");
Console.WriteLine("Created a new file in the root.");

isoStore.CreateFile("AnotherTopLevelDirectory/InsideDirectory/HereIAm.txt");
Console.WriteLine("Created a new file in the InsideDirectory.");
}

}
```

How to: Find Existing Files and Directories in Isolated Storage

Article • 09/15/2021

To search for a directory in isolated storage, use the [IsolatedStorageFile.GetDirectoryNames](#) method. This method takes a string that represents a search pattern. You can use both single-character (?) and multi-character (*) wildcard characters in the search pattern, but the wildcard characters must appear in the final portion of the name. For example, `directory1/*ect*` is a valid search string, but `*ect*/directory2` is not.

To search for a file, use the [IsolatedStorageFile.GetFileNames](#) method. The restriction for wildcard characters in search strings that applies to [GetDirectoryNames](#) also applies to [GetFileNames](#).

Neither of these methods is recursive; the [IsolatedStorageFile](#) class does not supply any methods for listing all directories or files in your store. However, recursive methods are shown in the following code example.

Example

The following code example illustrates how to create files and directories in an isolated store. First, a store that is isolated for user, domain, and assembly is retrieved and placed in the `isoStore` variable. The [CreateDirectory](#) method is used to set up a few different directories, and the [IsolatedStorageFileStream\(String, FileMode, IsolatedStorageFile\)](#) constructor creates some files in these directories. The code then loops through the results of the [GetAllDirectories](#) method. This method uses [GetDirectoryName](#) to find all the directory names in the current directory. These names are stored in an array, and then [GetAllDirectories](#) calls itself, passing in each directory it has found. As a result, all the directory names are returned in an array. Next, the code calls the [GetAllFiles](#) method. This method calls [GetAllDirectories](#) to find out the names of all the directories, and then it checks each directory for files by using the [GetFileNames](#) method. The result is returned in an array for display.

C#

```
using System;
using System.IO;
using System.IO.IsolatedStorage;
using System.Collections;
```

```

using System.Collections.Generic;

public class FindingExistingFilesAndDirectories
{
    // Retrieves an array of all directories in the store, and
    // displays the results.
    public static void Main()
    {
        // This part of the code sets up a few directories and files in the
        // store.
        IsolatedStorageFile isoStore =
IsolatedStorageFile.GetStore(IsolatedStorageScope.User |
    IsolatedStorageScope.Assembly, null, null);
        isoStore.CreateDirectory("TopLevelDirectory");
        isoStore.CreateDirectory("TopLevelDirectory/SecondLevel");

        isoStore.CreateDirectory("AnotherTopLevelDirectory/InsideDirectory");
        isoStore.CreateFile("InTheRoot.txt");

        isoStore.CreateFile("AnotherTopLevelDirectory/InsideDirectory/HereIAm.txt");
        // End of setup.

        Console.WriteLine('\r');
        Console.WriteLine("Here is a list of all directories in this
isolated store:");

        foreach (string directory in GetAllDirectories("*", isoStore))
        {
            Console.WriteLine(directory);
        }
        Console.WriteLine('\r');

        // Retrieve all the files in the directory by calling the GetFiles
        // method.

        Console.WriteLine("Here is a list of all the files in this isolated
store:");
        foreach (string file in GetAllFiles("*", isoStore)){
            Console.WriteLine(file);
        }
    } // End of Main.

    // Method to retrieve all directories, recursively, within a store.
    public static List<String> GetAllDirectories(string pattern,
IsolatedStorageFile storeFile)
    {
        // Get the root of the search string.
        string root = Path.GetDirectoryName(pattern);

        if (root != "")
        {
            root += "/";
        }

        // Retrieve directories.
    }
}

```

```

        List<String> directoryList = new List<String>
(storeFile.GetDirectoryNames(pattern));

        // Retrieve subdirectories of matches.
        for (int i = 0, max = directoryList.Count; i < max; i++)
        {
            string directory = directoryList[i] + "/";
            List<String> more = GetAllDirectories(root + directory + "*",
storeFile);

            // For each subdirectory found, add in the base path.
            for (int j = 0; j < more.Count; j++)
            {
                more[j] = directory + more[j];
            }

            // Insert the subdirectories into the list and
            // update the counter and upper bound.
            directoryList.InsertRange(i + 1, more);
            i += more.Count;
            max += more.Count;
        }

        return directoryList;
    }

    public static List<String> GetAllFiles(string pattern,
IsolatedStorageFile storeFile)
{
    // Get the root and file portions of the search string.
    string fileString = Path.GetFileName(pattern);

    List<String> fileList = new List<String>
(storeFile.GetFileNames(pattern));

    // Loop through the subdirectories, collect matches,
    // and make separators consistent.
    foreach (string directory in GetAllDirectories("*", storeFile))
    {
        foreach (string file in storeFile.GetFileNames(directory + "/" +
fileString))
        {
            fileList.Add((directory + "/" + file));
        }
    }

    return fileList;
} // End of GetFiles.
}

```

How to: Read and Write to Files in Isolated Storage

Article • 09/15/2021

To read from, or write to, a file in an isolated store, use an [IsolatedStorageFileStream](#) object with a stream reader ([StreamReader](#) object) or stream writer ([StreamWriter](#) object).

Example

The following code example obtains an isolated store and checks whether a file named TestStore.txt exists in the store. If it doesn't exist, it creates the file and writes "Hello Isolated Storage" to the file. If TestStore.txt already exists, the example code reads from the file.

C#

```
using System;
using System.IO;
using System.IO.IsolatedStorage;

namespace ConsoleApplication1
{
    class Program
    {
        static void Main(string[] args)
        {
            IsolatedStorageFile isoStore =
IsolatedStorageFile.GetStore(IsolatedStorageScope.User |
IsolatedStorageScope.Assembly, null, null);

            if (isoStore.FileExists("TestStore.txt"))
            {
                Console.WriteLine("The file already exists!");
                using (IsolatedStorageFileStream isoStream = new
IsolatedStorageFileStream("TestStore.txt", FileMode.Open, isoStore))
                {
                    using (StreamReader reader = new
StreamReader(isoStream))
                    {
                        Console.WriteLine("Reading contents:");
                        Console.WriteLine(reader.ReadToEnd());
                    }
                }
            }
            else
            {
```

```
        using (IsolatedStorageFileStream isoStream = new
IsolatedStorageFileStream("TestStore.txt", FileMode.CreateNew, isoStore))
    {
        using (StreamWriter writer = new
StreamWriter(isoStream))
    {
        writer.WriteLine("Hello Isolated Storage");
        Console.WriteLine("You have written to the file.");
    }
}
}
```

How to: Delete Files and Directories in Isolated Storage

Article • 09/15/2021

You can delete directories and files within an isolated storage file. Within a store, file and directory names are operating-system dependent and are specified as relative to the root of the virtual file system. They are not case-sensitive on Windows operating systems.

The [System.IO.IsolatedStorage.IsolatedStorageFile](#) class supplies two methods for deleting directories and files: [DeleteDirectory](#) and [DeleteFile](#). An [IsolatedStorageException](#) exception is thrown if you try to delete a file or directory that does not exist. If you include a wildcard character in the name, [DeleteDirectory](#) throws an [IsolatedStorageException](#) exception, and [DeleteFile](#) throws an [ArgumentException](#) exception.

The [DeleteDirectory](#) method fails if the directory contains any files or subdirectories. You can use the [GetFileNames](#) and [GetDirectoryName](#)s methods to retrieve the existing files and directories. For more information about searching the virtual file system of a store, see [How to: Find Existing Files and Directories in Isolated Storage](#).

Example

The following code example creates and then deletes several directories and files.

C#

```
using System;
using System.IO.IsolatedStorage;
using System.IO;

public class DeletingFilesDirectories
{
    public static void Main()
    {
        // Get a new isolated store for this user domain and assembly.
        // Put the store into an isolatedStorageFile object.

        IsolatedStorageFile isoStore =
IsolatedStorageFile.GetStore(IsolatedStorageScope.User |
                           IsolatedStorageScope.Domain | IsolatedStorageScope.Assembly,
null, null);

        Console.WriteLine("Creating Directories:");
    }
}
```

```
// This code creates several different directories.

isoStore.CreateDirectory("TopLevelDirectory");
Console.WriteLine("TopLevelDirectory");
isoStore.CreateDirectory("TopLevelDirectory/SecondLevel");
Console.WriteLine("TopLevelDirectory/SecondLevel");

// This code creates two new directories, one inside the other.

isoStore.CreateDirectory("AnotherTopLevelDirectory/InsideDirectory");
Console.WriteLine("AnotherTopLevelDirectory/InsideDirectory");
Console.WriteLine();

// This code creates a few files and places them in the directories.

Console.WriteLine("Creating Files:");

// This file is placed in the root.

IsolatedStorageFileStream isoStream1 = new
IsolatedStorageFileStream("InTheRoot.txt",
    FileMode.Create, isoStore);
Console.WriteLine("InTheRoot.txt");

isoStream1.Close();

// This file is placed in the InsideDirectory.

IsolatedStorageFileStream isoStream2 = new
IsolatedStorageFileStream(
    "AnotherTopLevelDirectory/InsideDirectory/HereIAm.txt",
FileMode.Create, isoStore);

Console.WriteLine("AnotherTopLevelDirectory/InsideDirectory/HereIAm.txt");
Console.WriteLine();

isoStream2.Close();

Console.WriteLine("Deleting File:");

// This code deletes the HereIAm.txt file.

isoStore.DeleteFile("AnotherTopLevelDirectory/InsideDirectory/HereIAm.txt");

Console.WriteLine("AnotherTopLevelDirectory/InsideDirectory/HereIAm.txt");
Console.WriteLine();

Console.WriteLine("Deleting Directory:");

// This code deletes the InsideDirectory.

isoStore.DeleteDirectory("AnotherTopLevelDirectory/InsideDirectory/");
```

```
        Console.WriteLine("AnotherTopLevelDirectory/InsideDirectory/");
        Console.WriteLine();
    } // End of main.
}
```

Pipe Operations in .NET

Article • 09/15/2021

Pipes provide a means for interprocess communication. There are two types of pipes:

- Anonymous pipes.

Anonymous pipes provide interprocess communication on a local computer.

Anonymous pipes require less overhead than named pipes but offer limited services. Anonymous pipes are one-way and cannot be used over a network. They support only a single server instance. Anonymous pipes are useful for communication between threads, or between parent and child processes where the pipe handles can be easily passed to the child process when it is created.

In .NET, you implement anonymous pipes by using the

[AnonymousPipeServerStream](#) and [AnonymousPipeClientStream](#) classes.

See [How to: Use Anonymous Pipes for Local Interprocess Communication](#).

- Named pipes.

Named pipes provide interprocess communication between a pipe server and one or more pipe clients. Named pipes can be one-way or duplex. They support message-based communication and allow multiple clients to connect simultaneously to the server process using the same pipe name. Named pipes also support impersonation, which enables connecting processes to use their own permissions on remote servers.

In .NET, you implement named pipes by using the [NamedPipeServerStream](#) and [NamedPipeClientStream](#) classes.

See [How to: Use Named Pipes for Network Interprocess Communication](#).

How to: Use Anonymous Pipes for Local Interprocess Communication

Article • 12/14/2022

Anonymous pipes provide interprocess communication on a local computer. They offer less functionality than named pipes, but also require less overhead. You can use anonymous pipes to make interprocess communication on a local computer easier. You cannot use anonymous pipes for communication over a network.

To implement anonymous pipes, use the [AnonymousPipeServerStream](#) and [AnonymousPipeClientStream](#) classes.

Example 1

The following example demonstrates a way to send a string from a parent process to a child process using anonymous pipes. This example creates an [AnonymousPipeServerStream](#) object in a parent process with a [PipeDirection](#) value of [Out](#). The parent process then creates a child process by using a client handle to create an [AnonymousPipeClientStream](#) object. The child process has a [PipeDirection](#) value of [In](#).

The parent process then sends a user-supplied string to the child process. The string is displayed to the console in the child process.

The following example shows the server process.

C#

```
using System;
using System.IO;
using System.IO.Pipes;
using System.Diagnostics;

class PipeServer
{
    static void Main()
    {
        Process pipeClient = new Process();

        pipeClient.StartInfo.FileName = "pipeClient.exe";

        using (AnonymousPipeServerStream pipeServer =
            new AnonymousPipeServerStream(PipeDirection.Out,
                HandleInheritance.Inheritable))
```

```

    {
        Console.WriteLine("[SERVER] Current TransmissionMode: {0}.",
            pipeServer.TransmissionMode);

        // Pass the client process a handle to the server.
        pipeClient.StartInfo.Arguments =
            pipeServer.GetClientHandleAsString();
        pipeClient.StartInfo.UseShellExecute = false;
        pipeClient.Start();

        pipeServer.DisposeLocalCopyOfClientHandle();

        try
        {
            // Read user input and send that to the client process.
            using (StreamWriter sw = new StreamWriter(pipeServer))
            {
                sw.AutoFlush = true;
                // Send a 'sync message' and wait for client to receive
                it.
                sw.WriteLine("SYNC");
                pipeServer.WaitForPipeDrain();
                // Send the console input to the client process.
                Console.Write("[SERVER] Enter text: ");
                sw.WriteLine(Console.ReadLine());
            }
        }
        // Catch the IOException that is raised if the pipe is broken
        // or disconnected.
        catch (IOException e)
        {
            Console.WriteLine("[SERVER] Error: {0}", e.Message);
        }
    }

    pipeClient.WaitForExit();
    pipeClient.Close();
    Console.WriteLine("[SERVER] Client quit. Server terminating.");
}
}

```

Example 2

The following example shows the client process. The server process starts the client process and gives that process a client handle. The resulting executable from the client code should be named `pipeClient.exe` and be copied to the same directory as the server executable before running the server process.

```

using System;
using System.IO;
using System.IO.Pipes;

class PipeClient
{
    static void Main(string[] args)
    {
        if (args.Length > 0)
        {
            using (PipeStream pipeClient =
                new AnonymousPipeClientStream(PipeDirection.In, args[0]))
            {
                Console.WriteLine("[CLIENT] Current TransmissionMode: {0}.",
                    pipeClient.TransmissionMode);

                using (StreamReader sr = new StreamReader(pipeClient))
                {
                    // Display the read text to the console
                    string temp;

                    // Wait for 'sync message' from the server.
                    do
                    {
                        Console.WriteLine("[CLIENT] Wait for sync...");  

                        temp = sr.ReadLine();
                    }
                    while (!temp.StartsWith("SYNC"));

                    // Read the server data and echo to the console.
                    while ((temp = sr.ReadLine()) != null)
                    {
                        Console.WriteLine("[CLIENT] Echo: " + temp);
                    }
                }
            }
            Console.Write("[CLIENT] Press Enter to continue...");  

            Console.ReadLine();
        }
    }
}

```

How to: Use Named Pipes for Network Interprocess Communication

Article • 12/30/2023

Named pipes provide interprocess communication between a pipe server and one or more pipe clients. They offer more functionality than anonymous pipes, which provide interprocess communication on a local computer. Named pipes support full duplex communication over a network and multiple server instances, message-based communication, and client impersonation, which enables connecting processes to use their own set of permissions on remote servers.

ⓘ Important

.NET on Linux uses Unix Domain Sockets (UDS) for the implementation of these APIs.

To implement name pipes, use the [NamedPipeServerStream](#) and [NamedPipeClientStream](#) classes.

Example 1

The following example demonstrates how to create a named pipe by using the [NamedPipeServerStream](#) class. In this example, the server process creates four threads. Each thread can accept a client connection. The connected client process then supplies the server with a file name. If the client has sufficient permissions, the server process opens the file and sends its contents back to the client.

C#

```
using System;
using System.IO;
using System.IO.Pipes;
using System.Text;
using System.Threading;

public class PipeServer
{
    private static int numThreads = 4;

    public static void Main()
    {
        int i;
```

```

Thread?[] servers = new Thread[numThreads];

Console.WriteLine("\n*** Named pipe server stream with impersonation
example ***\n");
Console.WriteLine("Waiting for client connect...\n");
for (i = 0; i < numThreads; i++)
{
    servers[i] = new Thread(ServerThread);
    servers[i]?.Start();
}
