        string contents = File.ReadAllText(fn);
        ss.WriteString(contents);
    }
}

```

Example 2

The following example shows the client process, which uses the [NamedPipeClientStream](#) class. The client connects to the server process and sends a file name to the server. The example uses impersonation, so the identity that is running the client application must have permission to access the file. The server then sends the contents of the file back to the client. The file contents are then displayed to the console.

```

C#

using System;
using System.Diagnostics;
using System.IO;
using System.IO.Pipes;
using System.Security.Principal;
using System.Text;
using System.Threading;

public class PipeClient
{
    private static int numClients = 4;

    public static void Main(string[] args)
    {

```

```

    if (args.Length > 0)
    {
        if (args[0] == "spawnclient")
        {
            var pipeClient =
                new NamedPipeClientStream(".", "testpipe",
                    PipeDirection.InOut, PipeOptions.None,
                    TokenImpersonationLevel.Impersonation);

            Console.WriteLine("Connecting to server...\n");
            pipeClient.Connect();

            var ss = new StreamString(pipeClient);
            // Validate the server's signature string.
            if (ss.ReadString() == "I am the one true server!")
            {
                // The client security token is sent with the first
write.
                // Send the name of the file whose contents are returned
                // by the server.
                ss.WriteString("c:\\textfile.txt");

                // Print the file to the screen.
                Console.Write(ss.ReadString());
            }
            else

    private UnicodeEncoding streamEncoding;

    public StreamString(Stream ioStream)
    {
        this.ioStream = ioStream;
        streamEncoding = new UnicodeEncoding();
    }

    public string ReadString()

```

```

{
    int len;
    len = ioStream.ReadByte() * 256;
    len += ioStream.ReadByte();
    var inBuffer = new byte[len];
    ioStream.Read(inBuffer, 0, len);

    return streamEncoding.GetString(inBuffer);
}

public int WriteString(string outString)
{
    byte[] outBuffer = streamEncoding.GetBytes(outString);
    int len = outBuffer.Length;
    if (len > UInt16.MaxValue)
    {
        len = (int)UInt16.MaxValue;
    }
    ioStream.WriteByte((byte)(len / 256));
    ioStream.WriteByte((byte)(len & 255));
    ioStream.Write(outBuffer, 0, len);
    ioStream.Flush();

    return outBuffer.Length + 2;
}
}

```

Robust Programming

The client and server processes in this example are intended to run on the same computer, so the server name provided to the `NamedPipeClientStream` object is `".."`. If the client and server processes were on separate computers, `".."` would be replaced with the network name of the computer that runs the server process.

System.IO.Pipelines in .NET

Article • 12/14/2022

[System.IO.Pipelines](#) is a library that is designed to make it easier to do high-performance I/O in .NET. It's a library targeting .NET Standard that works on all .NET implementations.

The library is available in the [System.IO.Pipelines](#) Nuget package.

What problem does System.IO.Pipelines solve

Apps that parse streaming data are composed of boilerplate code having many specialized and unusual code flows. The boilerplate and special case code is complex and difficult to maintain.

[System.IO.Pipelines](#) was architected to:

- Have high performance parsing streaming data.
- Reduce code complexity.

The following code is typical for a TCP server that receives line-delimited messages (delimited by `'\n'`) from a client:

C#

```
async Task ProcessLinesAsync(NetworkStream stream)
{
    var buffer = new byte[1024];
    await stream.ReadAsync(buffer, 0, buffer.Length);

    // Process a single line from the buffer
    ProcessLine(buffer);
}
```

The preceding code has several problems:

- The entire message (end of line) might not be received in a single call to `ReadAsync`.
- It's ignoring the result of `stream.ReadAsync`. `stream.ReadAsync` returns how much data was read.
- It doesn't handle the case where multiple lines are read in a single `ReadAsync` call.
- It allocates a `byte` array with each read.

To fix the preceding problems, the following changes are required:

- Buffer the incoming data until a new line is found.
- Parse all the lines returned in the buffer.
- It's possible that the line is bigger than 1 KB (1024 bytes). The code needs to resize the input buffer until the delimiter is found in order to fit the complete line inside the buffer.
 - If the buffer is resized, more buffer copies are made as longer lines appear in the input.
 - To reduce wasted space, compact the buffer used for reading lines.
- Consider using buffer pooling to avoid allocating memory repeatedly.
- The following code addresses some of these problems:

C#

```
async Task ProcessLinesAsync(NetworkStream stream)
{
    byte[] buffer = ArrayPool<byte>.Shared.Rent(1024);
    var bytesBuffered = 0;
    var bytesConsumed = 0;

    while (true)
    {
        // Calculate the amount of bytes remaining in the buffer.
        var bytesRemaining = buffer.Length - bytesBuffered;

        if (bytesRemaining == 0)
        {
            // Double the buffer size and copy the previously buffered data
            // into the new buffer.
            var newBuffer = ArrayPool<byte>.Shared.Rent(buffer.Length * 2);
            Buffer.BlockCopy(buffer, 0, newBuffer, 0, buffer.Length);
            // Return the old buffer to the pool.
            ArrayPool<byte>.Shared.Return(buffer);
            buffer = newBuffer;
            bytesRemaining = buffer.Length - bytesBuffered;
        }

        var bytesRead = await stream.ReadAsync(buffer, bytesBuffered,
bytesRemaining);
        if (bytesRead == 0)
        {
            // EOF
            break;
        }

        // Keep track of the amount of buffered bytes.
    }
}
```

```

        bytesBuffered += bytesRead;
        var linePosition = -1;

        do
        {
            // Look for a EOL in the buffered data.
            linePosition = Array.IndexOf(buffer, (byte)'\n', bytesConsumed,
                bytesBuffered - bytesConsumed);

            if (linePosition >= 0)
            {
                // Calculate the length of the line based on the offset.
                var lineLength = linePosition - bytesConsumed;

                // Process the line.
                ProcessLine(buffer, bytesConsumed, lineLength);

                // Move the bytesConsumed to skip past the line consumed
                // (including \n).
                bytesConsumed += lineLength + 1;
            }
        }
        while (linePosition >= 0);
    }
}

```

The previous code is complex and doesn't address all the problems identified. High-performance networking usually means writing complex code to maximize performance. `System.IO.Pipelines` was designed to make writing this type of code easier.

Pipe

The `Pipe` class can be used to create a `PipeWriter/PipeReader` pair. All data written into the `PipeWriter` is available in the `PipeReader`:

C#

```

var pipe = new Pipe();
PipeReader reader = pipe.Reader;
PipeWriter writer = pipe.Writer;

```

Pipe basic usage

C#

```

async Task ProcessLinesAsync(Socket socket)
{

```

```

        var pipe = new Pipe();
        Task writing = FillPipeAsync(socket, pipe.Writer);
        Task reading = ReadPipeAsync(pipe.Reader);

        await Task.WhenAll(reading, writing);
    }

async Task FillPipeAsync(Socket socket, PipeWriter writer)
{
    const int minimumBufferSize = 512;

    while (true)
    {
        // Allocate at least 512 bytes from the PipeWriter.
        Memory<byte> memory = writer.GetMemory(minimumBufferSize);
        try
        {
            int bytesRead = await socket.ReceiveAsync(memory,
SocketFlags.None);
            if (bytesRead == 0)
            {
                break;
            }
            // Tell the PipeWriter how much was read from the Socket.
            writer.Advance(bytesRead);
        }
        catch (Exception ex)
        {
            LogError(ex);
            break;
        }

        // Make the data available to the PipeReader.
        FlushResult result = await writer.FlushAsync();

        if (result.IsCompleted)
        {
            break;
        }
    }

    // By completing PipeWriter, tell the PipeReader that there's no more
    data coming.
    await writer.CompleteAsync();
}

async Task ReadPipeAsync(PipeReader reader)
{
    while (true)
    {
        ReadResult result = await reader.ReadAsync();
        ReadOnlySequence<byte> buffer = result.Buffer;

        while (TryReadLine(ref buffer, out ReadOnlySequence<byte> line))
        {

```

```

        // Process the line.
        ProcessLine(line);
    }

    // Tell the PipeReader how much of the buffer has been consumed.
    reader.AdvanceTo(buffer.Start, buffer.End);

    // Stop reading if there's no more data coming.
    if (result.IsCompleted)
    {
        break;
    }
}

// Mark the PipeReader as complete.
await reader.CompleteAsync();
}

bool TryReadLine(ref ReadOnlySequence<byte> buffer, out
ReadOnlySequence<byte> line)
{
    // Look for a EOL in the buffer.
    SequencePosition? position = buffer.PositionOf((byte)'\n');

    if (position == null)
    {
        line = default;
        return false;
    }

    // Skip the line + the \n.
    line = buffer.Slice(0, position.Value);
    buffer = buffer.Slice(buffer.GetPosition(1, position.Value));
    return true;
}

```

There are two loops:

- `FillPipeAsync` reads from the `Socket` and writes to the `PipeWriter`.
- `ReadPipeAsync` reads from the `PipeReader` and parses incoming lines.

There are no explicit buffers allocated. All buffer management is delegated to the `PipeReader` and `PipeWriter` implementations. Delegating buffer management makes it easier for consuming code to focus solely on the business logic.

In the first loop:

- `PipeWriter.GetMemory(Int32)` is called to get memory from the underlying writer.
- `PipeWriter.Advance(Int32)` is called to tell the `PipeWriter` how much data was written to the buffer.

- `PipeWriter.FlushAsync` is called to make the data available to the `PipeReader`.

In the second loop, the `PipeReader` consumes the buffers written by `PipeWriter`. The buffers come from the socket. The call to `PipeReader.ReadAsync`:

- Returns a `ReadResult` that contains two important pieces of information:
 - The data that was read in the form of `ReadOnlySequence<byte>`.
 - A boolean `IsCompleted` that indicates if the end of data (EOF) has been reached.

After finding the end of line (EOL) delimiter and parsing the line:

- The logic processes the buffer to skip what's already processed.
- `PipeReader.AdvanceTo` is called to tell the `PipeReader` how much data has been consumed and examined.

The reader and writer loops end by calling `Complete`. `Complete` lets the underlying Pipe release the memory it allocated.

Backpressure and flow control

Ideally, reading and parsing work together:

- The reading thread consumes data from the network and puts it in buffers.
- The parsing thread is responsible for constructing the appropriate data structures.

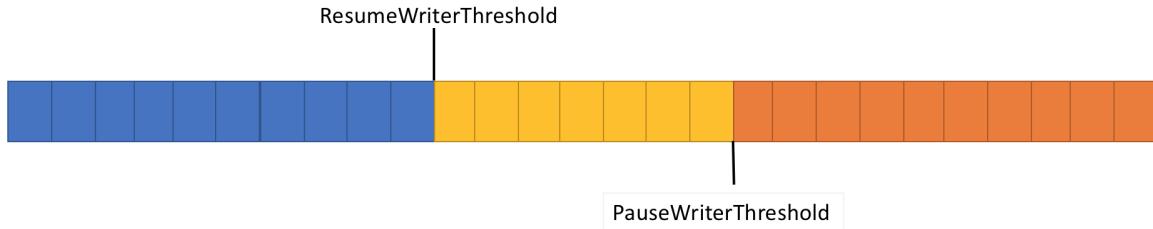

Typically, parsing takes more time than just copying blocks of data from the network:

- The reading thread gets ahead of the parsing thread.
- The reading thread has to either slow down or allocate more memory to store the data for the parsing thread.

For optimal performance, there's a balance between frequent pauses and allocating more memory.

To solve the preceding problem, the `Pipe` has two settings to control the flow of data:

- `PauseWriterThreshold`: Determines how much data should be buffered before calls to `FlushAsync` pause.
- `ResumeWriterThreshold`: Determines how much data the reader has to observe before calls to `PipeWriter.FlushAsync` resume.

PipeWriter.FlushAsync:

- Returns an incomplete `ValueTask<FlushResult>` when the amount of data in the `Pipe` crosses `PauseWriterThreshold`.
- Completes `ValueTask<FlushResult>` when it becomes lower than `ResumeWriterThreshold`.

Two values are used to prevent rapid cycling, which can occur if one value is used.

Examples

C#

```
// The Pipe will start returning incomplete tasks from FlushAsync until
// the reader examines at least 5 bytes.
var options = new PipeOptions(pauseWriterThreshold: 10,
resumeWriterThreshold: 5);
var pipe = new Pipe(options);
```

PipeScheduler

Typically when using `async` and `await`, asynchronous code resumes on either a `TaskScheduler` or the current `SynchronizationContext`.

When doing I/O, it's important to have fine-grained control over where the I/O is performed. This control allows taking advantage of CPU caches effectively. Efficient caching is critical for high-performance apps like web servers. `PipeScheduler` provides control over where asynchronous callbacks run. By default:

- The current `SynchronizationContext` is used.
- If there's no `SynchronizationContext`, it uses the thread pool to run callbacks.

C#

```
public static void Main(string[] args)
{
```

```

var writeScheduler = new SingleThreadPipeScheduler();
var readScheduler = new SingleThreadPipeScheduler();

// Tell the Pipe what schedulers to use and disable the
SynchronizationContext.
var options = new PipeOptions(readerScheduler: readScheduler,
                               writerScheduler: writeScheduler,
                               useSynchronizationContext: false);
var pipe = new Pipe(options);
}

// This is a sample scheduler that async callbacks on a single dedicated
thread.
public class SingleThreadPipeScheduler : PipeScheduler
{
    private readonly BlockingCollection<(Action<object> Action, object
State)> _queue =
    new BlockingCollection<(Action<object> Action, object State)>();
    private readonly Thread _thread;

    public SingleThreadPipeScheduler()
    {
        _thread = new Thread(DoWork);
        _thread.Start();
    }

    private void DoWork()
    {
        foreach (var item in _queue.GetConsumingEnumerable())
        {
            item.Action(item.State);
        }
    }

    public override void Schedule(Action<object?> action, object? state)
    {
        if (state is not null)
        {
            _queue.Add((action, state));
        }
        // else log the fact that _queue.Add was not called.
    }
}

```

`PipeScheduler.ThreadPool` is the `PipeScheduler` implementation that queues callbacks to the thread pool. `PipeScheduler.ThreadPool` is the default and generally the best choice. `PipeScheduler.Inline` can cause unintended consequences such as deadlocks.

Pipe reset

It's frequently efficient to reuse the `Pipe` object. To reset the pipe, call `PipeReader.Reset` when both the `PipeReader` and `PipeWriter` are complete.

PipeReader

`PipeReader` manages memory on the caller's behalf. Always call `PipeReader.AdvanceTo` after calling `PipeReader.ReadAsync`. This lets the `PipeReader` know when the caller is done with the memory so that it can be tracked. The `ReadOnlySequence<byte>` returned from `PipeReader.ReadAsync` is only valid until the call the `PipeReader.AdvanceTo`. It's illegal to use `ReadOnlySequence<byte>` after calling `PipeReader.AdvanceTo`.

`PipeReader.AdvanceTo` takes two `SequencePosition` arguments:

- The first argument determines how much memory was consumed.
- The second argument determines how much of the buffer was observed.

Marking data as consumed means that the pipe can return the memory to the underlying buffer pool. Marking data as observed controls what the next call to `PipeReader.ReadAsync` does. Marking everything as observed means that the next call to `PipeReader.ReadAsync` won't return until there's more data written to the pipe. Any other value will make the next call to `PipeReader.ReadAsync` return immediately with the observed *and* unobserved data, but not data that has already been consumed.

Read streaming data scenarios

There are a couple of typical patterns that emerge when trying to read streaming data:

- Given a stream of data, parse a single message.
- Given a stream of data, parse all available messages.

The following examples use the `TryParseLines` method for parsing messages from a `ReadOnlySequence<byte>`. `TryParseLines` parses a single message and updates the input buffer to trim the parsed message from the buffer. `TryParseLines` isn't part of .NET, it's a user written method used in the following sections.

C#

```
bool TryParseLines(ref ReadOnlySequence<byte> buffer, out Message message);
```

Read a single message

The following code reads a single message from a `PipeReader` and returns it to the caller.

C#

```
async ValueTask<Message?> ReadSingleMessageAsync(PipeReader reader,
    CancellationToken cancellationToken = default)
{
    while (true)
    {
        ReadResult result = await reader.ReadAsync(cancellationToken);
        ReadOnlySequence<byte> buffer = result.Buffer;

        // In the event that no message is parsed successfully, mark
        consumed
        // as nothing and examined as the entire buffer.
        SequencePosition consumed = buffer.Start;
        SequencePosition examined = buffer.End;

        try
        {
            if (TryParseLines(ref buffer, out Message message))
            {
                // A single message was successfully parsed so mark the
                start of the
                // parsed buffer as consumed. TryParseLines trims the buffer
                to
                // point to the data after the message was parsed.
                consumed = buffer.Start;

                // Examined is marked the same as consumed here, so the next
                call
                // to ReadSingleMessageAsync will process the next message
                if there's
                // one.
                examined = consumed;

                return message;
            }

            // There's no more data to be processed.
            if (result.IsCompleted)
            {
                if (buffer.Length > 0)
                {
                    // The message is incomplete and there's no more data to
                    process.
                    throw new InvalidDataException("Incomplete message.");
                }

                break;
            }
        }
        finally
```

```
        {
            reader.AdvanceTo(consumed, examined);
        }
    }

    return null;
}
```

The preceding code:

- Parses a single message.
- Updates the consumed `SequencePosition` and examined `SequencePosition` to point to the start of the trimmed input buffer.

The two `SequencePosition` arguments are updated because `TryParseLines` removes the parsed message from the input buffer. Generally, when parsing a single message from the buffer, the examined position should be one of the following:

- The end of the message.
- The end of the received buffer if no message was found.

The single message case has the most potential for errors. Passing the wrong values to `examined` can result in an out of memory exception or an infinite loop. For more information, see the [PipeReader common problems](#) section in this article.

Reading multiple messages

The following code reads all messages from a `PipeReader` and calls `ProcessMessageAsync` on each.

C#

```
async Task ProcessMessagesAsync(PipeReader reader, CancellationToken cancellationToken = default)
{
    try
    {
        while (true)
        {
            ReadResult result = await reader.ReadAsync(cancellationToken);
            ReadOnlySequence<byte> buffer = result.Buffer;

            try
            {
                // Process all messages from the buffer, modifying the input
                // buffer on each
                // iteration.
                while (TryParseLines(ref buffer, out Message message))

```

```

        {
            await ProcessMessageAsync(message);
        }

        // There's no more data to be processed.
        if (result.IsCompleted)
        {
            if (buffer.Length > 0)
            {
                // The message is incomplete and there's no more
                data to process.
                throw new InvalidDataException("Incomplete
message.");
            }
            break;
        }
    }
    finally
    {
        // Since all messages in the buffer are being processed, you
        can use the
        // remaining buffer's Start and End position to determine
        consumed and examined.
        reader.AdvanceTo(buffer.Start, buffer.End);
    }
}
finally
{
    await reader.CompleteAsync();
}
}

```

Cancellation

PipeReader.ReadAsync:

- Supports passing a `CancellationToken`.
- Throws an `OperationCanceledException` if the `CancellationToken` is canceled while there's a read pending.
- Supports a way to cancel the current read operation via `PipeReader.CancelPendingRead`, which avoids raising an exception. Calling `PipeReader.CancelPendingRead` causes the current or next call to `PipeReader.ReadAsync` to return a `ReadResult` with `IsCanceled` set to `true`. This can be useful for halting the existing read loop in a non-destructive and non-exceptional way.

```
private PipeReader reader;

public MyConnection(PipeReader reader)
{
    this.reader = reader;
}

public void Abort()
{
    // Cancel the pending read so the process loop ends without an
    // exception.
    reader.CancelPendingRead();
}

public async Task ProcessMessagesAsync()
{
    try
    {
        while (true)
        {
            ReadResult result = await reader.ReadAsync();
            ReadOnlySequence<byte> buffer = result.Buffer;

            try
            {
                if (result.IsCanceled)
                {
                    // The read was canceled. You can quit without reading
                    // the existing data.
                    break;
                }

                // Process all messages from the buffer, modifying the input
                // buffer on each
                // iteration.
                while (TryParseLines(ref buffer, out Message message))
                {
                    await ProcessMessageAsync(message);
                }

                // There's no more data to be processed.
                if (result.IsCompleted)
                {
                    break;
                }
            }
            finally
            {
                // Since all messages in the buffer are being processed, you
                // can use the
                // remaining buffer's Start and End position to determine
                // consumed and examined.
                reader.AdvanceTo(buffer.Start, buffer.End);
            }
        }
    }
}
```

```
        }
    }
    finally
    {
        await reader.CompleteAsync();
    }
}
```

PipeReader common problems

- Passing the wrong values to `consumed` or `examined` may result in reading already read data.
- Passing `buffer.End` as examined may result in:
 - Stalled data
 - Possibly an eventual Out of Memory (OOM) exception if data isn't consumed.
For example, `PipeReader.AdvanceTo(position, buffer.End)` when processing a single message at a time from the buffer.
- Passing the wrong values to `consumed` or `examined` may result in an infinite loop.
For example, `PipeReader.AdvanceTo(buffer.Start)` if `buffer.Start` hasn't changed will cause the next call to `PipeReader.ReadAsync` to return immediately before new data arrives.
- Passing the wrong values to `consumed` or `examined` may result in infinite buffering (eventual OOM).
- Using the `ReadOnlySequence<byte>` after calling `PipeReader.AdvanceTo` may result in memory corruption (use after free).
- Failing to call `PipeReader.Complete/CompleteAsync` may result in a memory leak.
- Checking `ReadResult.IsCompleted` and exiting the reading logic before processing the buffer results in data loss. The loop exit condition should be based on `ReadResult.Buffer.IsEmpty` and `ReadResult.IsCompleted`. Doing this incorrectly could result in an infinite loop.

Problematic code

✖ Data loss

The `ReadResult` can return the final segment of data when `IsCompleted` is set to `true`. Not reading that data before exiting the read loop will result in data loss.

⚠ Warning

Do **NOT** use the following code. Using this sample will result in data loss, hangs, security issues and should **NOT** be copied. The following sample is provided to explain **PipeReader Common problems**.

C#

```
Environment.FailFast("This code is terrible, don't use it!");
while (true)
{
    ReadResult result = await reader.ReadAsync(cancellationToken);
    ReadOnlySequence<byte> dataLossBuffer = result.Buffer;

    if (result.IsCompleted)
        break;

    Process(ref dataLossBuffer, out Message message);

    reader.AdvanceTo(dataLossBuffer.Start, dataLossBuffer.End);
}
```

⚠ Warning

Do **NOT** use the preceding code. Using this sample will result in data loss, hangs, security issues and should **NOT** be copied. The preceding sample is provided to explain **PipeReader Common problems**.

✖ Infinite loop

The following logic may result in an infinite loop if the `Result.IsCompleted` is `true` but there's never a complete message in the buffer.

⚠ Warning

Do **NOT** use the following code. Using this sample will result in data loss, hangs, security issues and should **NOT** be copied. The following sample is provided to explain **PipeReader Common problems**.

C#

```
Environment.FailFast("This code is terrible, don't use it!");
while (true)
```

```
{  
    ReadResult result = await reader.ReadAsync(cancellationToken);  
    ReadOnlySequence<byte> infiniteLoopBuffer = result.Buffer;  
    if (result.IsCompleted && infiniteLoopBuffer.IsEmpty)  
        break;  
  
    Process(ref infiniteLoopBuffer, out Message message);  
  
    reader.AdvanceTo(infiniteLoopBuffer.Start, infiniteLoopBuffer.End);  
}
```

⚠ Warning

Do **NOT** use the preceding code. Using this sample will result in data loss, hangs, security issues and should **NOT** be copied. The preceding sample is provided to explain [PipeReader Common problems](#).

Here's another piece of code with the same problem. It's checking for a non-empty buffer before checking `ReadResult.IsCompleted`. Because it's in an `else if`, it will loop forever if there's never a complete message in the buffer.

⚠ Warning

Do **NOT** use the following code. Using this sample will result in data loss, hangs, security issues and should **NOT** be copied. The following sample is provided to explain [PipeReader Common problems](#).

C#

```
Environment.FailFast("This code is terrible, don't use it!");  
while (true)  
{  
    ReadResult result = await reader.ReadAsync(cancellationToken);  
    ReadOnlySequence<byte> infiniteLoopBuffer = result.Buffer;  
  
    if (!infiniteLoopBuffer.IsEmpty)  
        Process(ref infiniteLoopBuffer, out Message message);  
  
    else if (result.IsCompleted)  
        break;  
  
    reader.AdvanceTo(infiniteLoopBuffer.Start, infiniteLoopBuffer.End);  
}
```

⚠ Warning

Do NOT use the preceding code. Using this sample will result in data loss, hangs, security issues and should NOT be copied. The preceding sample is provided to explain **PipeReader Common problems**.

✖ Unresponsive application

Unconditionally calling `PipeReader.AdvanceTo` with `buffer.End` in the `examined` position may result in the application becoming unresponsive when parsing a single message. The next call to `PipeReader.AdvanceTo` won't return until:

- There's more data written to the pipe.
- And the new data wasn't previously examined.

⚠ Warning

Do NOT use the following code. Using this sample will result in data loss, hangs, security issues and should NOT be copied. The following sample is provided to explain **PipeReader Common problems**.

C#

```
Environment.FailFast("This code is terrible, don't use it!");
while (true)
{
    ReadResult result = await reader.ReadAsync(cancellationToken);
    ReadOnlySequence<byte> hangBuffer = result.Buffer;

    Process(ref hangBuffer, out Message message);

    if (result.IsCompleted)
        break;

    reader.AdvanceTo(hangBuffer.Start, hangBuffer.End);

    if (message != null)
        return message;
}
```

⚠ Warning

Do NOT use the preceding code. Using this sample will result in data loss, hangs, security issues and should NOT be copied. The preceding sample is provided to explain **PipeReader Common problems**.

✖ Out of Memory (OOM)

With the following conditions, the following code keeps buffering until an [OutOfMemoryException](#) occurs:

- There's no maximum message size.
- The data returned from the `PipeReader` doesn't make a complete message. For example, it doesn't make a complete message because the other side is writing a large message (For example, a 4-GB message).

⚠ Warning

Do **NOT** use the following code. Using this sample will result in data loss, hangs, security issues and should **NOT** be copied. The following sample is provided to explain [PipeReader Common problems](#).

C#

```
Environment.FailFast("This code is terrible, don't use it!");
while (true)
{
    ReadResult result = await reader.ReadAsync(cancellationToken);
    ReadOnlySequence<byte> thisCouldOutOfMemory = result.Buffer;

    Process(ref thisCouldOutOfMemory, out Message message);

    if (result.IsCompleted)
        break;

    reader.AdvanceTo(thisCouldOutOfMemory.Start, thisCouldOutOfMemory.End);

    if (message != null)
        return message;
}
```

⚠ Warning

Do **NOT** use the preceding code. Using this sample will result in data loss, hangs, security issues and should **NOT** be copied. The preceding sample is provided to explain [PipeReader Common problems](#).

✖ Memory Corruption

When writing helpers that read the buffer, any returned payload should be copied before calling `Advance`. The following example will return memory that the `Pipe` has

discarded and may reuse it for the next operation (read/write).

⚠ Warning

Do **NOT** use the following code. Using this sample will result in data loss, hangs, security issues and should **NOT** be copied. The following sample is provided to explain **PipeReader Common problems**.

C#

```
public class Message
{
    public ReadOnlySequence<byte> CorruptedPayload { get; set; }
}
```

C#

```
Environment.FailFast("This code is terrible, don't use it!");
Message message = null;

while (true)
{
    ReadResult result = await reader.ReadAsync(cancellationToken);
    ReadOnlySequence<byte> buffer = result.Buffer;

    ReadHeader(ref buffer, out int length);

    if (length <= buffer.Length)
    {
        message = new Message
        {
            // Slice the payload from the existing buffer
            CorruptedPayload = buffer.Slice(0, length)
        };

        buffer = buffer.Slice(length);
    }

    if (result.IsCompleted)
        break;

    reader.AdvanceTo(buffer.Start, buffer.End);

    if (message != null)
    {
        // This code is broken since reader.AdvanceTo() was called with
        // a position *after* the buffer
        // was captured.
        break;
    }
}
```

```
    }

    return message;
}
```

⚠ Warning

Do NOT use the preceding code. Using this sample will result in data loss, hangs, security issues and should NOT be copied. The preceding sample is provided to explain **PipeReader Common problems**.

PipeWriter

The [PipeWriter](#) manages buffers for writing on the caller's behalf. `PipeWriter` implements `IBufferWriter<byte>`. `IBufferWriter<byte>` makes it possible to get access to buffers to perform writes without extra buffer copies.

C#

```
async Task WriteHelloAsync(PipeWriter writer, CancellationToken cancellationToken = default)
{
    // Request at least 5 bytes from the PipeWriter.
    Memory<byte> memory = writer.GetMemory(5);

    // Write directly into the buffer.
    int written = Encoding.ASCII.GetBytes("Hello".AsSpan(), memory.Span);

    // Tell the writer how many bytes were written.
    writer.Advance(written);

    await writer.FlushAsync(cancellationToken);
}
```

The previous code:

- Requests a buffer of at least 5 bytes from the `PipeWriter` using [GetMemory](#).
- Writes bytes for the ASCII string `"Hello"` to the returned `Memory<byte>`.
- Calls [Advance](#) to indicate how many bytes were written to the buffer.
- Flushes the `PipeWriter`, which sends the bytes to the underlying device.

The previous method of writing uses the buffers provided by the `PipeWriter`. It could also have used [PipeWriter.WriteAsync](#), which:

- Copies the existing buffer to the `PipeWriter`.
- Calls `GetSpan`, `Advance` as appropriate and calls `FlushAsync`.

C#

```
async Task WriteHelloAsync(PipeWriter writer, CancellationToken cancellationToken = default)
{
    byte[] helloBytes = Encoding.ASCII.GetBytes("Hello");

    // Write helloBytes to the writer, there's no need to call Advance here
    // (Write does that).
    await writer.WriteAsync(helloBytes, cancellationToken);
}
```

Cancellation

`FlushAsync` supports passing a `CancellationToken`. Passing a `CancellationToken` results in an `OperationCanceledException` if the token is canceled while there's a flush pending. `PipeWriter.FlushAsync` supports a way to cancel the current flush operation via `PipeWriter.CancelPendingFlush` without raising an exception. Calling `PipeWriter.CancelPendingFlush` causes the current or next call to `PipeWriter.FlushAsync` or `PipeWriter.WriteAsync` to return a `FlushResult` with `IsCanceled` set to `true`. This can be useful for halting the yielding flush in a non-destructive and non-exceptional way.

PipeWriter common problems

- `GetSpan` and `GetMemory` return a buffer with at least the requested amount of memory. **Don't** assume exact buffer sizes.
- There's no guarantee that successive calls will return the same buffer or the same-sized buffer.
- A new buffer must be requested after calling `Advance` to continue writing more data. The previously acquired buffer can't be written to.
- Calling `GetMemory` or `GetSpan` while there's an incomplete call to `FlushAsync` isn't safe.
- Calling `Complete` or `CompleteAsync` while there's unflushed data can result in memory corruption.

Tips for using PipeReader and PipeWriter

The following tips will help you use the `System.IO.Pipelines` classes successfully:

- Always complete the `PipeReader` and `PipeWriter`, including an exception where applicable.
- Always call `PipeReader.AdvanceTo` after calling `PipeReader.ReadAsync`.
- Periodically `await PipeWriter.FlushAsync` while writing, and always check `FlushResult.IsCompleted`. Abort writing if `IsCompleted` is `true`, as that indicates the reader is completed and no longer cares about what is written.
- Do call `PipeWriter.FlushAsync` after writing something that you want the `PipeReader` to have access to.
- Do not call `FlushAsync` if the reader can't start until `FlushAsync` finishes, as that may cause a deadlock.
- Ensure that only one context "owns" a `PipeReader` or `PipeWriter` or accesses them. These types are not thread-safe.
- Never access a `ReadResult.Buffer` after calling `AdvanceTo` or completing the `PipeReader`.

IDuplexPipe

The `IDuplexPipe` is a contract for types that support both reading and writing. For example, a network connection would be represented by an `IDuplexPipe`.

Unlike `Pipe`, which contains a `PipeReader` and a `PipeWriter`, `IDuplexPipe` represents a single side of a full duplex connection. That means what is written to the `PipeWriter` will not be read from the `PipeReader`.

Streams

When reading or writing stream data, you typically read data using a de-serializer and write data using a serializer. Most of these read and write stream APIs have a `Stream` parameter. To make it easier to integrate with these existing APIs, `PipeReader` and `PipeWriter` expose an `AsStream` method. `AsStream` returns a `Stream` implementation around the `PipeReader` or `PipeWriter`.

Stream example

`PipeReader` and `PipeWriter` instances can be created using the static `Create` methods given a `Stream` object and optional corresponding creation options.

The `StreamPipeReaderOptions` allow for control over the creation of the `PipeReader` instance with the following parameters:

- `StreamPipeReaderOptions.BufferSize` is the minimum buffer size in bytes used when renting memory from the pool, and defaults to `4096`.
- `StreamPipeReaderOptions.LeaveOpen` flag determines whether or not the underlying stream is left open after the `PipeReader` completes, and defaults to `false`.
- `StreamPipeReaderOptions.MinimumReadSize` represents the threshold of remaining bytes in the buffer before a new buffer is allocated, and defaults to `1024`.
- `StreamPipeReaderOptions.Pool` is the `MemoryPool<byte>` used when allocating memory, and defaults to `null`.

The `StreamPipeWriterOptions` allow for control over the creation of the `PipeWriter` instance with the following parameters:

- `StreamPipeWriterOptions.LeaveOpen` flag determines whether or not the underlying stream is left open after the `PipeWriter` completes, and defaults to `false`.
- `StreamPipeWriterOptions.MinimumBufferSize` represents the minimum buffer size to use when renting memory from the `Pool`, and defaults to `4096`.
- `StreamPipeWriterOptions.Pool` is the `MemoryPool<byte>` used when allocating memory, and defaults to `null`.

Important

When creating `PipeReader` and `PipeWriter` instances using the `Create` methods, you need to consider the `Stream` object lifetime. If you need access to the stream after the reader or writer is done with it, you'll need to set the `LeaveOpen` flag to `true` on the creation options. Otherwise, the stream will be closed.

The following code demonstrates the creation of `PipeReader` and `PipeWriter` instances using the `Create` methods from a stream.

C#

```
using System.Buffers;
using System.IO.Pipelines;
using System.Text;

class Program
{
    static async Task Main()
    {
```

```
using var stream = File.OpenRead("lorem-ipsum.txt");

var reader = PipeReader.Create(stream);
var writer = PipeWriter.Create(
    Console.OpenStandardOutput(),
    new StreamPipeWriterOptions(leaveOpen: true));

WriteUserCancellationPrompt();

var processMessagesTask = ProcessMessagesAsync(reader, writer);
var userCanceled = false;
var cancelProcessingTask = Task.Run(() =>
{
    while (char.ToUpperInvariant(Console.ReadKey().KeyChar) != 'C')
    {
        WriteUserCancellationPrompt();
    }

    userCanceled = true;

    // No exceptions thrown
    reader.CancelPendingRead();
    writer.CancelPendingFlush();
});

await Task.WhenAny(cancelProcessingTask, processMessagesTask);

Console.WriteLine(
    $"\\n\\nProcessing {(userCanceled ? "cancelled" : "completed")}.\\n");
}

static void WriteUserCancellationPrompt() =>
Console.WriteLine("Press 'C' to cancel processing...\\n");

static async Task ProcessMessagesAsync(
    PipeReader reader,
    PipeWriter writer)
{
    try
    {
        while (true)
        {
            ReadResult readResult = await reader.ReadAsync();
            ReadOnlySequence<byte> buffer = readResult.Buffer;

            try
            {
                if (readResult.IsCanceled)
                {
                    break;
                }

                if (TryParseLines(ref buffer, out string message))
                {

```

```

        FlushResult flushResult =
            await WriteMessagesAsync(writer, message);

        if (flushResult.IsCanceled ||
flushResult.IsCompleted)
        {
            break;
        }

        if (readResult.IsCompleted)
        {
            if (!buffer.IsEmpty)
            {
                throw new InvalidDataException("Incomplete
message.");
            }
            break;
        }
    }
    finally
    {
        reader.AdvanceTo(buffer.Start, buffer.End);
    }
}
}

catch (Exception ex)
{
    Console.Error.WriteLine(ex);
}
finally
{
    await reader.CompleteAsync();
    await writer.CompleteAsync();
}
}

static bool TryParseLines(
    ref ReadOnlySequence<byte> buffer,
    out string message)
{
    SequencePosition? position;
    StringBuilder outputMessage = new();

    while(true)
    {
        position = buffer.PositionOf((byte)'\n');

        if (!position.HasValue)
            break;

        outputMessage.Append(Encoding.ASCII.GetString(buffer.Slice(buffer.Start,
position.Value)))
                    .AppendLine();
    }
}

```

```
        buffer = buffer.Slice(buffer.GetPosition(1, position.Value));
    };

    message = outputMessage.ToString();
    return message.Length != 0;
}

static ValueTask<FlushResult> WriteMessagesAsync(
    PipeWriter writer,
    string message) =>
    writer.WriteAsync(Encoding.ASCII.GetBytes(message));
}
```

The application uses a [StreamReader](#) to read the *lorem-ipsum.txt* file as a stream, and it must end with a blank line. The [FileStream](#) is passed to [PipeReader.Create](#), which instantiates a [PipeReader](#) object. The console application then passes its standard output stream to [PipeWriter.Create](#) using [Console.OpenStandardOutput\(\)](#). The example supports [cancellation](#).

Work with Buffers in .NET

Article • 02/08/2023

This article provides an overview of types that help read data that runs across multiple buffers. They're primarily used to support [PipeReader](#) objects.

IBufferWriter<T>

[System.Buffers.IBufferWriter<T>](#) is a contract for synchronous buffered writing. At the lowest level, the interface:

- Is basic and not difficult to use.
- Allows access to a [Memory<T>](#) or [Span<T>](#). The [Memory<T>](#) or [Span<T>](#) can be written to and you can determine how many [T](#) items were written.

C#

```
void WriteHello(IBufferWriter<byte> writer)
{
    // Request at least 5 bytes.
    Span<byte> span = writer.GetSpan(5);
    ReadOnlySpan<char> helloSpan = "Hello".AsSpan();
    int written = Encoding.ASCII.GetBytes(helloSpan, span);

    // Tell the writer how many bytes were written.
    writer.Advance(written);
}
```

The preceding method:

- Requests a buffer of at least 5 bytes from the [IBufferWriter<byte>](#) using [GetSpan\(5\)](#).
- Writes bytes for the ASCII string "Hello" to the returned [Span<byte>](#).
- Calls [IBufferWriter<T>](#) to indicate how many bytes were written to the buffer.

This method of writing uses the [Memory<T>/Span<T>](#) buffer provided by the [IBufferWriter<T>](#). Alternatively, the [Write](#) extension method can be used to copy an existing buffer to the [IBufferWriter<T>](#). [Write](#) does the work of calling [GetSpan](#)/[Advance](#) as appropriate, so there's no need to call [Advance](#) after writing:

C#

```

void WriteHello(IBufferWriter<byte> writer)
{
    byte[] helloBytes = Encoding.ASCII.GetBytes("Hello");

    // Write helloBytes to the writer. There's no need to call Advance here
    // since Write calls Advance.
    writer.Write(helloBytes);
}

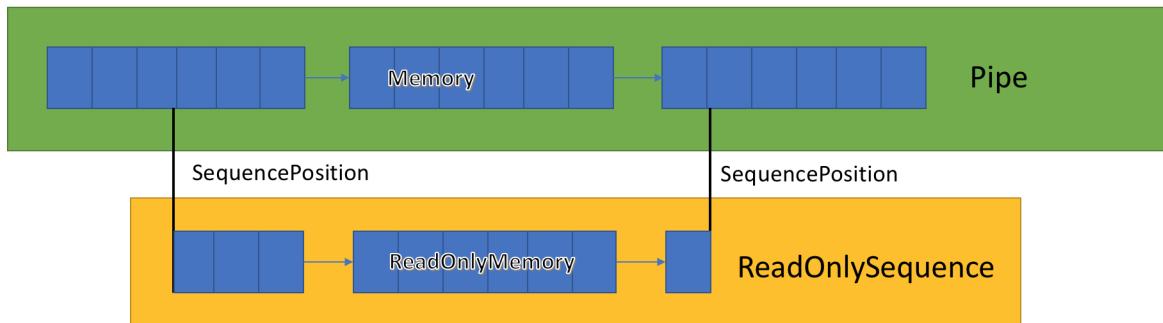

```

`ArrayBufferWriter<T>` is an implementation of `IBufferWriter<T>` whose backing store is a single contiguous array.

IBufferWriter common problems

- `GetSpan` and `GetMemory` return a buffer with at least the requested amount of memory. Don't assume exact buffer sizes.
- There's no guarantee that successive calls will return the same buffer or the same-sized buffer.
- A new buffer must be requested after calling `Advance` to continue writing more data. A previously acquired buffer cannot be written to after `Advance` has been called.

ReadOnlySequence<T>

`ReadOnlySequence<T>` is a struct that can represent a contiguous or noncontiguous sequence of `T`. It can be constructed from:

1. A `T[]`
2. A `ReadOnlyMemory<T>`
3. A pair of linked list node `ReadOnlySequenceSegment<T>` and index to represent the start and end position of the sequence.

The third representation is the most interesting one as it has performance implications on various operations on the `ReadOnlySequence<T>`:

| Representation | Operation | Complexity |
|---|--|--|
| <code>T[] / ReadOnlyMemory<T></code> | <code>Length</code> | <code>O(1)</code> |
| <code>T[] / ReadOnlyMemory<T></code> | <code>GetPosition(long)</code> | <code>O(1)</code> |
| <code>T[] / ReadOnlyMemory<T></code> | <code>Slice(int, int)</code> | <code>O(1)</code> |
| <code>T[] / ReadOnlyMemory<T></code> | <code>Slice(SequencePosition, SequencePosition)</code> | <code>O(1)</code> |
| <code>ReadOnlySequenceSegment<T></code> | <code>Length</code> | <code>O(1)</code> |
| <code>ReadOnlySequenceSegment<T></code> | <code>GetPosition(long)</code> | <code>O(number of segments)</code> |
| <code>ReadOnlySequenceSegment<T></code> | <code>Slice(int, int)</code> | <code>O(number of segments)</code> |
| <code>ReadOnlySequenceSegment<T></code> | <code>Slice(SequencePosition, SequencePosition)</code> | <code>O(1)</code> |

Because of this mixed representation, the `ReadOnlySequence<T>` exposes indexes as `SequencePosition` instead of an integer. A `SequencePosition`:

- Is an opaque value that represents an index into the `ReadOnlySequence<T>` where it originated.
- Consists of two parts, an integer and an object. What these two values represent are tied to the implementation of `ReadOnlySequence<T>`.

Access data

The `ReadOnlySequence<T>` exposes data as an enumerable of `ReadOnlyMemory<T>`. Enumerating each of the segments can be done using a basic foreach:

C#

```
long FindIndexOf(in ReadOnlySequence<byte> buffer, byte data)
{
    long position = 0;

    foreach (ReadOnlyMemory<byte> segment in buffer)
    {
        ReadOnlySpan<byte> span = segment.Span;
```

```

        var index = span.IndexOf(data);
        if (index != -1)
        {
            return position + index;
        }

        position += span.Length;
    }

    return -1;
}

```

The preceding method searches each segment for a specific byte. If you need to keep track of each segment's `SequencePosition`, `ReadOnlySequence<T>.TryGet` is more appropriate. The next sample changes the preceding code to return a `SequencePosition` instead of an integer. Returning a `SequencePosition` has the benefit of allowing the caller to avoid a second scan to get the data at a specific index.

C#

```

SequencePosition? FindIndexOf(in ReadOnlySequence<byte> buffer, byte data)
{
    SequencePosition position = buffer.Start;
    SequencePosition result = position;

    while (buffer.TryGet(ref position, out ReadOnlyMemory<byte> segment))
    {
        ReadOnlySpan<byte> span = segment.Span;
        var index = span.IndexOf(data);
        if (index != -1)
        {
            return buffer.GetPosition(index, result);
        }

        result = position;
    }
    return null;
}

```

The combination of `SequencePosition` and `TryGet` acts like an enumerator. The `position` field is modified at the start of each iteration to be start of each segment within the `ReadOnlySequence<T>`.

The preceding method exists as an extension method on `ReadOnlySequence<T>`. `PositionOf` can be used to simplify the preceding code:

C#

```
SequencePosition? FindIndex0f(in ReadOnlySequence<byte> buffer, byte data)
=> buffer.PositionOf(data);
```

Process a `ReadOnlySequence<T>`

Processing a `ReadOnlySequence<T>` can be challenging since data may be split across multiple segments within the sequence. For the best performance, split code into two paths:

- A fast path that deals with the single segment case.
- A slow path that deals with the data split across segments.

There are a few approaches that can be used to process data in multi-segmented sequences:

- Use the `SequenceReader<T>`.
- Parse data segment by segment, keeping track of the `SequencePosition` and index within the segment parsed. This avoids unnecessary allocations but may be inefficient, especially for small buffers.
- Copy the `ReadOnlySequence<T>` to a contiguous array and treat it like a single buffer:
 - If the size of the `ReadOnlySequence<T>` is small, it may be reasonable to copy the data into a stack-allocated buffer using the `stackalloc` operator.
 - Copy the `ReadOnlySequence<T>` into a pooled array using `ArrayPool<T>.Shared`.
 - Use `ReadOnlySequence<T>.ToArray()`. This isn't recommended in hot paths as it allocates a new `T[]` on the heap.

The following examples demonstrate some common cases for processing

`ReadOnlySequence<byte>`:

Process binary data

The following example parses a 4-byte big-endian integer length from the start of the `ReadOnlySequence<byte>`.

C#

```
bool TryParseHeaderLength(ref ReadOnlySequence<byte> buffer, out int length)
{
    // If there's not enough space, the length can't be obtained.
    if (buffer.Length < 4)
    {
```

```

        length = 0;
        return false;
    }

    // Grab the first 4 bytes of the buffer.
    var lengthSlice = buffer.Slice(buffer.Start, 4);
    if (lengthSlice.IsSingleSegment)
    {
        // Fast path since it's a single segment.
        length =
BinaryPrimitives.ReadInt32BigEndian(lengthSlice.First.Span);
    }
    else
    {
        // There are 4 bytes split across multiple segments. Since it's so
        small, it
            // can be copied to a stack allocated buffer. This avoids a heap
        allocation.
        Span<byte> stackBuffer = stackalloc byte[4];
        lengthSlice.CopyTo(stackBuffer);
        length = BinaryPrimitives.ReadInt32BigEndian(stackBuffer);
    }

    // Move the buffer 4 bytes ahead.
    buffer = buffer.Slice(lengthSlice.End);

    return true;
}

```

Process text data

The following example:

- Finds the first newline (\r\n) in the `ReadOnlySequence<byte>` and returns it via the `out 'line'` parameter.
- Trims that line, excluding the `\r\n` from the input buffer.

C#

```

static bool TryParseLine(ref ReadOnlySequence<byte> buffer, out
ReadOnlySequence<byte> line)
{
    SequencePosition position = buffer.Start;
    SequencePosition previous = position;
    var index = -1;
    line = default;

    while (buffer.TryGet(ref position, out ReadOnlyMemory<byte> segment))
    {
        ReadOnlySpan<byte> span = segment.Span;

```

```

    // Look for \r in the current segment.
    index = span.IndexOf((byte)'\r');

    if (index != -1)
    {
        // Check next segment for \n.
        if (index + 1 >= span.Length)
        {
            var next = position;
            if (!buffer.TryGet(ref next, out ReadOnlyMemory<byte>
nextSegment))
            {
                // You're at the end of the sequence.
                return false;
            }
            else if (nextSegment.Span[0] == (byte)'\n')
            {
                // A match was found.
                break;
            }
        }
        // Check the current segment of \n.
        else if (span[index + 1] == (byte)'\n')
        {
            // It was found.
            break;
        }
    }

    previous = position;
}

if (index != -1)
{
    // Get the position just before the \r\n.
    var delimiter = buffer.GetPosition(index, previous);

    // Slice the line (excluding \r\n).
    line = buffer.Slice(buffer.Start, delimiter);

    // Slice the buffer to get the remaining data after the line.
    buffer = buffer.Slice(buffer.GetPosition(2, delimiter));
    return true;
}

return false;
}

```

Empty segments

It's valid to store empty segments inside of a `ReadOnlySequence<T>`. Empty segments may occur while enumerating segments explicitly:

C#

```
static void EmptySegments()
{
    // This logic creates a ReadOnlySequence<byte> with 4 segments,
    // two of which are empty.
    var first = new BufferSegment(new byte[0]);
    var last = first.Append(new byte[] { 97 })
        .Append(new byte[0]).Append(new byte[] { 98 });

    // Construct the ReadOnlySequence<byte> from the linked list segments.
    var data = new ReadOnlySequence<byte>(first, 0, last, 1);

    // Slice using numbers.
    var sequence1 = data.Slice(0, 2);

    // Slice using SequencePosition pointing at the empty segment.
    var sequence2 = data.Slice(data.Start, 2);

    Console.WriteLine($"sequence1.Length={sequence1.Length}"); // sequence1.Length=2
    Console.WriteLine($"sequence2.Length={sequence2.Length}"); // sequence2.Length=2

    // sequence1.FirstSpan.Length=1
    Console.WriteLine($"sequence1.FirstSpan.Length={sequence1.FirstSpan.Length}");

    // Slicing using SequencePosition will Slice the ReadOnlySequence<byte>
    // directly
    // on the empty segment!
    // sequence2.FirstSpan.Length=0
    Console.WriteLine($"sequence2.FirstSpan.Length={sequence2.FirstSpan.Length}");

    // The following code prints 0, 1, 0, 1.
    SequencePosition position = data.Start;
    while (data.TryGet(ref position, out ReadOnlyMemory<byte> memory))
    {
        Console.WriteLine(memory.Length);
    }
}

class BufferSegment : ReadOnlySequenceSegment<byte>
{
    public BufferSegment(Memory<byte> memory)
    {
        Memory = memory;
    }

    public BufferSegment Append(Memory<byte> memory)
    {
        var segment = new BufferSegment(memory)
        {
```

```

        RunningIndex = RunningIndex + Memory.Length
    };
    Next = segment;
    return segment;
}
}

```

The preceding code creates a `ReadOnlySequence<byte>` with empty segments and shows how those empty segments affect the various APIs:

- `ReadOnlySequence<T>.Slice` with a `SequencePosition` pointing to an empty segment preserves that segment.
- `ReadOnlySequence<T>.Slice` with an int skips over the empty segments.
- Enumerating the `ReadOnlySequence<T>` enumerates the empty segments.

Potential problems with `ReadOnlySequence<T>` and `SequencePosition`

There are several unusual outcomes when dealing with a `ReadOnlySequence<T>/SequencePosition` vs. a normal `ReadOnlySpan<T>/ReadOnlyMemory<T>/T[]/int`:

- `SequencePosition` is a position marker for a specific `ReadOnlySequence<T>`, not an absolute position. Because it's relative to a specific `ReadOnlySequence<T>`, it doesn't have meaning if used outside of the `ReadOnlySequence<T>` where it originated.
- Arithmetic can't be performed on `SequencePosition` without the `ReadOnlySequence<T>`. That means doing basic things like `position++` is written `position = ReadOnlySequence<T>.GetPosition(1, position)`.
- `GetPosition(long)` does **not** support negative indexes. That means it's impossible to get the second to last character without walking all segments.
- Two `SequencePosition` can't be compared, making it difficult to:
 - Know if one position is greater than or less than another position.
 - Write some parsing algorithms.
- `ReadOnlySequence<T>` is bigger than an object reference and should be passed by `in` or `ref` where possible. Passing `ReadOnlySequence<T>` by `in` or `ref` reduces copies of the `struct`.
- Empty segments:
 - Are valid within a `ReadOnlySequence<T>`.
 - Can appear when iterating using the `ReadOnlySequence<T>.TryGet` method.
 - Can appear slicing the sequence using the `ReadOnlySequence<T>.Slice()` method with `SequencePosition` objects.

SequenceReader<T>

SequenceReader<T>:

- Is a new type that was introduced in .NET Core 3.0 to simplify the processing of a `ReadOnlySequence<T>`.
- Unifies the differences between a single segment `ReadOnlySequence<T>` and multi-segment `ReadOnlySequence<T>`.
- Provides helpers for reading binary and text data (`byte` and `char`) that may or may not be split across segments.

There are built-in methods for dealing with processing both binary and delimited data. The following section demonstrates what those same methods look like with the `SequenceReader<T>`:

Access data

`SequenceReader<T>` has methods for enumerating data inside of the `ReadOnlySequence<T>` directly. The following code is an example of processing a `ReadOnlySequence<byte>` a `byte` at a time:

C#

```
while (reader.TryRead(out byte b))
{
    Process(b);
}
```

The `CurrentSpan` exposes the current segment's `Span`, which is similar to what was done in the method manually.

Use position

The following code is an example implementation of `FindIndexOf` using the `SequenceReader<T>`:

C#

```
SequencePosition? FindIndexOf(in ReadOnlySequence<byte> buffer, byte data)
{
    var reader = new SequenceReader<byte>(buffer);

    while (!reader.End)
```

```
{  
    // Search for the byte in the current span.  
    var index = reader.CurrentSpan.IndexOf(data);  
    if (index != -1)  
    {  
        // It was found, so advance to the position.  
        reader.Advance(index);  
  
        return reader.Position;  
    }  
    // Skip the current segment since there's nothing in it.  
    reader.Advance(reader.CurrentSpan.Length);  
}  
  
return null;  
}
```

Process binary data

The following example parses a 4-byte big-endian integer length from the start of the `ReadOnlySequence<byte>`.

C#

```
bool TryParseHeaderLength(ref ReadOnlySequence<byte> buffer, out int length)  
{  
    var reader = new SequenceReader<byte>(buffer);  
    return reader.TryReadBigEndian(out length);  
}
```

Process text data

C#

```
static ReadOnlySpan<byte> NewLine => new byte[] { (byte)'\\r', (byte)'\\n' };  
  
static bool TryParseLine(ref ReadOnlySequence<byte> buffer,  
                        out ReadOnlySequence<byte> line)  
{  
    var reader = new SequenceReader<byte>(buffer);  
  
    if (reader.TryReadTo(out line, NewLine))  
    {  
        buffer = buffer.Slice(reader.Position);  
  
        return true;  
    }  
  
    line = default;
```

```
    return false;  
}
```

SequenceReader<T> common problems

- Because `SequenceReader<T>` is a mutable struct, it should always be passed by [reference](#).
- `SequenceReader<T>` is a [ref struct](#) so it can only be used in synchronous methods and can't be stored in fields. For more information, see [Avoid allocations](#).
- `SequenceReader<T>` is optimized for use as a forward-only reader. `Rewind` is intended for small backups that can't be addressed utilizing other `Read`, `Peek`, and `IsNext` APIs.

Memory-mapped files

Article • 12/14/2022

A memory-mapped file contains the contents of a file in virtual memory. This mapping between a file and memory space enables an application, including multiple processes, to modify the file by reading and writing directly to the memory. You can use managed code to access memory-mapped files in the same way that native Windows functions access memory-mapped files, as described in [Managing Memory-Mapped Files](#).

There are two types of memory-mapped files:

- Persisted memory-mapped files

Persisted files are memory-mapped files that are associated with a source file on a disk. When the last process has finished working with the file, the data is saved to the source file on the disk. These memory-mapped files are suitable for working with extremely large source files.

- Non-persisted memory-mapped files

Non-persisted files are memory-mapped files that are not associated with a file on a disk. When the last process has finished working with the file, the data is lost and the file is reclaimed by garbage collection. These files are suitable for creating shared memory for inter-process communications (IPC).

Processes, Views, and Managing Memory

Memory-mapped files can be shared across multiple processes. Processes can map to the same memory-mapped file by using a common name that is assigned by the process that created the file.

To work with a memory-mapped file, you must create a view of the entire memory-mapped file or a part of it. You can also create multiple views to the same part of the memory-mapped file, thereby creating concurrent memory. For two views to remain concurrent, they have to be created from the same memory-mapped file.

Multiple views may also be necessary if the file is greater than the size of the application's logical memory space available for memory mapping (2 GB on a 32-bit computer).

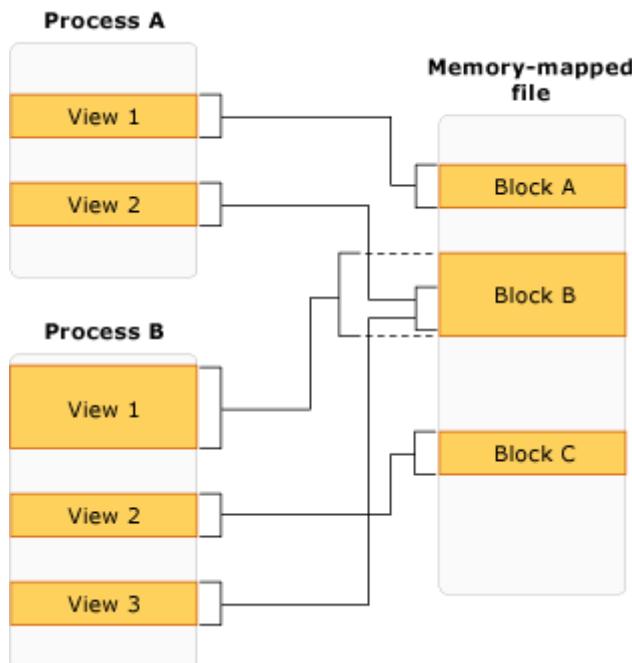

There are two types of views: stream access view and random access view. Use stream access views for sequential access to a file; this is recommended for non-persisted files

and IPC. Random access views are preferred for working with persisted files.

Memory-mapped files are accessed through the operating system's memory manager, so the file is automatically partitioned into a number of pages and accessed as needed. You do not have to handle the memory management yourself.

The following illustration shows how multiple processes can have multiple and overlapping views to the same memory-mapped file at the same time.

The following image shows multiple and overlapped views to a memory-mapped file:

Programming with Memory-Mapped Files

The following table provides a guide for using memory-mapped file objects and their members.

| Task | Methods or properties to use |
|--|---|
| To obtain a MemoryMappedFile object that represents a persisted memory-mapped file from a file on disk. | MemoryMappedFile.CreateFromFile method. |
| To obtain a MemoryMappedFile object that represents a non-persisted memory-mapped file (not associated with a file on disk). | MemoryMappedFile.CreateNew method. - or - MemoryMappedFile.CreateOrOpen method. |
| To obtain a MemoryMappedFile object of an existing memory- | MemoryMappedFile.OpenExisting method. |

| Task | Methods or properties to use |
|--|---|
| mapped file (either persisted or non-persisted). | |
| To obtain a UnmanagedMemoryStream object for a sequentially accessed view to the memory-mapped file. | MemoryMappedFile.CreateViewStream method. |
| To obtain a UnmanagedMemoryAccessor object for a random access view to a memory-mapped file. | MemoryMappedFile.CreateViewAccessor method. |
| To obtain a SafeMemoryMappedViewHandle object to use with unmanaged code. | MemoryMappedFile.SafeMemoryMappedFileHandle property. - or - |
| | MemoryMappedViewAccessor.SafeMemoryMappedViewHandle property. - or - |
| (To determine the current system page size, use the Environment.SystemPageSize property.) | CreateNew method with the MemoryMappedFileOptions.DelayAllocatePages value. - or - CreateOrOpen methods that have a MemoryMappedFileOptions enumeration as a parameter. |

Security

You can apply access rights when you create a memory-mapped file, by using the following methods that take a [MemoryMappedFileAccess](#) enumeration as a parameter:

- [MemoryMappedFile.CreateFromFile](#)
- [MemoryMappedFile.CreateNew](#)
- [MemoryMappedFile.CreateOrOpen](#)

You can specify access rights for opening an existing memory-mapped file by using the [OpenExisting](#) methods that take an [MemoryMappedFileRights](#) as a parameter.

In addition, you can include a [MemoryMappedFileSecurity](#) object that contains predefined access rules.

To apply new or changed access rules to a memory-mapped file, use the [SetAccessControl](#) method. To retrieve access or audit rules from an existing file, use the [GetAccessControl](#) method.

Examples

Persisted Memory-Mapped Files

The [CreateFromFile](#) methods create a memory-mapped file from an existing file on disk.

The following example creates a memory-mapped view of a part of an extremely large file and manipulates a portion of it.

C#

```
using System;
using System.IO;
using System.IO.MemoryMappedFiles;
using System.Runtime.InteropServices;

class Program
{
    static void Main(string[] args)
    {
        long offset = 0x10000000; // 256 megabytes
        long length = 0x20000000; // 512 megabytes

        // Create the memory-mapped file.
        using (var mmf =
MemoryMappedFile.CreateFromFile(@"c:\ExtremelyLargeImage.data",
 FileMode.Open, "ImgA"))
        {
            // Create a random access view, from the 256th megabyte (the
            offset)
            // to the 768th megabyte (the offset plus length).
            using (var accessor = mmf.CreateViewAccessor(offset, length))
            {
                int colorSize = Marshal.SizeOf(typeof(MyColor));
                MyColor color;

                // Make changes to the view.
                for (long i = 0; i < length; i += colorSize)
                {

```

```

                accessor.Read(i, out color);
                color.Brighten(10);
                accessor.Write(i, ref color);
            }
        }
    }
}

public struct MyColor
{
    public short Red;
    public short Green;
    public short Blue;
    public short Alpha;

    // Make the view brighter.
    public void Brighten(short value)
    {
        Red = (short)Math.Min(short.MaxValue, (int)Red + value);
        Green = (short)Math.Min(short.MaxValue, (int)Green + value);
        Blue = (short)Math.Min(short.MaxValue, (int)Blue + value);
        Alpha = (short)Math.Min(short.MaxValue, (int)Alpha + value);
    }
}

```

The following example opens the same memory-mapped file for another process.

C#

```

using System;
using System.IO.MemoryMappedFiles;
using System.Runtime.InteropServices;

class Program
{
    static void Main(string[] args)
    {
        // Assumes another process has created the memory-mapped file.
        using (var mmf = MemoryMappedFile.OpenExisting("ImgA"))
        {
            using (var accessor = mmf.CreateViewAccessor(4000000, 2000000))
            {
                int colorSize = Marshal.SizeOf(typeof(MyColor));
                MyColor color;

                // Make changes to the view.
                for (long i = 0; i < 1500000; i += colorSize)
                {
                    accessor.Read(i, out color);
                    color.Brighten(20);
                    accessor.Write(i, ref color);
                }
            }
        }
    }
}

```

```

        }
    }
}

public struct MyColor
{
    public short Red;
    public short Green;
    public short Blue;
    public short Alpha;

    // Make the view brighter.
    public void Brighten(short value)
    {
        Red = (short)Math.Min(short.MaxValue, (int)Red + value);
        Green = (short)Math.Min(short.MaxValue, (int)Green + value);
        Blue = (short)Math.Min(short.MaxValue, (int)Blue + value);
        Alpha = (short)Math.Min(short.MaxValue, (int)Alpha + value);
    }
}

```

Non-Persisted Memory-Mapped Files

The [CreateNew](#) and [CreateOrOpen](#) methods create a memory-mapped file that is not mapped to an existing file on disk.

The following example consists of three separate processes (console applications) that write Boolean values to a memory-mapped file. The following sequence of actions occur:

1. `Process A` creates the memory-mapped file and writes a value to it.
2. `Process B` opens the memory-mapped file and writes a value to it.
3. `Process C` opens the memory-mapped file and writes a value to it.
4. `Process A` reads and displays the values from the memory-mapped file.
5. After `Process A` is finished with the memory-mapped file, the file is immediately reclaimed by garbage collection.

To run this example, do the following:

1. Compile the applications and open three Command Prompt windows.
2. In the first Command Prompt window, run `Process A`.

3. In the second Command Prompt window, run **Process B**.

4. Return to **Process A** and press ENTER.

5. In the third Command Prompt window, run **Process C**.

6. Return to **Process A** and press ENTER.

The output of **Process A** is as follows:

Console

```
Start Process B and press ENTER to continue.  
Start Process C and press ENTER to continue.  
Process A says: True  
Process B says: False  
Process C says: True
```

Process A

C#

```
using System;  
using System.IO;  
using System.IO.MemoryMappedFiles;  
using System.Threading;  
  
class Program  
{  
    // Process A:  
    static void Main(string[] args)  
    {  
        using (MemoryMappedFile mmf = MemoryMappedFile.CreateNew("testmap",  
10000))  
        {  
            bool mutexCreated;  
            Mutex mutex = new Mutex(true, "testmapmutex", out mutexCreated);  
            using (MemoryMappedViewStream stream = mmf.CreateViewStream())  
            {  
                BinaryWriter writer = new BinaryWriter(stream);  
                writer.Write(1);  
            }  
            mutex.ReleaseMutex();  
  
            Console.WriteLine("Start Process B and press ENTER to  
continue.");  
            Console.ReadLine();  
  
            Console.WriteLine("Start Process C and press ENTER to  
continue.");  
            Console.ReadLine();
```

```

        mutex.WaitOne();
        using (MemoryMappedViewStream stream = mmf.CreateViewStream())
        {
            BinaryReader reader = new BinaryReader(stream);
            Console.WriteLine("Process A says: {0}",
reader.ReadBoolean());
            Console.WriteLine("Process B says: {0}",
reader.ReadBoolean());
            Console.WriteLine("Process C says: {0}",
reader.ReadBoolean());
        }
        mutex.ReleaseMutex();
    }
}

```

Process B

C#

```

using System;
using System.IO;
using System.IO.MemoryMappedFiles;
using System.Threading;

class Program
{
    // Process B:
    static void Main(string[] args)
    {
        try
        {
            using (MemoryMappedFile mmf =
MemoryMappedFile.OpenExisting("testmap"))
            {

                Mutex mutex = Mutex.OpenExisting("testmapmutex");
                mutex.WaitOne();

                using (MemoryMappedViewStream stream =
mmf.CreateViewStream(1, 0))
                {
                    BinaryWriter writer = new BinaryWriter(stream);
                    writer.Write(0);
                }
                mutex.ReleaseMutex();
            }
        }
        catch (FileNotFoundException)
        {
            Console.WriteLine("Memory-mapped file does not exist. Run
Process A first.");
        }
    }
}

```

```
        }
    }
}
```

Process C

C#

```
using System;
using System.IO;
using System.IO.MemoryMappedFiles;
using System.Threading;

class Program
{
    // Process C:
    static void Main(string[] args)
    {
        try
        {
            using (MemoryMappedFile mmf =
MemoryMappedFile.OpenExisting("testmap"))
            {

                Mutex mutex = Mutex.OpenExisting("testmapmutex");
                mutex.WaitOne();

                using (MemoryMappedViewStream stream =
mmf.CreateViewStream(2, 0))
                {
                    BinaryWriter writer = new BinaryWriter(stream);
                    writer.Write(1);
                }
                mutex.ReleaseMutex();
            }
        }
        catch (FileNotFoundException)
        {
            Console.WriteLine("Memory-mapped file does not exist. Run
Process A first, then B.");
        }
    }
}
```

System.IO.FileStream class

Article • 01/08/2024

This article provides supplementary remarks to the reference documentation for this API.

Use the [FileStream](#) class to read from, write to, open, and close files on a file system, and to manipulate other file-related operating system handles, including pipes, standard input, and standard output. You can use the [Read](#), [Write](#), [CopyTo](#), and [Flush](#) methods to perform synchronous operations, or the [ReadAsync](#), [WriteAsync](#), [CopyToAsync](#), and [FlushAsync](#) methods to perform asynchronous operations. Use the asynchronous methods to perform resource-intensive file operations without blocking the main thread. This performance consideration is particularly important in a Windows 8.x Store app or desktop app where a time-consuming stream operation can block the UI thread and make your app appear as if it is not working. [FileStream](#) buffers input and output for better performance.

ⓘ Important

This type implements the [IDisposable](#) interface. When you have finished using the type, you should dispose of it either directly or indirectly. To dispose of the type directly, call its [Dispose](#) method in a `try/catch` block. To dispose of it indirectly, use a language construct such as `using` (in C#) or `Using` (in Visual Basic). For more information, see the "Using an Object that Implements [IDisposable](#)" section in the [IDisposable](#) interface topic.

The [IsAsync](#) property detects whether the file handle was opened asynchronously. You specify this value when you create an instance of the [FileStream](#) class using a constructor that has an `isAsync`, `useAsync`, or `options` parameter. When the property is `true`, the stream utilizes overlapped I/O to perform file operations asynchronously. However, the [IsAsync](#) property does not have to be `true` to call the [ReadAsync](#), [WriteAsync](#), or [CopyToAsync](#) method. When the [IsAsync](#) property is `false` and you call the asynchronous read and write operations, the UI thread is still not blocked, but the actual I/O operation is performed synchronously.

The [Seek](#) method supports random access to files. [Seek](#) allows the read/write position to be moved to any position within the file. This is done with byte offset reference point parameters. The byte offset is relative to the seek reference point, which can be the beginning, the current position, or the end of the underlying file, as represented by the three members of the [SeekOrigin](#) enumeration.

Note

Disk files always support random access. At the time of construction, the `CanSeek` property value is set to `true` or `false` depending on the underlying file type. If the underlying file type is `FILE_TYPE_DISK`, as defined in `winbase.h`, the `CanSeek` property value is `true`. Otherwise, the `CanSeek` property value is `false`.

If a process terminates with part of a file locked or closes a file that has outstanding locks, the behavior is undefined.

For directory operations and other file operations, see the [File](#), [Directory](#), and [Path](#) classes. The [File](#) class is a utility class that has static methods primarily for the creation of [FileStream](#) objects based on file paths. The [MemoryStream](#) class creates a stream from a byte array and is similar to the [FileStream](#) class.

For a list of common file and directory operations, see [Common I/O Tasks](#).

Detection of stream position changes

When a [FileStream](#) object does not have an exclusive hold on its handle, another thread could access the file handle concurrently and change the position of the operating system's file pointer that is associated with the file handle. In this case, the cached position in the [FileStream](#) object and the cached data in the buffer could be compromised. The [FileStream](#) object routinely performs checks on methods that access the cached buffer to ensure that the operating system's handle position is the same as the cached position used by the [FileStream](#) object.

If an unexpected change in the handle position is detected in a call to the [Read](#) method, .NET discards the contents of the buffer and reads the stream from the file again. This can affect performance, depending on the size of the file and any other processes that could affect the position of the file stream.

If an unexpected change in the handle position is detected in a call to the [Write](#) method, the contents of the buffer are discarded and an [IOException](#) exception is thrown.

A [FileStream](#) object will not have an exclusive hold on its handle when either the [SafeFileHandle](#) property is accessed to expose the handle or the [FileStream](#) object is given the [SafeFileHandle](#) property in its constructor.

System.IO.FileSystemWatcher class

Article • 01/08/2024

This article provides supplementary remarks to the reference documentation for this API.

Use [FileSystemWatcher](#) to watch for changes in a specified directory. You can watch for changes in files and subdirectories of the specified directory. You can create a component to watch files on a local computer, a network drive, or a remote computer.

To watch for changes in all files, set the [Filter](#) property to an empty string ("") or use wildcards ("*.*"). To watch a specific file, set the [Filter](#) property to the file name. For example, to watch for changes in the file MyDoc.txt, set the [Filter](#) property to "MyDoc.txt". You can also watch for changes in a certain type of file. For example, to watch for changes in text files, set the [Filter](#) property to "*.txt".

There are several types of changes you can watch for in a directory or file. For example, you can watch for changes in [Attributes](#), the [LastWrite](#) date and time, or the [Size](#) of files or directories. This is done by setting the [NotifyFilter](#) property to one of the [NotifyFilters](#) values. For more information on the type of changes you can watch, see [NotifyFilters](#).

You can watch for renaming, deletion, or creation of files or directories. For example, to watch for renaming of text files, set the [Filter](#) property to "*.txt" and call the [WaitForChanged](#) method with a [Renamed](#) specified for its parameter.

The Windows operating system notifies your component of file changes in a buffer created by the [FileSystemWatcher](#). If there are many changes in a short time, the buffer can overflow. This causes the component to lose track of changes in the directory, and it will only provide blanket notification. Increasing the size of the buffer with the [InternalBufferSize](#) property is expensive, as it comes from non-paged memory that cannot be swapped out to disk, so keep the buffer as small yet large enough to not miss any file change events. To avoid a buffer overflow, use the [NotifyFilter](#) and [IncludeSubdirectories](#) properties so you can filter out unwanted change notifications.

For a list of initial property values for an instance of [FileSystemWatcher](#), see the [FileSystemWatcher](#) constructor.

Considerations when using the [FileSystemWatcher](#) class:

- Hidden files are not ignored.

- In some systems, [FileSystemWatcher](#) reports changes to files using the short 8.3 file name format. For example, a change to "LongFileName.LongExtension" could be reported as "LongFil~.Lon".
- This class contains a link demand and an inheritance demand at the class level that applies to all members. A [SecurityException](#) is thrown when either the immediate caller or the derived class does not have full-trust permission. For details about security demands, see [Link Demands](#).
- The maximum size you can set for the [InternalBufferSize](#) property for monitoring a directory over the network is 64 KB.

Copy and move folders

The operating system and [FileSystemWatcher](#) object interpret a cut-and-paste action or a move action as a rename action for a folder and its contents. If you cut and paste a folder with files into a folder being watched, the [FileSystemWatcher](#) object reports only the folder as new, but not its contents because they are essentially only renamed.

To be notified that the contents of folders have been moved or copied into a watched folder, provide [OnChanged](#) and [OnRenamed](#) event handler methods as suggested in the following table.

[+] [Expand table](#)

| Event Handler | Events Handled | Performs |
|---------------------------|---|---|
| OnChanged | Changed , Created , Deleted | Report changes in file attributes, created files, and deleted files. |
| OnRenamed | Renamed | List the old and new paths of renamed files and folders, expanding recursively if needed. |

Events and buffer sizes

Note that several factors can affect which file system change events are raised, as described by the following:

- Common file system operations might raise more than one event. For example, when a file is moved from one directory to another, several [OnChanged](#) and some [OnCreated](#) and [OnDeleted](#) events might be raised. Moving a file is a complex operation that consists of multiple simple operations, therefore raising multiple

events. Likewise, some applications (for example, antivirus software) might cause additional file system events that are detected by [FileSystemWatcher](#).

- The [FileSystemWatcher](#) can watch disks as long as they are not switched or removed. The [FileSystemWatcher](#) does not raise events for CDs and DVDs, because time stamps and properties cannot change. Remote computers must have one of the required platforms installed for the component to function properly.

Note that a [FileSystemWatcher](#) may miss an event when the buffer size is exceeded. To avoid missing events, follow these guidelines:

- Increase the buffer size by setting the [InternalBufferSize](#) property.
- Avoid watching files with long file names, because a long file name contributes to filling up the buffer. Consider renaming these files using shorter names.
- Keep your event handling code as short as possible.

System.AppContext class

Article • 01/08/2024

This article provides supplementary remarks to the reference documentation for this API.

The [AppContext](#) class enables library writers to provide a uniform opt-out mechanism for new functionality for their users. It establishes a loosely coupled contract between components in order to communicate an opt-out request. This capability is typically important when a change is made to existing functionality. Conversely, there is already an implicit opt-in for new functionality.

AppContext for library developers

Libraries use the [AppContext](#) class to define and expose compatibility switches, while library users can set those switches to affect the library behavior. By default, libraries provide the new functionality, and they only alter it (that is, they provide the previous functionality) if the switch is set. This allows libraries to provide new behavior for an existing API while continuing to support callers who depend on the previous behavior.

Define the switch name

The most common way to allow consumers of your library to opt out of a change of behavior is to define a named switch. Its `value` element is a name/value pair that consists of the name of a switch and its [Boolean](#) value. By default, the switch is always implicitly `false`, which provides the new behavior (and makes the new behavior opt-in by default). Setting the switch to `true` enables it, which provides the legacy behavior. Explicitly setting the switch to `false` also provides the new behavior.

It's beneficial to use a consistent format for switch names, since they're a formal contract exposed by a library. The following are two obvious formats:

- *Switch.namespace.switchname*
- *Switch.library.switchname*

Once you define and document the switch, callers can use it by calling the [AppContext.SetSwitch\(String, Boolean\)](#) method programmatically. .NET Framework apps can also use the switch by adding an `<AppContextSwitchOverrides>` element to their application configuration file or by using the registry. For more information about how

callers use and set the value of [AppContext](#) configuration switches, see the [AppContext for library consumers](#) section.

In .NET Framework, when the common language runtime runs an application, it automatically reads the registry's compatibility settings and loads the application configuration file to populate the application's [AppContext](#) instance. Because the [AppContext](#) instance is populated either programmatically by the caller or by the runtime, .NET Framework apps don't have to take any action, such as calling the [SetSwitch](#) method, to configure the [AppContext](#) instance.

Check the setting

You can check if a consumer has declared the value of the switch and act appropriately by calling the [AppContext.TryGetSwitch](#) method. The method returns `true` if the `switchName` argument is found, and its `isEnabled` argument indicates the value of the switch. Otherwise, the method returns `false`.

Example

The following example illustrates the use of the [AppContext](#) class to allow the customer to choose the original behavior of a library method. The following is version 1.0 of a library named `StringLibrary`. It defines a `SubstringStartsAt` method that performs an ordinal comparison to determine the starting index of a substring within a larger string.

C#

```
using System;
using System.Reflection;

[assembly: AssemblyVersion("1.0.0.0")]

public static class StringLibrary1
{
    public static int SubstringStartsAt(string fullString, string substr)
    {
        return fullString.IndexOf(substr, StringComparison.Ordinal);
    }
}
```

The following example then uses the library to find the starting index of the substring "archæ" in "The archaeologist". Because the method performs an ordinal comparison, the substring cannot be found.

C#

```

using System;

public class Example1
{
    public static void Main()
    {
        string value = "The archaeologist";
        string substring = "archæ";
        int position = StringLibrary1.SubstringStartsAt(value, substring);
        if (position >= 0)
            Console.WriteLine("'{}' found in '{}' starting at position
{2}",
                            substring, value, position);
        else
            Console.WriteLine("'{}' not found in '{}'", substring, value);
    }
}

// The example displays the following output:
//      'archæ' not found in 'The archaeologist'

```

Version 2.0 of the library, however, changes the `SubstringStartsAt` method to use culture-sensitive comparison.

C#

```

using System;
using System.Reflection;

[assembly: AssemblyVersion("2.0.0.0")]

public static class StringLibrary2
{
    public static int SubstringStartsAt(string fullString, string substr)
    {
        return fullString.IndexOf(substr, StringComparison.CurrentCulture);
    }
}

```

When the app is recompiled to run against the new version of the library, it now reports that the substring "archæ" is found at index 4 in "The archaeologist".

C#

```

using System;

public class Example2
{
    public static void Main()
    {
        string value = "The archaeologist";

```

```

        string substring = "archæ";
        int position = StringLibrary2.SubstringStartsAt(value, substring);
        if (position >= 0)
            Console.WriteLine("'{0}' found in '{1}' starting at position
{2}",
                            substring, value, position);
        else
            Console.WriteLine("'{0}' not found in '{1}'", substring, value);
    }
}
// The example displays the following output:
//      'archæ' found in 'The archaeologist' starting at position 4

```

This change can be prevented from breaking the applications that depend on the original behavior by defining a switch. In this case, the switch is named

`StringLibrary.DoNotUseCultureSensitiveComparison`. Its default value, `false`, indicates that the library should perform its version 2.0 culture-sensitive comparison. `true` indicates that the library should perform its version 1.0 ordinal comparison. A slight modification of the previous code allows the library consumer to set the switch to determine the kind of comparison the method performs.

C#

```

using System;
using System.Reflection;

[assembly: AssemblyVersion("2.0.0.0")]

public static class StringLibrary
{
    public static int SubstringStartsAt(string fullString, string substr)
    {
        bool flag;
        if
(ApplicationContext.TryGetSwitch("StringLibrary.DoNotUseCultureSensitiveComparison",
out flag) && flag == true)
            return fullString.IndexOf(substr, StringComparison.Ordinal);
        else
            return fullString.IndexOf(substr, StringComparison.CurrentCulture);
    }
}

```

A .NET Framework application can then use the following configuration file to restore the version 1.0 behavior.

XML

```

<configuration>
  <runtime>

```

```
<AppContextSwitchOverrides  
value="StringLibrary.DoNotUseCultureSensitiveComparison=true" />  
</runtime>  
</configuration>
```

When the application is run with the configuration file present, it produces the following output:

Output

```
'archæ' not found in 'The archaeologist'
```

AppContext for library consumers

If you're the consumer of a library, the [AppContext](#) class allows you to take advantage of a library or library method's opt-out mechanism for new functionality. Individual methods of the class library that you are calling define particular switches that enable or disable a new behavior. The value of the switch is a Boolean. If it is `false`, which is typically the default value, the new behavior is enabled; if it is `true`, the new behavior is disabled, and the member behaves as it did previously.

You can set the value of a switch by calling the [AppContext.SetSwitch\(String, Boolean\)](#) method in your code. The `switchName` argument defines the switch name, and the `isEnabled` property defines the value of the switch. Because [AppContext](#) is a static class, it is available on a per-application domain basis. Calling the [AppContext.SetSwitch\(String, Boolean\)](#) has application scope; that is, it affects only the application.

.NET Framework apps have additional ways to set the value of a switch:

- By adding an `<AppContextSwitchOverrides>` element to the `<runtime>` section of the app.config file. The switch has a single attribute, `value`, whose value is a string that represents a key/value pair containing both the switch name and its value.

To define multiple switches, separate each switch's key/value pair in the `<AppContextSwitchOverrides>` element's `value` attribute with a semicolon. In that case, the `<AppContextSwitchOverrides>` element has the following format:

XML

```
<AppContextSwitchOverrides  
value="switchName1=value1;switchName2=value2" />
```

Using the `<AppContextSwitchOverrides>` element to define a configuration setting has application scope; that is, it affects only the application.

ⓘ Note

For information on the switches defined by .NET Framework, see `<AppContextSwitchOverrides>` element.

- By adding an entry to the registry. Add a new string value to the `HKLM\SOFTWARE\Microsoft\.NETFramework\AppBarContext` subkey. Set the name of the entry to the name of the switch. Set its value to one of the following options: `True`, `true`, `False`, or `false`. If the runtime encounters any other value, it ignores the switch.

On a 64-bit operating system, you must also add the same entry to the `HKLM\SOFTWARE\Wow6432Node\Microsoft\.NETFramework\AppBarContext` subkey.

Using the registry to define an `AppBarContext` switch has machine scope; that is, it affects every application running on the machine.

For ASP.NET and ASP.NET Core applications, you set a switch by adding an `<Add>` element to the `<appSettings>` section of the web.config file. For example:

XML

```
<appSettings>
  <add key="AppBarContext.SetSwitch:switchName1" value="switchValue1" />
  <add key="AppBarContext.SetSwitch:switchName2" value="switchValue2" />
</appSettings>
```

If you set the same switch in more than one way, the order of precedence for determining which setting overrides the others is:

1. The programmatic setting.
2. The setting in the app.config file (for .NET Framework apps) or the web.config file (for ASP.NET Core apps).
3. The registry setting (for .NET Framework apps only).

The following is a simple application that passes a file URI to the `Path.GetDirectoryName` method. It throws an `ArgumentException` because `file://` is no longer a valid part of a file path.

C#

```
using System;
using System.IO;
using System.Runtime.Versioning;

// [assembly: TargetFramework(".NETFramework, Version=v4.6.2")]

public class Example
{
    public static void Main()
    {

        Console.WriteLine(Path.GetDirectoryName("file://c/temp/dirlist.txt"));
    }
}

// The example displays the following output:
//     Unhandled Exception: System.ArgumentException: The path is not of a
legal form.
//         at System.IO.Path.NewNormalizePathLimitedChecks(String path, Int32
maxPathLength, Boolean expandShortPaths)
//         at System.IO.Path.NormalizePath(String path, Boolean fullCheck,
Int32 maxPathLength, Boolean expandShortPaths)
//         at System.IO.Path.InternalGetDirectoryName(String path)
//         at Example.Main()
```

To restore the method's previous behavior and prevent the exception, you can add the `Switch.System.IO.UseLegacyPathHandling` switch to the application configuration file for the example:

XML

```
<configuration>
    <runtime>
        <AppContextSwitchOverrides
value="Switch.System.IO.UseLegacyPathHandling=true" />
    </runtime>
</configuration>
```

Console apps in .NET

Article • 09/15/2021

.NET applications can use the [System.Console](#) class to read characters from and write characters to the console. Data from the console is read from the standard input stream, data to the console is written to the standard output stream, and error data to the console is written to the standard error output stream. These streams are automatically associated with the console when the application starts and are presented as the [In](#), [Out](#), and [Error](#) properties, respectively.

The value of the [Console.In](#) property is a [System.IO.TextReader](#) object, whereas the values of the [Console.Out](#) and [Console.Error](#) properties are [System.IO.TextWriter](#) objects. You can associate these properties with streams that do not represent the console, making it possible for you to point the stream to a different location for input or output. For example, you can redirect the output to a file by setting the [Console.Out](#) property to a [System.IO.StreamWriter](#), which encapsulates a [System.IO.FileStream](#) by means of the [Console.SetOut](#) method. The [Console.In](#) and [Console.Out](#) properties do not need to refer to the same stream.

Note

For more information about building console applications, including examples in C#, Visual Basic, and C++, see the documentation for the [Console](#) class.

If the console does not exist, for example, in a Windows Forms application, output written to the standard output stream will not be visible, because there is no console to write the information to. Writing information to an inaccessible console does not cause an exception to be raised. (You can always change the application type to [Console Application](#), for example, in the project property pages in Visual Studio).

The [System.Console](#) class has methods that can read individual characters or entire lines from the console. Other methods convert data and format strings, and then write the formatted strings to the console. For more information on formatting strings, see [Formatting types](#).

Tip

Console applications lack a message pump that starts by default. Therefore, console calls to Microsoft Win32 timers might fail.

System.Console class

Article • 01/08/2024

This article provides supplementary remarks to the reference documentation for this API.

The console is an operating system window where users interact with the operating system or with a text-based console application by entering text input through the computer keyboard, and by reading text output from the computer terminal. For example, in the Windows operating system, the console is called the Command Prompt window and accepts MS-DOS commands. The [Console](#) class provides basic support for applications that read characters from, and write characters to, the console.

Console I/O streams

When a console application starts, the operating system automatically associates three I/O streams with the console: standard input stream, standard output stream, and standard error output stream. Your application can read user input from the standard input stream; write normal data to the standard output stream; and write error data to the standard error output stream. These streams are presented to your application as the values of the [Console.In](#), [Console.Out](#), and [Console.Error](#) properties.

By default, the value of the [In](#) property is a [System.IO.TextReader](#) object that represents the keyboard, and the values of the [Out](#) and [Error](#) properties are [System.IO.TextWriter](#) objects that represent a console window. However, you can set these properties to streams that do not represent the console window or keyboard; for example, you can set these properties to streams that represent files. To redirect the standard input, standard output, or standard error stream, call the [Console.SetIn](#), [Console.SetOut](#), or [Console.SetError](#) method, respectively. I/O operations that use these streams are synchronized, which means that multiple threads can read from, or write to, the streams. This means that methods that are ordinarily asynchronous, such as [TextReader.ReadLineAsync](#), execute synchronously if the object represents a console stream.

Note

Do not use the [Console](#) class to display output in unattended applications, such as server applications. Calls to methods such as [Console.Write](#) and [Console.WriteLine](#) have no effect in GUI applications.

`Console` class members that work normally when the underlying stream is directed to a console might throw an exception if the stream is redirected, for example, to a file. Program your application to catch `System.IO.IOException` exceptions if you redirect a standard stream. You can also use the `IsOutputRedirected`, `IsInputRedirected`, and `IsErrorRedirected` properties to determine whether a standard stream is redirected before performing an operation that throws an `System.IO.IOException` exception.

It is sometimes useful to explicitly call the members of the stream objects represented by the `In`, `Out`, and `Error` properties. For example, by default, the `Console.ReadLine` method reads input from the standard input stream. Similarly, the `Console.WriteLine` method writes data to the standard output stream, and the data is followed by the default line termination string, which can be found at `Environment.NewLine`. However, the `Console` class does not provide a corresponding method to write data to the standard error output stream, or a property to change the line termination string for data written to that stream.

You can solve this problem by setting the `TextWriter.NewLine` property of the `Out` or `Error` property to another line termination string. For example, the following C# statement sets the line termination string for the standard error output stream to two carriage return and line feed sequences:

```
Console.Error.NewLine = "\r\n\r\n";
```

You can then explicitly call the `WriteLine` method of the error output stream object, as in the following C# statement:

```
Console.Error.WriteLine();
```

Screen buffer and console window

Two closely related features of the console are the screen buffer and the console window. Text is actually read from or written to streams owned by the console, but appear to be read from or written to an area owned by the console called the screen buffer. The screen buffer is an attribute of the console, and is organized as a rectangular grid of rows and columns where each grid intersection, or character cell, can contain a character. Each character has its own foreground color, and each character cell has its own background color.

The screen buffer is viewed through a rectangular region called the console window. The console window is another attribute of the console; it is not the console itself, which is an operating system window. The console window is arranged in rows and columns, is less than or equal to the size of the screen buffer, and can be moved to view different

areas of the underlying screen buffer. If the screen buffer is larger than the console window, the console automatically displays scroll bars so the console window can be repositioned over the screen buffer area.

A cursor indicates the screen buffer position where text is currently read or written. The cursor can be hidden or made visible, and its height can be changed. If the cursor is visible, the console window position is moved automatically so the cursor is always in view.

The origin for character cell coordinates in the screen buffer is the upper left corner, and the positions of the cursor and the console window are measured relative to that origin. Use zero-based indexes to specify positions; that is, specify the topmost row as row 0, and the leftmost column as column 0. The maximum value for the row and column indexes is [Int16.MaxValue](#).

Unicode support for the console

In general, the console reads input and writes output by using the current console code page, which the system locale defines by default. A code page can handle only a subset of available Unicode characters, so if you try to display characters that are not mapped by a particular code page, the console won't be able to display all characters or represent them accurately. The following example illustrates this problem. It tries to display the characters of the Cyrillic alphabet from U+0410 to U+044F to the console. If you run the example on a system that uses console code page 437, each character is replaced by a question mark (?), because Cyrillic characters do not map to the characters in code page 437.

C#

```
using System;

public class Example3
{
    public static void Main()
    {
        // Create a Char array for the modern Cyrillic alphabet,
        // from U+0410 to U+044F.
        int nChars = 0x044F - 0x0410 + 1;
        char[] chars = new char[nChars];
        ushort codePoint = 0x0410;
        for (int ctr = 0; ctr < chars.Length; ctr++)
        {
            chars[ctr] = (char)codePoint;
            codePoint++;
        }
    }
}
```

In addition to supporting code pages, the [Console](#) class supports UTF-8 encoding with the [UTF8Encoding](#) class. Beginning with the .NET Framework 4.5, the [Console](#) class also supports UTF-16 encoding with the [UnicodeEncoding](#) class. To display Unicode characters to the console, you set the [OutputEncoding](#) property to either [UTF8Encoding](#) or [UnicodeEncoding](#).

Support for Unicode characters requires the encoder to recognize a particular Unicode character, and also requires a font that has the glyphs needed to render that character. To successfully display Unicode characters to the console, the console font must be set to a non-raster or TrueType font such as Consolas or Lucida Console. The following example shows how you can programmatically change the font from a raster font to Lucida Console.

C#

```
using System;
using System.Runtime.InteropServices;

public class Example2
{
    [DllImport("kernel32.dll", SetLastError = true)]
    static extern IntPtr GetStdHandle(int nStdHandle);

    [DllImport("kernel32.dll", CharSet = CharSet.Unicode, SetLastError =
true)]
    static extern bool GetCurrentConsoleFontEx(
        IntPtr consoleOutput,
        bool maximumWindow,
        ref CONSOLE_FONT_INFO_EX lpConsoleCurrentFontEx);

    [DllImport("kernel32.dll", SetLastError = true)]
    static extern bool SetCurrentConsoleFontEx(
        IntPtr consoleOutput,
        bool maximumWindow,
        ref CONSOLE_FONT_INFO_EX lpConsoleCurrentFontEx);
}
```

```

        IntPtr consoleOutput,
        bool maximumWindow,
        CONSOLE_FONT_INFO_EX consoleCurrentFontEx);

private const int STD_OUTPUT_HANDLE = -11;
private const int TMPF_TRUETYPE = 4;
private const int LF_FACESIZE = 32;
private static IntPtr INVALID_HANDLE_VALUE = new IntPtr(-1);

public static unsafe void Main()
{
    string fontName = "Lucida Console";
    IntPtr hnd = GetStdHandle(STD_OUTPUT_HANDLE);
    if (hnd != INVALID_HANDLE_VALUE)
    {
        CONSOLE_FONT_INFO_EX info = new CONSOLE_FONT_INFO_EX();
        info.cbSize = (uint)Marshal.SizeOf(info);
        bool tt = false;
        // First determine whether there's already a TrueType font.
        if (GetCurrentConsoleFontEx(hnd, false, ref info))
        {
            tt = (info.FontFamily & TMPF_TRUETYPE) == TMPF_TRUETYPE;
            if (tt)
            {
                Console.WriteLine("The console already is using a
TrueType font.");
                return;
            }
            // Set console font to Lucida Console.
            CONSOLE_FONT_INFO_EX newInfo = new CONSOLE_FONT_INFO_EX();
            newInfo.cbSize = (uint)Marshal.SizeOf(newInfo);
            newInfo.FontFamily = TMPF_TRUETYPE;
            IntPtr ptr = new IntPtr(newInfo.FaceName);
            Marshal.Copy(fontName.ToCharArray(), 0, ptr,
fontName.Length);
            // Get some settings from current font.
            newInfo.dwFontSize = new COORD(info.dwFontSize.X,
info.dwFontSize.Y);
            newInfo.FontWeight = info.FontWeight;
            SetCurrentConsoleFontEx(hnd, false, newInfo);
        }
    }
}

[StructLayout(LayoutKind.Sequential)]
internal struct COORD
{
    internal short X;
    internal short Y;

    internal COORD(short x, short y)
    {
        X = x;
        Y = y;
    }
}

```

```

    }

[StructLayout(LayoutKind.Sequential)]
internal unsafe struct CONSOLE_FONT_INFO_EX
{
    internal uint cbSize;
    internal uint nFont;
    internal COORD dwFontSize;
    internal int FontFamily;
    internal int FontWeight;
    internal fixed char FaceName[LF_FACESIZE];
}
}

```

However, TrueType fonts can display only a subset of glyphs. For example, the Lucida Console font displays only 643 of the approximately 64,000 available characters from U+0021 to U+FB02. To see which characters a particular font supports, open the **Fonts** applet in Control Panel, choose the **Find a character** option, and choose the font whose character set you'd like to examine in the **Font** list of the **Character Map** window.

Windows uses font linking to display glyphs that are not available in a particular font. For information about font linking to display additional character sets, see [Globalization Step-by-Step: Fonts](#). Linked fonts are defined in the HKEY_LOCAL_MACHINE\SOFTWARE\Microsoft\Windows NT\CurrentVersion\FontLink\SystemLink subkey of the registry. Each entry associated with this subkey corresponds to the name of a base font, and its value is a string array that defines the font files and the fonts that are linked to the base font. Each member of the array defines a linked font and takes the form *font-file-name,font-name*. The following example illustrates how you can programmatically define a linked font named SimSun found in a font file named simsun.ttc that displays Simplified Han characters.

C#

```

using Microsoft.Win32;
using System;

public class Example
{
    public static void Main()
    {
        string valueName = "Lucida Console";
        string newFont = "simsun.ttc,SimSun";
        string[] fonts = null;
        RegistryValueKind kind = 0;
        bool toAdd;

        RegistryKey key = Registry.LocalMachine.OpenSubKey(
            @"Software\Microsoft\Windows

```

```

NT\CurrentVersion\FontLink\SystemLink",
    true);
if (key == null) {
    Console.WriteLine("Font linking is not enabled.");
}
else {
    // Determine if the font is a base font.
    string[] names = key.GetValueNames();
    if (Array.Exists(names, s => s.Equals(valueName,
                                                StringComparison.OrdinalIgnoreCase)))
{
    // Get the value's type.
    kind = key.GetValueKind(valueName);

    // Type should be RegistryValueKind.MultiString, but we can't be
sure.
    switch (kind) {
        case RegistryValueKind.String:
            fonts = new string[] { (string) key.GetValue(valueName) };
            break;
        case RegistryValueKind.MultiString:
            fonts = (string[]) key.GetValue(valueName);
            break;
        case RegistryValueKind.None:
            // Do nothing.
            fonts = new string[] { };
            break;
    }
    // Determine whether SimSun is a linked font.
    if (Array.FindIndex(fonts, s =>s.IndexOf("SimSun",
                                                StringComparison.OrdinalIgnoreCase)
>=0) >= 0) {
        Console.WriteLine("Font is already linked.");
        toAdd = false;
    }
    else {
        // Font is not a linked font.
        toAdd = true;
    }
}
else {
    // Font is not a base font.
    toAdd = true;
    fonts = new string[] { };
}

if (toAdd) {
    Array.Resize(ref fonts, fonts.Length + 1);
    fonts[fonts.GetUpperBound(0)] = newFont;
    // Change REG_SZ to REG_MULTI_SZ.
    if (kind == RegistryValueKind.String)
        key.DeleteValue(valueName, false);

    key.SetValue(valueName, fonts, RegistryValueKind.MultiString);
    Console.WriteLine("SimSun added to the list of linked fonts.");
}

```

```
        }

        if (key != null) key.Close();
    }
}
```

Unicode support for the console has the following limitations:

- UTF-32 encoding is not supported. The only supported Unicode encodings are UTF-8 and UTF-16, which are represented by the [UTF8Encoding](#) and [UnicodeEncoding](#) classes, respectively.
- Bidirectional output is not supported.
- Display of characters outside the Basic Multilingual Plane (that is, of surrogate pairs) is not supported, even if they are defined in a linked font file.
- Display of characters in complex scripts is not supported.
- Combining character sequences (that is, characters that consist of a base character and one or more combining characters) are displayed as separate characters. To work around this limitation, you can normalize the string to be displayed by calling the [String.Normalize](#) method before sending output to the console. In the following example, a string that contains the combining character sequence U+0061 U+0308 is displayed to the console as two characters before the output string is normalized, and as a single character after the [String.Normalize](#) method is called.

```
C#  
  
using System;  
using System.IO;  
  
public class Example1  
{  
    public static void Main()  
    {  
        char[] chars = { '\u0061', '\u0308' };  
  
        string combining = new String(chars);  
        Console.WriteLine(combining);  
  
        combining = combining.Normalize();  
        Console.WriteLine(combining);  
    }  
}  
// The example displays the following output:
```

```
//      a"  
//      ä
```

Normalization is a viable solution only if the Unicode standard for the character includes a pre-composed form that corresponds to a particular combining character sequence.

- If a font provides a glyph for a code point in the private use area, that glyph will be displayed. However, because characters in the private use area are application-specific, this may not be the expected glyph.

The following example displays a range of Unicode characters to the console. The example accepts three command-line parameters: the start of the range to display, the end of the range to display, and whether to use the current console encoding (`false`) or UTF-16 encoding (`true`). It assumes that the console is using a TrueType font.

C#

```
using System;  
using System.IO;  
using System.Globalization;  
using System.Text;  
  
public static class DisplayChars  
{  
    private static void Main(string[] args)  
    {  
        uint rangeStart = 0;  
        uint rangeEnd = 0;  
        bool setOutputEncodingToUnicode = true;  
        // Get the current encoding so we can restore it.  
        Encoding originalOutputEncoding = Console.OutputEncoding;  
  
        try  
        {  
            switch(args.Length)  
            {  
                case 2:  
                    rangeStart = uint.Parse(args[0], NumberStyles.HexNumber);  
                    rangeEnd = uint.Parse(args[1], NumberStyles.HexNumber);  
                    setOutputEncodingToUnicode = true;  
                    break;  
                case 3:  
                    if (!uint.TryParse(args[0], NumberStyles.HexNumber, null,  
out rangeStart))  
                        throw new ArgumentException(String.Format("{0} is not a  
valid hexadecimal number.", args[0]));  
  
                    if (!uint.TryParse(args[1], NumberStyles.HexNumber, null, out  
rangeEnd))
```

```

        throw new ArgumentException(String.Format("{0} is not a
valid hexadecimal number.", args[1]));

        bool.TryParse(args[2], out setOutputEncodingToUnicode);
        break;
    default:
        Console.WriteLine("Usage: {0} <{1}> <{2}> [{3}]",
            Environment.GetCommandLineArgs()[0],
            "startingCodePointInHex",
            "endingCodePointInHex",
            "<setOutputEncodingToUnicode?{true|false,
default:false}>");
        return;
    }

    if (setOutputEncodingToUnicode) {
        // This won't work before .NET Framework 4.5.
        try {
            // Set encoding using endianness of this system.
            // We're interested in displaying individual Char objects, so
            // we don't want a Unicode BOM or exceptions to be thrown on
            // invalid Char values.
            Console.OutputEncoding = new UnicodeEncoding(!
BitConverter.IsLittleEndian, false);
            Console.WriteLine("\nOutput encoding set to UTF-16");
        }
        catch (IOException) {
            Console.OutputEncoding = new UTF8Encoding();

                // Note that the console will interpret the high and low
            }
        }
    }
}

```

```
//      004e0  З  З  Й  й - Й  й  Ö  ö -- Ø  ø  Ø  ø - Õ  õ  Ý  ý  
//      004f0  ÿ  ý  ÿ  ý - Ӧ  Ӧ  Ӯ  Ӯ  Ӱ  Ӱ  Ӳ  Ӳ  Ӵ  Ӵ  Ӷ  Ӷ
```

Common operations

The [Console](#) class contains the following methods for reading console input and writing console output:

- The overloads of the [ReadKey](#) method read an individual character.
- The [ReadLine](#) method reads an entire line of input.
- The [Write](#) method overloads convert an instance of a value type, an array of characters, or a set of objects to a formatted or unformatted string, and then write that string to the console.
- A parallel set of [WriteLine](#) method overloads output the same string as the [Write](#) overloads but also add a line termination string.

The [Console](#) class also contains methods and properties to perform the following operations:

- Get or set the size of the screen buffer. The [BufferSize](#) and [BufferWidth](#) properties let you get or set the buffer height and width, respectively, and the [SetBufferSize](#) method lets you set the buffer size in a single method call.
- Get or set the size of the console window. The [WindowHeight](#) and [WindowWidth](#) properties let you get or set the window height and width, respectively, and the [SetWindowSize](#) method lets you set the window size in a single method call.
- Get or set the size of the cursor. The [CursorSize](#) property specifies the height of the cursor in a character cell.
- Get or set the position of the console window relative to the screen buffer. The [WindowTop](#) and [WindowLeft](#) properties let you get or set the top row and leftmost column of the screen buffer that appears in the console window, and the [SetWindowPosition](#) method lets you set these values in a single method call.
- Get or set the position of the cursor by getting or setting the [CursorTop](#) and [CursorLeft](#) properties, or set the position of the cursor by calling the [SetCursorPosition](#) method.
- Move or clear data in the screen buffer by calling the [MoveBufferArea](#) or [Clear](#) method.

- Get or set the foreground and background colors by using the [ForegroundColor](#) and [BackgroundColor](#) properties, or reset the background and foreground to their default colors by calling the [ResetColor](#) method.
- Play the sound of a beep through the console speaker by calling the [Beep](#) method.

.NET Core notes

In .NET Framework on the desktop, the [Console](#) class uses the encoding returned by `GetConsoleCP` and `GetConsoleOutputCP`, which typically is a code page encoding. For example code, on systems whose culture is English (United States), code page 437 is the encoding that is used by default. However, .NET Core may make only a limited subset of these encodings available. Where this is the case, [Encoding.UTF8](#) is used as the default encoding for the console.

If your app depends on specific code page encodings, you can still make them available by doing the following *before* you call any [Console](#) methods:

1. Retrieve the [EncodingProvider](#) object from the `CodePagesEncodingProvider.Instance` property.
2. Pass the [EncodingProvider](#) object to the [Encoding.RegisterProvider](#) method to make the additional encodings supported by the encoding provider available.

The [Console](#) class will then automatically use the default system encoding rather than UTF8, provided that you have registered the encoding provider before calling any [Console](#) output methods.

Examples

The following example demonstrates how to read data from, and write data to, the standard input and output streams. Note that these streams can be redirected by using the [SetIn](#) and [SetOut](#) methods.

C#

```
using System;

public class Example4
{
    public static void Main()
    {
        Console.Write("Hello ");
        Console.WriteLine("World!");
    }
}
```

```
        Console.Write("Enter your name: ");
        string name = Console.ReadLine();
        Console.Write("Good day, ");
        Console.Write(name);
        Console.WriteLine("!");
    }
}

// The example displays output similar to the following:
//      Hello World!
//      Enter your name: James
//      Good day, James!
```

System.Random class

Article • 01/08/2024

This article provides supplementary remarks to the reference documentation for this API.

The [Random](#) class represents a pseudo-random number generator, which is an algorithm that produces a sequence of numbers that meet certain statistical requirements for randomness.

Pseudo-random numbers are chosen with equal probability from a finite set of numbers. The chosen numbers are not completely random because a mathematical algorithm is used to select them, but they are sufficiently random for practical purposes. The implementation of the [Random](#) class is based on a modified version of Donald E. Knuth's subtractive random number generator algorithm. For more information, see D. E. Knuth. *The Art of Computer Programming, Volume 2: Seminumerical Algorithms*. Addison-Wesley, Reading, MA, third edition, 1997.

To generate a cryptographically secure random number, such as one that's suitable for creating a random password, use the [RNGCryptoServiceProvider](#) class or derive a class from [System.Security.Cryptography.RandomNumberGenerator](#).

Instantiate the random number generator

You instantiate the random number generator by providing a seed value (a starting value for the pseudo-random number generation algorithm) to a [Random](#) class constructor. You can supply the seed value either explicitly or implicitly:

- The [Random\(Int32\)](#) constructor uses an explicit seed value that you supply.
- The [Random\(\)](#) constructor uses the default seed value. This is the most common way of instantiating the random number generator.

In .NET Framework, the default seed value is time-dependent. In .NET Core, the default seed value is produced by the thread-static, pseudo-random number generator.

If the same seed is used for separate [Random](#) objects, they will generate the same series of random numbers. This can be useful for creating a test suite that processes random values, or for replaying games that derive their data from random numbers. However, note that [Random](#) objects in processes running under different versions of .NET Framework may return different series of random numbers even if they're instantiated with identical seed values.

To produce different sequences of random numbers, you can make the seed value time-dependent, thereby producing a different series with each new instance of [Random](#). The parameterized [Random\(Int32\)](#) constructor can take an [Int32](#) value based on the number of ticks in the current time, whereas the parameterless [Random\(\)](#) constructor uses the system clock to generate its seed value. However, on .NET Framework only, because the clock has finite resolution, using the parameterless constructor to create different [Random](#) objects in close succession creates random number generators that produce identical sequences of random numbers. The following example illustrates how two [Random](#) objects that are instantiated in close succession in a .NET Framework application generate an identical series of random numbers. On most Windows systems, [Random](#) objects created within 15 milliseconds of one another are likely to have identical seed values.

C#

```
byte[] bytes1 = new byte[100];
byte[] bytes2 = new byte[100];
Random rnd1 = new Random();
Random rnd2 = new Random();

rnd1.NextBytes(bytes1);
rnd2.NextBytes(bytes2);

Console.WriteLine("First Series:");
for (int ctr = bytes1.GetLowerBound(0);
    ctr <= bytes1.GetUpperBound(0);
    ctr++) {
    Console.Write("{0, 5}", bytes1[ctr]);
    if ((ctr + 1) % 10 == 0) Console.WriteLine();
}

Console.WriteLine();

Console.WriteLine("Second Series:");
for (int ctr = bytes2.GetLowerBound(0);
    ctr <= bytes2.GetUpperBound(0);
    ctr++) {
    Console.Write("{0, 5}", bytes2[ctr]);
    if ((ctr + 1) % 10 == 0) Console.WriteLine();
}

// The example displays output like the following:
//      First Series:
//      97  129  149  54   22  208  120  105  68  177
//      113  214   30  172   74  218  116  230   89   18
//      12   112  130  105  116  180  190  200  187  120
//      7   198  233  158   58   51   50  170   98   23
//      21     1  113   74  146  245   34  255   96   24
//      232  255   23     9  167  240  255   44  194   98
//      18   175  173  204  169  171  236   127  114   23
```

```

//      167  202  132   65  253   11  254   56  214  127
//      145  191  104  163  143    7  174  224  247   73
//      52    6  231  255    5  101   83  165  160  231
//
//      Second Series:
//      97  129  149   54   22  208  120  105   68  177
//     113  214   30  172   74  218  116  230   89   18
//      12  112  130  105  116  180  190  200  187  120
//      7   198  233  158   58   51   50  170   98   23
//     21    1  113   74  146  245   34  255   96   24
//    232  255   23    9  167  240  255   44  194  98
//     18  175  173  204  169  171  236  127  114   23
//    167  202  132   65  253   11  254   56  214  127
//    145  191  104  163  143    7  174  224  247   73
//      52    6  231  255    5  101   83  165  160  231

```

To avoid this problem, create a single [Random](#) object instead of multiple objects. Note that the `Random` class in .NET Core does not have this limitation.

Avoid multiple instantiations

On .NET Framework, initializing two random number generators in a tight loop or in rapid succession creates two random number generators that can produce identical sequences of random numbers. In most cases, this is not the developer's intent and can lead to performance issues, because instantiating and initializing a random number generator is a relatively expensive process.

Both to improve performance and to avoid inadvertently creating separate random number generators that generate identical numeric sequences, we recommend that you create one [Random](#) object to generate many random numbers over time, instead of creating new [Random](#) objects to generate one random number.

However, the [Random](#) class isn't thread safe. If you call [Random](#) methods from multiple threads, follow the guidelines discussed in the next section.

Thread safety

Instead of instantiating individual [Random](#) objects, we recommend that you create a single [Random](#) instance to generate all the random numbers needed by your app.

However, [Random](#) objects are not thread safe. If your app calls [Random](#) methods from multiple threads, you must use a synchronization object to ensure that only one thread can access the random number generator at a time. If you don't ensure that the [Random](#) object is accessed in a thread-safe way, calls to methods that return random numbers return 0.

The following example uses the C# [lock Statement](#), the F# [lock function](#) and the Visual Basic [SyncLock statement](#) to ensure that a single random number generator is accessed by 11 threads in a thread-safe manner. Each thread generates 2 million random numbers, counts the number of random numbers generated and calculates their sum, and then updates the totals for all threads when it finishes executing.

C#

```
using System;
using System.Threading;

public class Example13
{
    [ThreadStatic] static double previous = 0.0;
    [ThreadStatic] static int perThreadCtr = 0;
    [ThreadStatic] static double perThreadTotal = 0.0;
    static CancellationTokenSource source;
    static CountdownEvent countdown;
    static Object randLock, numericLock;
    static Random rand;
    double totalValue = 0.0;
    int totalCount = 0;

    public Example13()
    {
        rand = new Random();
        randLock = new Object();
        numericLock = new Object();
        countdown = new CountdownEvent(1);
        source = new CancellationTokenSource();
    }

    public static void Main()
    {
        Example13 ex = new Example13();
        Thread.CurrentThread.Name = "Main";
        ex.Execute();
    }

    private void Execute()
    {
        CancellationToken token = source.Token;

        for (int threads = 1; threads <= 10; threads++)
        {
            Thread newThread = new Thread(this.GetRandomNumbers);
            newThread.Name = threads.ToString();
            newThread.Start(token);
        }
        this.GetRandomNumbers(token);

        countdown.Signal();
        // Make sure all threads have finished.
    }
}
```

```

        countdown.Wait();
        source.Dispose();

        Console.WriteLine("\nTotal random numbers generated: {0:N0}",
totalCount);
        Console.WriteLine("Total sum of all random numbers: {0:N2}",
totalValue);
        Console.WriteLine("Random number mean: {0:N4}", totalValue /
totalCount);
    }

    private void GetRandomNumbers(Object o)
{
    CancellationToken token = (CancellationToken)o;
    double result = 0.0;
    countdown.AddCount(1);

    try
    {
        for (int ctr = 0; ctr < 2000000; ctr++)
        {
            // Make sure there's no corruption of Random.
            token.ThrowIfCancellationRequested();

            lock (randLock)
            {
                result = rand.NextDouble();
            }
            // Check for corruption of Random instance.
            if ((result == previous) && result == 0)
            {
                source.Cancel();
            }
            else
            {
                previous = result;
            }
            perThreadCtr++;
            perThreadTotal += result;
        }
    }

    Console.WriteLine("Thread {0} finished execution.",
Thread.CurrentThread.Name);
    Console.WriteLine("Random numbers generated: {0:N0}",
perThreadCtr);
    Console.WriteLine("Sum of random numbers: {0:N2}",
perThreadTotal);
    Console.WriteLine("Random number mean: {0:N4}\n",
perThreadTotal / perThreadCtr);

    // Update overall totals.
    lock (numericLock)
    {
        totalCount += perThreadCtr;
        totalValue += perThreadTotal;
    }
}

```

```
        }
    }
    catch (OperationCanceledException e)
    {
        Console.WriteLine("Corruption in Thread {1}", e.GetType().Name,
Thread.CurrentThread.Name);
    }
    finally
    {
        countdown.Signal();
    }
}
}

// The example displays output like the following:
//      Thread 6 finished execution.
//      Random numbers generated: 2,000,000
//      Sum of random numbers: 1,000,491.05
//      Random number mean: 0.5002
//
//      Thread 10 finished execution.
//      Random numbers generated: 2,000,000
//      Sum of random numbers: 999,329.64
//      Random number mean: 0.4997
//
//      Thread 4 finished execution.
//      Random numbers generated: 2,000,000
//      Sum of random numbers: 1,000,166.89
//      Random number mean: 0.5001
//
//      Thread 8 finished execution.
//      Random numbers generated: 2,000,000
//      Sum of random numbers: 999,628.37
//      Random number mean: 0.4998
//
//      Thread Main finished execution.
//      Random numbers generated: 2,000,000
//      Sum of random numbers: 999,920.89
//      Random number mean: 0.5000
//
//      Thread 3 finished execution.
//      Random numbers generated: 2,000,000
//      Sum of random numbers: 999,370.45
//      Random number mean: 0.4997
//
//      Thread 7 finished execution.
//      Random numbers generated: 2,000,000
//      Sum of random numbers: 999,330.92
//      Random number mean: 0.4997
//
//      Thread 9 finished execution.
//      Random numbers generated: 2,000,000
//      Sum of random numbers: 1,000,172.79
//      Random number mean: 0.5001
//
//      Thread 5 finished execution.
```

```

//      Random numbers generated: 2,000,000
//      Sum of random numbers: 1,000,079.43
//      Random number mean: 0.5000
//
//      Thread 1 finished execution.
//      Random numbers generated: 2,000,000
//      Sum of random numbers: 999,817.91
//      Random number mean: 0.4999
//
//      Thread 2 finished execution.
//      Random numbers generated: 2,000,000
//      Sum of random numbers: 999,930.63
//      Random number mean: 0.5000
//
//      Total random numbers generated: 22,000,000
//      Total sum of all random numbers: 10,998,238.98
//      Random number mean: 0.4999

```

The example ensures thread-safety in the following ways:

- The [ThreadStaticAttribute](#) attribute is used to define thread-local variables that track the total number of random numbers generated and their sum for each thread.
- A lock (the `lock` statement in C#, the `lock` function in F# and the `SyncLock` statement in Visual Basic) protects access to the variables for the total count and sum of all random numbers generated on all threads.
- A semaphore (the [CountdownEvent](#) object) is used to ensure that the main thread blocks until all other threads complete execution.
- The example checks whether the random number generator has become corrupted by determining whether two consecutive calls to random number generation methods return 0. If corruption is detected, the example uses the [CancellationTokenSource](#) object to signal that all threads should be canceled.
- Before generating each random number, each thread checks the state of the [CancellationToken](#) object. If cancellation is requested, the example calls the [CancellationToken.ThrowIfCancellationRequested](#) method to cancel the thread.

The following example is identical to the first, except that it uses a [Task](#) object and a lambda expression instead of [Thread](#) objects.

C#

```

using System;
using System.Collections.Generic;
using System.Threading;
using System.Threading.Tasks;

```

```
public class Example15
{
    static Object randLock, numericLock;
    static Random rand;
    static CancellationTokenSource source;
    double totalValue = 0.0;
    int totalCount = 0;

    public Example15()
    {
        rand = new Random();
        randLock = new Object();
        numericLock = new Object();
        source = new CancellationTokenSource();
    }

    public static async Task Main()
    {
        Example15 ex = new Example15();
        Thread.CurrentThread.Name = "Main";
        await ex.Execute();
    }

    private async Task Execute()
    {
        List<Task> tasks = new List<Task>();

        for (int ctr = 0; ctr <= 10; ctr++)
        {
            CancellationToken token = source.Token;
            int taskNo = ctr;
            tasks.Add(Task.Run(() =>
            {
                double previous = 0.0;
                int taskCtr = 0;
                double taskTotal = 0.0;
                double result = 0.0;

                for (int n = 0; n < 2000000; n++)
                {
                    // Make sure there's no corruption of Random.
                    token.ThrowIfCancellationRequested();

                    lock (randLock)
                    {
                        result = rand.NextDouble();
                    }
                    // Check for corruption of Random instance.
                    if ((result == previous) && result == 0)
                    {
                        source.Cancel();
                    }
                    else
                    {
                        previous = result;
                    }
                }
            }));
        }
    }
}
```

```

        }
        taskCtr++;
        taskTotal += result;
    }

    // Show result.
    Console.WriteLine("Task {0} finished execution.",
taskNo);
    Console.WriteLine("Random numbers generated: {0:N0}",
taskCtr);
    Console.WriteLine("Sum of random numbers: {0:N2}",
taskTotal);
    Console.WriteLine("Random number mean: {0:N4}\n",
taskTotal / taskCtr);

    // Update overall totals.
    lock (numericLock)
    {
        totalCount += taskCtr;
        totalValue += taskTotal;
    }
},
token));
}
try
{
    await Task.WhenAll(tasks.ToArray());
    Console.WriteLine("\nTotal random numbers generated: {0:N0}",
totalCount);
    Console.WriteLine("Total sum of all random numbers: {0:N2}",
totalValue);
    Console.WriteLine("Random number mean: {0:N4}", totalValue /
totalCount);
}
catch (AggregateException e)
{
    foreach (Exception inner in e.InnerExceptions)
    {
        TaskCanceledException canc = inner as TaskCanceledException;
        if (canc != null)
            Console.WriteLine("Task #{0} cancelled.", canc.Task.Id);
        else
            Console.WriteLine("Exception: {0}",
inner.GetType().Name);
    }
}
finally
{
    source.Dispose();
}
}
}

// The example displays output like the following:
//      Task 1 finished execution.
//      Random numbers generated: 2,000,000

```

```
//      Sum of random numbers: 1,000,502.47
//      Random number mean: 0.5003
//
//      Task 0 finished execution.
//      Random numbers generated: 2,000,000
//      Sum of random numbers: 1,000,445.63
//      Random number mean: 0.5002
//
//      Task 2 finished execution.
//      Random numbers generated: 2,000,000
//      Sum of random numbers: 1,000,556.04
//      Random number mean: 0.5003
//
//      Task 3 finished execution.
//      Random numbers generated: 2,000,000
//      Sum of random numbers: 1,000,178.87
//      Random number mean: 0.5001
//
//      Task 4 finished execution.
//      Random numbers generated: 2,000,000
//      Sum of random numbers: 999,819.17
//      Random number mean: 0.4999
//
//      Task 5 finished execution.
//      Random numbers generated: 2,000,000
//      Sum of random numbers: 1,000,190.58
//      Random number mean: 0.5001
//
//      Task 6 finished execution.
//      Random numbers generated: 2,000,000
//      Sum of random numbers: 999,720.21
//      Random number mean: 0.4999
//
//      Task 7 finished execution.
//      Random numbers generated: 2,000,000
//      Sum of random numbers: 999,000.96
//      Random number mean: 0.4995
//
//      Task 8 finished execution.
//      Random numbers generated: 2,000,000
//      Sum of random numbers: 999,499.33
//      Random number mean: 0.4997
//
//      Task 9 finished execution.
//      Random numbers generated: 2,000,000
//      Sum of random numbers: 1,000,193.25
//      Random number mean: 0.5001
//
//      Task 10 finished execution.
//      Random numbers generated: 2,000,000
//      Sum of random numbers: 999,960.82
//      Random number mean: 0.5000
//
//      Total random numbers generated: 22,000,000
```

```
//      Total sum of all random numbers: 11,000,067.33
//      Random number mean: 0.5000
```

It differs from the first example in the following ways:

- The variables to keep track of the number of random numbers generated and their sum in each task are local to the task, so there is no need to use the [ThreadStaticAttribute](#) attribute.
- The static [Task.WaitAll](#) method is used to ensure that the main thread doesn't complete before all tasks have finished. There is no need for the [CountdownEvent](#) object.
- The exception that results from task cancellation is surfaced in the [Task.WaitAll](#) method. In the previous example, it is handled by each thread.

Generate different types of random numbers

The random number generator provides methods that let you generate the following kinds of random numbers:

- A series of [Byte](#) values. You determine the number of byte values by passing an array initialized to the number of elements you want the method to return to the [NextBytes](#) method. The following example generates 20 bytes.

C#

```
Random rnd = new Random();
Byte[] bytes = new Byte[20];
rnd.NextBytes(bytes);
for (int ctr = 1; ctr <= bytes.Length; ctr++)
{
    Console.Write("{0,3} ", bytes[ctr - 1]);
    if (ctr % 10 == 0) Console.WriteLine();
}

// The example displays output like the following:
//      141    48    189    66    134    212    211    71    161    56
//      181    166   220   133     9    252    222    57    62    62
```

- A single integer. You can choose whether you want an integer from 0 to a maximum value ([Int32.MaxValue](#) - 1) by calling the [Next\(\)](#) method, an integer between 0 and a specific value by calling the [Next\(Int32\)](#) method, or an integer within a range of values by calling the [Next\(Int32, Int32\)](#) method. In the parameterized overloads, the specified maximum value is exclusive; that is, the actual maximum number generated is one less than the specified value.

The following example calls the [Next\(Int32, Int32\)](#) method to generate 10 random numbers between -10 and 10. Note that the second argument to the method specifies the exclusive upper bound of the range of random values returned by the method. In other words, the largest integer that the method can return is one less than this value.

C#

```
Random rnd = new Random();
for (int ctr = 0; ctr < 10; ctr++)
{
    Console.WriteLine("{0,3} ", rnd.Next(-10, 11));
}

// The example displays output like the following:
//    2     9    -3     2     4    -7    -3    -8    -8      5
```

- A single floating-point value from 0.0 to less than 1.0 by calling the [NextDouble](#) method. The exclusive upper bound of the random number returned by the method is 1, so its actual upper bound is 0.9999999999999978. The following example generates 10 random floating-point numbers.

C#

```
Random rnd = new Random();
for (int ctr = 0; ctr < 10; ctr++)
{
    Console.WriteLine("{0,-19:R} ", rnd.NextDouble());
    if ((ctr + 1) % 3 == 0) Console.WriteLine();
}

// The example displays output like the following:
//    0.7911680553998649    0.0903414949264105    0.79776258291572455
//    0.615568345233597    0.652644504165577    0.84023809378977776
//    0.099662564741290441   0.91341467383942321   0.96018602045261581
//    0.74772306473354022
```

ⓘ Important

The [Next\(Int32, Int32\)](#) method allows you to specify the range of the returned random number. However, the `maxValue` parameter, which specifies the upper range returned number, is an exclusive, not an inclusive, value. This means that the method call `Next(0, 100)` returns a value between 0 and 99, and not between 0 and 100.

You can also use the [Random](#) class for such tasks as generating [random Boolean values](#), generating [random floating-point values in a specified range](#), generating [Generate random 64-bit integers](#), and [retrieving a unique element from an array or collection](#).

Substitute your own algorithm

You can implement your own random number generator by inheriting from the [Random](#) class and supplying your random number generation algorithm. To supply your own algorithm, you must override the [Sample](#) method, which implements the random number generation algorithm. You should also override the [Next\(\)](#), [Next\(Int32, Int32\)](#), and [NextBytes](#) methods to ensure that they call your overridden [Sample](#) method. You don't have to override the [Next\(Int32\)](#) and [NextDouble](#) methods.

For an example that derives from the [Random](#) class and modifies its default pseudo-random number generator, see the [Sample](#) reference page.

Retrieve the same sequence of random values

Sometimes you want to generate the same sequence of random numbers in software test scenarios and in game playing. Testing with the same sequence of random numbers allows you to detect regressions and confirm bug fixes. Using the same sequence of random number in games allows you to replay previous games.

You can generate the same sequence of random numbers by providing the same seed value to the [Random\(Int32\)](#) constructor. The seed value provides a starting value for the pseudo-random number generation algorithm. The following example uses 100100 as an arbitrary seed value to instantiate the [Random](#) object, displays 20 random floating-point values, and persists the seed value. It then restores the seed value, instantiates a new random number generator, and displays the same 20 random floating-point values. Note that the example may produce different sequences of random numbers if run on different versions of .NET.

C#

```
using System;
using System.IO;

public class Example12
{
    public static void Main()
    {
        int seed = 100100;
        ShowRandomNumbers(seed);
        Console.WriteLine();
    }

    static void ShowRandomNumbers(int seed)
    {
        Random r = new Random(seed);
        for (int i = 0; i < 20; i++)
        {
            double d = r.NextDouble();
            Console.WriteLine(d);
        }
    }
}
```

```
PersistSeed(seed);

        DisplayNewRandomNumbers();
    }

private static void ShowRandomNumbers(int seed)
{
    Random rnd = new Random(seed);
    for (int ctr = 0; ctr <= 20; ctr++)
        Console.WriteLine(rnd.NextDouble());
}

private static void PersistSeed(int seed)
{
    FileStream fs = new FileStream(@".\seed.dat", FileMode.Create);
    BinaryWriter bin = new BinaryWriter(fs);
    bin.Write(seed);
    bin.Close();
}

private static void DisplayNewRandomNumbers()
{
    FileStream fs = new FileStream(@".\seed.dat", FileMode.Open);
    BinaryReader bin = new BinaryReader(fs);
    int seed = bin.ReadInt32();
    bin.Close();

    Random rnd = new Random(seed);
    for (int ctr = 0; ctr <= 20; ctr++)
        Console.WriteLine(rnd.NextDouble());
}

// The example displays output like the following:
//      0.500193602172748
//      0.0209461245783354
//      0.465869495396442

//          0.4228545699375
//          0.523320379910674
//          0.157783938645285
```

Retrieve unique sequences of random numbers

Providing different seed values to instances of the [Random](#) class causes each random number generator to produce a different sequence of values. You can provide a seed value either explicitly by calling the [Random\(Int32\)](#) constructor, or implicitly by calling the [Random\(\)](#) constructor. Most developers call the parameterless constructor, which uses the system clock. The following example uses this approach to instantiate two [Random](#) instances. Each instance displays a series of 10 random integers.

C#

```
using System;
using System.Threading;

public class Example16
{
    public static void Main()
    {
        Console.WriteLine("Instantiating two random number generators...");
        Random rnd1 = new Random();
        Thread.Sleep(2000);
        Random rnd2 = new Random();

        Console.WriteLine("\nThe first random number generator:");
        for (int ctr = 1; ctr <= 10; ctr++)
            Console.WriteLine("    {0}", rnd1.Next());
```

```

        Console.WriteLine("\nThe second random number generator:");
        for (int ctr = 1; ctr <= 10; ctr++)
            Console.WriteLine("    {0}", rnd2.Next());
    }
}

// The example displays output like the following:
//     Instantiating two random number generators...
//
//         The first random number generator:
//
//             643164361
//
//             1606571630
//
//             1725607587
//
//             2138048432
//
//             496874898
//
//             1969147632
//
//             2034533749
//
//             1840964542
//
//             412380298
//
//             47518930
//
//         The second random number generator:
//
//             1251659083
//
//             1514185439
//
//             1465798544
//
//             517841554
//
//             1821920222
//
//             195154223
//
//             1538948391
//
//             1548375095
//
//             546062716
//
//             897797880

```

However, because of its finite resolution, the system clock doesn't detect time differences that are less than approximately 15 milliseconds. Therefore, if your code calls the [Random\(\)](#) overload on .NET Framework to instantiate two [Random](#) objects in succession, you might inadvertently be providing the objects with identical seed values. (The [Random](#) class in .NET Core does not have this limitation.) To see this in the previous example, comment out the [Thread.Sleep](#) method call, and compile and run the example again.

To prevent this from happening, we recommend that you instantiate a single [Random](#) object rather than multiple ones. However, since [Random](#) isn't thread safe, you must use some synchronization device if you access a [Random](#) instance from multiple threads; for more information, see the [Thread safety](#) section. Alternately, you can use a delay mechanism, such as the [Sleep](#) method used in the previous example, to ensure that the instantiations occur more than 15 millisecond apart.

Retrieve integers in a specified range

You can retrieve integers in a specified range by calling the [Next\(Int32, Int32\)](#) method, which lets you specify both the lower and the upper bound of the numbers you'd like the random number generator to return. The upper bound is an exclusive, not an inclusive, value. That is, it isn't included in the range of values returned by the method. The following example uses this method to generate random integers between -10 and 10. Note that it specifies 11, which is one greater than the desired value, as the value of the `maxValue` argument in the method call.

C#

```
Random rnd = new Random();
for (int ctr = 1; ctr <= 15; ctr++)
{
    Console.WriteLine("{0,3}    ", rnd.Next(-10, 11));
    if (ctr % 5 == 0) Console.WriteLine();
}

// The example displays output like the following:
//      -2      -5      -1      -2      10
//      -3       6      -4      -8       3
//      -7      10       5      -2       4
```

Retrieve integers with a specified number of digits

You can call the [Next\(Int32, Int32\)](#) method to retrieve numbers with a specified number of digits. For example, to retrieve numbers with four digits (that is, numbers that range from 1000 to 9999), you call the [Next\(Int32, Int32\)](#) method with a `minValue` value of 1000 and a `maxValue` value of 10000, as the following example shows.

C#

```
Random rnd = new Random();
for (int ctr = 1; ctr <= 50; ctr++)
{
    Console.WriteLine("{0,3}    ", rnd.Next(1000, 10000));
    if (ctr % 10 == 0) Console.WriteLine();
}

// The example displays output like the following:
//      9570      8979      5770      1606      3818      4735      8495      7196      7070
//      2313
//      5279      6577      5104      5734      4227      3373      7376      6007      8193
//      5540
//      7558      3934      3819      7392      1113      7191      6947      4963      9179
//      7907
```

```
//      3391    6667    7269    1838    7317    1981    5154    7377    3297  
5320  
//      9869    8694    2684    4949    2999    3019    2357    5211    9604  
2593
```

Retrieve floating-point values in a specified range

The [NextDouble](#) method returns random floating-point values that range from 0 to less than 1. However, you'll often want to generate random values in some other range.

If the interval between the minimum and maximum desired values is 1, you can add the difference between the desired starting interval and 0 to the number returned by the [NextDouble](#) method. The following example does this to generate 10 random numbers between -1 and 0.

C#

```
Random rnd = new Random();  
for (int ctr = 1; ctr <= 10; ctr++)  
    Console.WriteLine(rnd.NextDouble() - 1);  
  
// The example displays output like the following:  
//      -0.930412760437658  
//      -0.164699016215605  
//      -0.9851692803135  
//      -0.43468508843085  
//      -0.177202483255976  
//      -0.776813320245972  
//      -0.0713201854710096  
//      -0.0912875561468711  
//      -0.540621722368813  
//      -0.232211863730201
```

To generate random floating-point numbers whose lower bound is 0 but upper bound is greater than 1 (or, in the case of negative numbers, whose lower bound is less than -1 and upper bound is 0), multiply the random number by the non-zero bound. The following example does this to generate 20 million random floating-point numbers that range from 0 to [Int64.MaxValue](#). It also displays the distribution of the random values generated by the method.

C#

```
const long ONE_TENTH = 922337203685477581;  
  
Random rnd = new Random();
```

```

double number;
int[] count = new int[10];

// Generate 20 million integer values between.
for (int ctr = 1; ctr <= 20000000; ctr++)
{
    number = rnd.NextDouble() * Int64.MaxValue;
    // Categorize random numbers into 10 groups.
    count[(int)(number / ONE_TENTH)]++;
}
// Display breakdown by range.
Console.WriteLine("{0,28} {1,32} {2,7}\n", "Range", "Count", "Pct.");
for (int ctr = 0; ctr <= 9; ctr++)
    Console.WriteLine("{0,25:N0}-{1,25:N0} {2,8:N0} {3,7:P2}", ctr *
ONE_TENTH,
                      ctr < 9 ? ctr * ONE_TENTH + ONE_TENTH - 1 :
Int64.MaxValue,
                      count[ctr], count[ctr] / 20000000.0);

// The example displays output like the following:
//          Range           Count
Pct.
//
//          0- 922,337,203,685,477,580 1,996,148   9.98
%
//      922,337,203,685,477,581-1,844,674,407,370,955,161 2,000,293   10.00
%
//      1,844,674,407,370,955,162-2,767,011,611,056,432,742 2,000,094   10.00
%
//      2,767,011,611,056,432,743-3,689,348,814,741,910,323 2,000,159   10.00
%
//      3,689,348,814,741,910,324-4,611,686,018,427,387,904 1,999,552   10.00
%

%

```

To generate random floating-point numbers between two arbitrary values, like the [Next\(Int32, Int32\)](#) method does for integers, use the following formula:

C#

```
Random.NextDouble() * (maxValue - minValue) + minValue
```

The following example generates 1 million random numbers that range from 10.0 to 11.0, and displays their distribution.

C#

```
Random rnd = new Random();
int lowerBound = 10;
int upperBound = 11;
int[] range = new int[10];
for (int ctr = 1; ctr <= 1000000; ctr++)
{
    Double value = rnd.NextDouble() * (upperBound - lowerBound) +
lowerBound;
    range[(int)Math.Truncate((value - lowerBound) * 10)]++;
}

for (int ctr = 0; ctr <= 9; ctr++)
{
    Double lowerRange = 10 + ctr * .1;
    Console.WriteLine("{0:N1} to {1:N1}: {2,8:N0} ({3,7:P2})",
                      lowerRange, lowerRange + .1, range[ctr],
                      range[ctr] / 1000000.0);
}

// The example displays output like the following:
//      10.0 to 10.1:  99,929  ( 9.99 %)
//      10.1 to 10.2:  100,189  (10.02 %)
//      10.2 to 10.3:  99,384  ( 9.94 %)
//      10.3 to 10.4:  100,240  (10.02 %)
//      10.4 to 10.5:  99,397  ( 9.94 %)
//      10.5 to 10.6:  100,580  (10.06 %)
//      10.6 to 10.7:  100,293  (10.03 %)
//      10.7 to 10.8:  100,135  (10.01 %)
//      10.8 to 10.9:  99,905  ( 9.99 %)
//      10.9 to 11.0:  99,948  ( 9.99 %)
```

Generate random Boolean values

The [Random](#) class doesn't provide methods that generate [Boolean](#) values. However, you can define your own class or method to do that. The following example defines a class, [BooleanGenerator](#), with a single method, [NextBoolean](#). The [BooleanGenerator](#) class stores a [Random](#) object as a private variable. The [NextBoolean](#) method calls the [Random.Next\(Int32, Int32\)](#) method and passes the result to the [Convert.ToBoolean\(Int32\)](#) method. Note that 2 is used as the argument to specify the upper bound of the random number. Since this is an exclusive value, the method call returns either 0 or 1.

C#

```

using System;

public class Example1
{
    public static void Main()
    {
        // Instantiate the Boolean generator.
        BooleanGenerator boolGen = new BooleanGenerator();
        int totalTrue = 0, totalFalse = 0;

        // Generate 1,000 random Booleans, and keep a running total.
        for (int ctr = 0; ctr < 1000000; ctr++)
        {
            bool value = boolGen.NextBoolean();
            if (value)
                totalTrue++;
            else
                totalFalse++;
        }
        Console.WriteLine("Number of true values: {0,7:N0} ({1:P3})",
                          totalTrue,
                          ((double)totalTrue) / (totalTrue + totalFalse));
        Console.WriteLine("Number of false values: {0,7:N0} ({1:P3})",
                          totalFalse,
                          ((double)totalFalse) / (totalTrue + totalFalse));
    }
}

public class BooleanGenerator
{
    Random rnd;

    public BooleanGenerator()
    {
        rnd = new Random();
    }

    public bool NextBoolean()
    {
        return rnd.Next(0, 2) == 1;
    }
}
// The example displays output like the following:
//      Number of true values: 500,004 (50.000 %)
//      Number of false values: 499,996 (50.000 %)

```

Instead of creating a separate class to generate random `Boolean` values, the example could simply have defined a single method. In that case, however, the `Random` object should have been defined as a class-level variable to avoid instantiating a new `Random` instance in each method call. In Visual Basic, the `Random` instance can be defined as a

Static variable in the `NextBoolean` method. The following example provides an implementation.

C#

```
Random rnd = new Random();

int totalTrue = 0, totalFalse = 0;

// Generate 1,000,000 random Booleans, and keep a running total.
for (int ctr = 0; ctr < 1000000; ctr++)
{
    bool value = NextBoolean();
    if (value)
        totalTrue++;
    else
        totalFalse++;
}
Console.WriteLine("Number of true values: {0,7:N0} ({1:P3})",
                  totalTrue,
                  ((double)totalTrue) / (totalTrue + totalFalse));
Console.WriteLine("Number of false values: {0,7:N0} ({1:P3})",
                  totalFalse,
                  ((double)totalFalse) / (totalTrue + totalFalse));

bool NextBoolean()
{
    return rnd.Next(0, 2) == 1;

// The example displays output like the following:
//      Number of true values: 499,777 (49.978 %)
//      Number of false values: 500,223 (50.022 %)
```

Generate random 64-bit integers

The overloads of the `Next` method return 32-bit integers. However, in some cases, you might want to work with 64-bit integers. You can do this as follows:

1. Call the `NextDouble` method to retrieve a double-precision floating point value.
2. Multiply that value by `Int64.MaxValue`.

The following example uses this technique to generate 20 million random long integers and categorizes them in 10 equal groups. It then evaluates the distribution of the random numbers by counting the number in each group from 0 to `Int64.MaxValue`. As the output from the example shows, the numbers are distributed more or less equally through the range of a long integer.

C#

```
const long ONE_TENTH = 922337203685477581;

Random rnd = new Random();
long number;
int[] count = new int[10];

// Generate 20 million long integers.
for (int ctr = 1; ctr <= 20000000; ctr++)
{
    number = (long)(rnd.NextDouble() * Int64.MaxValue);
    // Categorize random numbers.
    count[(int)(number / ONE_TENTH)]++;
}

// Display breakdown by range.
Console.WriteLine("{0,28} {1,32} {2,7}\n", "Range", "Count", "Pct.");
for (int ctr = 0; ctr <= 9; ctr++)
    Console.WriteLine("{0,25:N0}-{1,25:N0} {2,8:N0} {3,7:P2}", ctr *
ONE_TENTH,
                      ctr < 9 ? ctr * ONE_TENTH + ONE_TENTH - 1 :
Int64.MaxValue,
                      count[ctr], count[ctr] / 20000000.0);

// The example displays output like the following:
//          Range           Count
Pct.
//
//          0- 922,337,203,685,477,580  1,996,148   9.98
%
//          922,337,203,685,477,581-1,844,674,407,370,955,161  2,000,293   10.00
%
//          1,844,674,407,370,955,162-2,767,011,611,056,432,742  2,000,094   10.00
%
//          2,767,011,611,056,432,743-3,689,348,814,741,910,323  2,000,159   10.00
%
//          3,689,348,814,741,910,324-4,611,686,018,427,387,904  1,999,552   10.00
%
//          4,611,686,018,427,387,905-5,534,023,222,112,865,485  1,998,248   9.99
%
//          5,534,023,222,112,865,486-6,456,360,425,798,343,066  2,000,696   10.00
%
//          6,456,360,425,798,343,067-7,378,697,629,483,820,647  2,001,637   10.01
%
//          7,378,697,629,483,820,648-8,301,034,833,169,298,228  2,002,870   10.01
%
//          8,301,034,833,169,298,229-9,223,372,036,854,775,807  2,000,303   10.00
```

An alternative technique that uses bit manipulation does not generate truly random numbers. This technique calls [Next\(\)](#) to generate two integers, left-shifts one by 32 bits, and ORs them together. This technique has two limitations:

1. Because bit 31 is the sign bit, the value in bit 31 of the resulting long integer is always 0. This can be addressed by generating a random 0 or 1, left-shifting it 31 bits, and ORing it with the original random long integer.
2. More seriously, because the probability that the value returned by `Next()` will be 0, there will be few if any random numbers in the range 0x0-0x00000000FFFFFFFFFF.

Retrieve bytes in a specified range

The overloads of the `Next` method allow you to specify the range of random numbers, but the `NextBytes` method does not. The following example implements a `NextBytes` method that lets you specify the range of the returned bytes. It defines a `Random2` class that derives from `Random` and overloads its `NextBytes` method.

C#

```
using System;

public class Example3
{
    public static void Main()
    {
        Random2 rnd = new Random2();
        Byte[] bytes = new Byte[10000];
        int[] total = new int[101];
        rnd.NextBytes(bytes, 0, 101);

        // Calculate how many of each value we have.
        foreach (var value in bytes)
            total[value]++;

        // Display the results.
        for (int ctr = 0; ctr < total.Length; ctr++)
        {
            Console.Write("{0,3}: {1,-3}    ", ctr, total[ctr]);
            if ((ctr + 1) % 5 == 0) Console.WriteLine();
        }
    }

    public class Random2 : Random
    {
        public Random2() : base()
        { }

        public Random2(int seed) : base(seed)
        { }

        public void NextBytes(Byte[] bytes, byte minValue, byte maxValue)
        {

```

```

        for (int ctr = bytes.GetLowerBound(0); ctr <=
bytes.GetUpperBound(0); ctr++)
            bytes[ctr] = (byte)Next(minValue, maxValue);
    }
}

// The example displays output like the following:
//      0: 115      1: 119      2: 92      3: 98      4: 92
//      5: 102      6: 103      7: 84      8: 93      9: 116
//     10: 91      11: 98      12: 106     13: 91      14: 92
//     15: 101      16: 100      17: 96      18: 97      19: 100
//     20: 101      21: 106      22: 112     23: 82      24: 85
//     25: 102      26: 107      27: 98      28: 106     29: 102
//     30: 109      31: 108      32: 94      33: 101     34: 107
//     35: 101      36: 86       37: 100     38: 101     39: 102
//     40: 113      41: 95       42: 96       43: 89      44: 99
//     45: 81       46: 89       47: 105     48: 100     49: 85
//     50: 103      51: 103      52: 93       53: 89      54: 91
//     55: 97       56: 105      57: 97       58: 110     59: 86
//     60: 116      61: 94       62: 117     63: 98      64: 110
//     65: 93       66: 102      67: 100     68: 105     69: 83
//     70: 81       71: 97       72: 85       73: 70      74: 98
//     75: 100      76: 110      77: 114     78: 83      79: 90
//     80: 96       81: 112      82: 102     83: 102     84: 99
//     85: 81       86: 100      87: 93       88: 99      89: 118
//     90: 95       91: 124      92: 108     93: 96      94: 104
//     95: 106      96: 99       97: 99       98: 92      99: 99
//    100: 108

```

The `NextBytes(Byte[], Byte, Byte)` method wraps a call to the `Next(Int32, Int32)` method and specifies the minimum value and one greater than the maximum value (in this case, 0 and 101) that we want returned in the byte array. Because we are sure that the integer values returned by the `Next` method are within the range of the `Byte` data type, we can safely cast them (in C# and F#) or convert them (in Visual Basic) from integers to bytes.

Retrieve an element from an array or collection at random

Random numbers often serve as indexes to retrieve values from arrays or collections. To retrieve a random index value, you can call the `Next(Int32, Int32)` method, and use the lower bound of the array as the value of its `minValue` argument and one greater than the upper bound of the array as the value of its `maxValue` argument. For a zero-based array, this is equivalent to its `Length` property, or one greater than the value returned by the `Array.GetUpperBound` method. The following example randomly retrieves the name of a city in the United States from an array of cities.

C#

```
String[] cities = { "Atlanta", "Boston", "Chicago", "Detroit",
                    "Fort Wayne", "Greensboro", "Honolulu", "Indianapolis",
                    "Jersey City", "Kansas City", "Los Angeles",
                    "Milwaukee", "New York", "Omaha", "Philadelphia",
                    "Raleigh", "San Francisco", "Tulsa", "Washington" };
Random rnd = new Random();
int index = rnd.Next(0, cities.Length);
Console.WriteLine("Today's city of the day: {0}",
                  cities[index]);

// The example displays output like the following:
// Today's city of the day: Honolulu
```

Retrieve a unique element from an array or collection

A random number generator can always return duplicate values. As the range of numbers becomes smaller or the number of values generated becomes larger, the probability of duplicates grows. If random values must be unique, more numbers are generated to compensate for duplicates, resulting in increasingly poor performance.

There are a number of techniques to handle this scenario. One common solution is to create an array or collection that contains the values to be retrieved, and a parallel array that contains random floating-point numbers. The second array is populated with random numbers at the time the first array is created, and the [Array.Sort\(Array, Array\)](#) method is used to sort the first array by using the values in the parallel array.

For example, if you're developing a Solitaire game, you want to ensure that each card is used only once. Instead of generating random numbers to retrieve a card and tracking whether that card has already been dealt, you can create a parallel array of random numbers that can be used to sort the deck. Once the deck is sorted, your app can maintain a pointer to indicate the index of the next card on the deck.

The following example illustrates this approach. It defines a `Card` class that represents a playing card and a `Dealer` class that deals a deck of shuffled cards. The `Dealer` class constructor populates two arrays: a `deck` array that has class scope and that represents all the cards in the deck; and a local `order` array that has the same number of elements as the `deck` array and is populated with randomly generated `Double` values. The [Array.Sort\(Array, Array\)](#) method is then called to sort the `deck` array based on the values in the `order` array.

C#

```
using System;

// A class that represents an individual card in a playing deck.
public class Card
{
    public Suit Suit;
    public FaceValue FaceValue;

    public override String ToString()
    {
        return String.Format("{0:F} of {1:F}", this.FaceValue, this.Suit);
    }
}

public enum Suit { Hearts, Diamonds, Spades, Clubs };

public enum FaceValue
{
    Ace = 1, Two, Three, Four, Five, Six,
    Seven, Eight, Nine, Ten, Jack, Queen,
    King
};

public class Dealer
{
    Random rnd;
    // A deck of cards, without Jokers.
    Card[] deck = new Card[52];
    // Parallel array for sorting cards.
    Double[] order = new Double[52];
    // A pointer to the next card to deal.
    int ptr = 0;
    // A flag to indicate the deck is used.
    bool mustReshuffle = false;

    public Dealer()
    {
        rnd = new Random();
        // Initialize the deck.
        int deckCtr = 0;
        foreach (var suit in Enum.GetValues(typeof(Suit)))
        {
            foreach (var faceValue in Enum.GetValues(typeof(FaceValue)))
            {
                Card card = new Card();
                card.Suit = (Suit)suit;
                card.FaceValue = (FaceValue)faceValue;
                deck[deckCtr] = card;
                deckCtr++;
            }
        }
    }
}
```

```

        for (int ctr = 0; ctr < order.Length; ctr++)
            order[ctr] = rnd.NextDouble();

        Array.Sort(order, deck);
    }

    public Card[] Deal(int numberToDeal)
    {
        if (mustReshuffle)
        {
            Console.WriteLine("There are no cards left in the deck");
            return null;
        }

        Card[] cardsDealt = new Card[numberToDeal];
        for (int ctr = 0; ctr < numberToDeal; ctr++)
        {
            cardsDealt[ctr] = deck[ptr];
            ptr++;
            if (ptr == deck.Length)
                mustReshuffle = true;

            if (mustReshuffle & ctr < numberToDeal - 1)
            {
                Console.WriteLine("Can only deal the {0} cards remaining on
the deck.",
                                   ctr + 1);
                return cardsDealt;
            }
        }
        return cardsDealt;
    }
}

public class Example17
{
    public static void Main()
    {
        Dealer dealer = new Dealer();
        ShowCards(dealer.Deal(20));
    }

    private static void ShowCards(Card[] cards)
    {
        foreach (var card in cards)
            if (card != null)
                Console.WriteLine("{0} of {1}", card.FaceValue, card.Suit);
    }
}

// The example displays output like the following:
//      Six of Diamonds
//      King of Clubs
//      Eight of Clubs
//      Seven of Clubs
//      Queen of Clubs

```

```
//      King of Hearts
//      Three of Spades
//      Ace of Clubs
//      Four of Hearts
//      Three of Diamonds
//      Nine of Diamonds
//      Two of Hearts
//      Ace of Hearts
//      Three of Hearts
//      Four of Spades
//      Eight of Hearts
//      Queen of Diamonds
//      Two of Clubs
//      Four of Diamonds
//      Jack of Hearts
```

.NET dependency injection

Article • 12/15/2023

.NET supports the dependency injection (DI) software design pattern, which is a technique for achieving [Inversion of Control \(IoC\)](#) between classes and their dependencies. Dependency injection in .NET is a built-in part of the framework, along with configuration, logging, and the options pattern.

A *dependency* is an object that another object depends on. Examine the following `MessageWriter` class with a `Write` method that other classes depend on:

C#

```
public class MessageWriter
{
    public void Write(string message)
    {
        Console.WriteLine($"MessageWriter.Write(message: \"{message}\")");
    }
}
```

A class can create an instance of the `MessageWriter` class to make use of its `Write` method. In the following example, the `MessageWriter` class is a dependency of the `Worker` class:

C#

```
public class Worker : BackgroundService
{
    private readonly MessageWriter _messageWriter = new();

    protected override async Task ExecuteAsync(CancellationToken stoppingToken)
    {
        while (!stoppingToken.IsCancellationRequested)
        {
            _messageWriter.Write($"Worker running at:
{DateTimeOffset.Now}");
            await Task.Delay(1_000, stoppingToken);
        }
    }
}
```

The class creates and directly depends on the `MessageWriter` class. Hard-coded dependencies, such as in the previous example, are problematic and should be avoided

for the following reasons:

- To replace `MessageWriter` with a different implementation, the `Worker` class must be modified.
- If `MessageWriter` has dependencies, they must also be configured by the `Worker` class. In a large project with multiple classes depending on `MessageWriter`, the configuration code becomes scattered across the app.
- This implementation is difficult to unit test. The app should use a mock or stub `MessageWriter` class, which isn't possible with this approach.

Dependency injection addresses these problems through:

- The use of an interface or base class to abstract the dependency implementation.
- Registration of the dependency in a service container. .NET provides a built-in service container, `IServiceProvider`. Services are typically registered at the app's start-up and appended to an `IServiceCollection`. Once all services are added, you use `BuildServiceProvider` to create the service container.
- *Injection* of the service into the constructor of the class where it's used. The framework takes on the responsibility of creating an instance of the dependency and disposing of it when it's no longer needed.

As an example, the `IMessageWriter` interface defines the `Write` method:

C#

```
namespace DependencyInjection.Example;

public interface IMessageWriter
{
    void Write(string message);
}
```

This interface is implemented by a concrete type, `MessageWriter`:

C#

```
namespace DependencyInjection.Example;

public class MessageWriter : IMessageWriter
{
    public void Write(string message)
    {
        Console.WriteLine($"MessageWriter.Write(message: \"{message}\")");
    }
}
```

The sample code registers the `IMessageWriter` service with the concrete type `MessageWriter`. The `AddSingleton` method registers the service with a singleton lifetime, the lifetime of the app. [Service lifetimes](#) are described later in this article.

C#

```
using DependencyInjection.Example;

HostApplicationBuilder builder = Host.CreateApplicationBuilder(args);

builder.Services.AddHostedService<Worker>();
builder.Services.AddSingleton<IMessageWriter, MessageWriter>();

using IHost host = builder.Build();

host.Run();
```

In the preceding code, the sample app:

- Creates a host app builder instance.
- Configures the services by registering:
 - The `Worker` as a hosted service. For more information, see [Worker Services in .NET](#).
 - The `IMessageWriter` interface as a singleton service with a corresponding implementation of the `MessageWriter` class.
- Builds the host and runs it.

The host contains the dependency injection service provider. It also contains all the other relevant services required to automatically instantiate the `Worker` and provide the corresponding `IMessageWriter` implementation as an argument.

C#

```
namespace DependencyInjection.Example;

public sealed class Worker(IMessageWriter messageWriter) : BackgroundService
{
    protected override async Task ExecuteAsync(CancellationToken stoppingToken)
    {
        while (!stoppingToken.IsCancellationRequested)
        {
            messageWriter.Write($"Worker running at: {DateTimeOffset.Now}");
            await Task.Delay(1_000, stoppingToken);
        }
    }
}
```

```
    }  
}
```

By using the DI pattern, the worker service:

- Doesn't use the concrete type `MessageWriter`, only the `IMessageWriter` interface that implements it. That makes it easy to change the implementation that the worker service uses without modifying the worker service.
- Doesn't create an instance of `MessageWriter`. The instance is created by the DI container.

The implementation of the `IMessageWriter` interface can be improved by using the built-in logging API:

```
C#  
  
namespace DependencyInjection.Example;  
  
public class LoggingMessageWriter(  
    ILogger<LoggingMessageWriter> logger) : IMessageWriter  
{  
    public void Write(string message) =>  
        logger.LogInformation("Info: {Msg}", message);  
}
```

The updated `AddSingleton` method registers the new `IMessageWriter` implementation:

```
C#  
  
builder.Services.AddSingleton<IMessageWriter, LoggingMessageWriter>();
```

The `HostApplicationBuilder` (`builder`) type is part of the `Microsoft.Extensions.Hosting` NuGet package.

`LoggingMessageWriter` depends on `ILogger<TCategoriesName>`, which it requests in the constructor. `ILogger<TCategoriesName>` is a [framework-provided service](#).

It's not unusual to use dependency injection in a chained fashion. Each requested dependency in turn requests its own dependencies. The container resolves the dependencies in the graph and returns the fully resolved service. The collective set of dependencies that must be resolved is typically referred to as a *dependency tree*, *dependency graph*, or *object graph*.

The container resolves `ILogger<TCategoriesName>` by taking advantage of [\(generic\) open types](#), eliminating the need to register every [\(generic\) constructed type](#).

With dependency injection terminology, a service:

- Is typically an object that provides a service to other objects, such as the `IMessageWriter` service.
- Is not related to a web service, although the service may use a web service.

The framework provides a robust logging system. The `IMessageWriter` implementations shown in the preceding examples were written to demonstrate basic DI, not to implement logging. Most apps shouldn't need to write loggers. The following code demonstrates using the default logging, which only requires the `Worker` to be registered as a hosted service [AddHostedService](#):

C#

```
public class Worker : BackgroundService
{
    private readonly ILogger<Worker> _logger;

    public Worker(ILogger<Worker> logger) =>
        _logger = logger;

    protected override async Task ExecuteAsync(CancellationToken stoppingToken)
    {
        while (!stoppingToken.IsCancellationRequested)
        {
            _logger.LogInformation("Worker running at: {time}",
DateTimeOffset.Now);
            await Task.Delay(1_000, stoppingToken);
        }
    }
}
```

Using the preceding code, there is no need to update `Program.cs`, because logging is provided by the framework.

Multiple constructor discovery rules

When a type defines more than one constructor, the service provider has logic for determining which constructor to use. The constructor with the most parameters where the types are DI-resolvable is selected. Consider the following C# example service:

C#

```
public class ExampleService
{
    public ExampleService()
```

```
{  
}  
  
public ExampleService(ILogger<ExampleService> logger)  
{  
    // omitted for brevity  
}  
  
public ExampleService(FooService fooService, BarService barService)  
{  
    // omitted for brevity  
}  
}
```

In the preceding code, assume that logging has been added and is resolvable from the service provider but the `FooService` and `BarService` types are not. The constructor with the `ILogger<ExampleService>` parameter is used to resolve the `ExampleService` instance. Even though there's a constructor that defines more parameters, the `FooService` and `BarService` types are not DI-resolvable.

If there's ambiguity when discovering constructors, an exception is thrown. Consider the following C# example service:

C#

```
public class ExampleService  
{  
    public ExampleService()  
    {  
    }  
  
    public ExampleService(ILogger<ExampleService> logger)  
    {  
        // omitted for brevity  
    }  
  
    public ExampleService(IOptions<ExampleOptions> options)  
    {  
        // omitted for brevity  
    }  
}
```

⚠ Warning

The `ExampleService` code with ambiguous DI-resolvable type parameters would throw an exception. Do **not** do this—it's intended to show what is meant by "ambiguous DI-resolvable types".

In the preceding example, there are three constructors. The first constructor is parameterless and requires no services from the service provider. Assume that both logging and options have been added to the DI container and are DI-resolvable services. When the DI container attempts to resolve the `ExampleService` type, it will throw an exception, as the two constructors are ambiguous.

You can avoid ambiguity by defining a constructor that accepts both DI-resolvable types instead:

C#

```
public class ExampleService
{
    public ExampleService()
    {

    }

    public ExampleService(
        ILogger<ExampleService> logger,
        IOptions<ExampleOptions> options)
    {
        // omitted for brevity
    }
}
```

Register groups of services with extension methods

Microsoft Extensions uses a convention for registering a group of related services. The convention is to use a single `Add{GROUP_NAME}` extension method to register all of the services required by a framework feature. For example, the `AddOptions` extension method registers all of the services required for using options.

Framework-provided services

When using any of the available host or app builder patterns, defaults are applied and services are registered by the framework. Consider some of the most popular host and app builder patterns:

- `Host.CreateDefaultBuilder()`
- `Host.CreateApplicationBuilder()`
- `WebHost.CreateDefaultBuilder()`
- `WebApplication.CreateBuilder()`

- `WebAssemblyHostBuilder.CreateDefault`
- `MauiApp.CreateBuilder`

After creating a builder from any of these APIs, the `IServiceCollection` has services defined by the framework, depending on [how the host was configured](#). For apps based on the .NET templates, the framework could register hundreds of services.

The following table lists a small sample of these framework-registered services:

[] [Expand table](#)

| Service Type | Lifetime |
|---|-----------|
| <code>Microsoft.Extensions.DependencyInjection.IServiceScopeFactory</code> | Singleton |
| <code>IHostApplicationLifetime</code> | Singleton |
| <code>Microsoft.Extensions.Logging.ILogger<TCategoryName></code> | Singleton |
| <code>Microsoft.Extensions.Logging.ILoggerFactory</code> | Singleton |
| <code>Microsoft.Extensions.ObjectPool.ObjectPoolProvider</code> | Singleton |
| <code>Microsoft.Extensions.Options.IConfigureOptions<TOptions></code> | Transient |
| <code>Microsoft.Extensions.Options.IOptions<TOptions></code> | Singleton |
| <code>System.Diagnostics.DiagnosticListener</code> | Singleton |
| <code>System.Diagnostics.DiagnosticSource</code> | Singleton |

Service lifetimes

Services can be registered with one of the following lifetimes:

- Transient
- Scoped
- Singleton

The following sections describe each of the preceding lifetimes. Choose an appropriate lifetime for each registered service.

Transient

Transient lifetime services are created each time they're requested from the service container. This lifetime works best for lightweight, stateless services. Register transient

services with [AddTransient](#).

In apps that process requests, transient services are disposed at the end of the request.

Scoped

For web applications, a scoped lifetime indicates that services are created once per client request (connection). Register scoped services with [AddScoped](#).

In apps that process requests, scoped services are disposed at the end of the request.

When using Entity Framework Core, the [AddDbContext](#) extension method registers `DbContext` types with a scoped lifetime by default.

Note

Do **not** resolve a scoped service from a singleton and be careful not to do so indirectly, for example, through a transient service. It may cause the service to have incorrect state when processing subsequent requests. It's fine to:

- Resolve a singleton service from a scoped or transient service.
- Resolve a scoped service from another scoped or transient service.

By default, in the development environment, resolving a service from another service with a longer lifetime throws an exception. For more information, see [Scope validation](#).

Singleton

Singleton lifetime services are created either:

- The first time they're requested.
- By the developer, when providing an implementation instance directly to the container. This approach is rarely needed.

Every subsequent request of the service implementation from the dependency injection container uses the same instance. If the app requires singleton behavior, allow the service container to manage the service's lifetime. Don't implement the singleton design pattern and provide code to dispose of the singleton. Services should never be disposed by code that resolved the service from the container. If a type or factory is registered as a singleton, the container disposes the singleton automatically.

Register singleton services with [AddSingleton](#). Singleton services must be thread safe and are often used in stateless services.

In apps that process requests, singleton services are disposed when the [ServiceProvider](#) is disposed on application shutdown. Because memory is not released until the app is shut down, consider memory use with a singleton service.

Service registration methods

The framework provides service registration extension methods that are useful in specific scenarios:

[+] Expand table

| Method | Automatic object disposal | Multiple implementations | Pass args |
|--|---------------------------|--------------------------|-----------|
| Add{LIFETIME}<{SERVICE}, {IMPLEMENTATION}>() | Yes | Yes | No |
| Example: | | | |
| services.AddSingleton<IMyDep, MyDep>(); | | | |
| Add{LIFETIME}<{SERVICE}>(sp => new {IMPLEMENTATION}) | Yes | Yes | Yes |
| Examples: | | | |
| services.AddSingleton<IMyDep>(sp => new MyDep()); services.AddSingleton<IMyDep>(sp => new MyDep(99)); | | | |
| Add{LIFETIME}<{IMPLEMENTATION}>() | Yes | No | No |
| Example: | | | |
| services.AddSingleton<MyDep>(); | | | |
| AddSingleton<{SERVICE}>(new {IMPLEMENTATION}) | No | Yes | Yes |
| Examples: | | | |
| services.AddSingleton<IMyDep>(new MyDep()); services.AddSingleton<IMyDep>(new MyDep(99)); | | | |

| Method | Automatic object disposal | Multiple implementations | Pass args |
|------------------------------------|---------------------------------|-----------------------------|--------------|
| AddSingleton(new {IMPLEMENTATION}) | No | No | Yes |

Examples:

```
services.AddSingleton(new MyDep());
services.AddSingleton(new MyDep(99));
```

For more information on type disposal, see the [Disposal of services](#) section.

Registering a service with only an implementation type is equivalent to registering that service with the same implementation and service type. This is why multiple implementations of a service cannot be registered using the methods that don't take an explicit service type. These methods can register multiple *instances* of a service, but they will all have the same *implementation* type.

Any of the above service registration methods can be used to register multiple service instances of the same service type. In the following example, `AddSingleton` is called twice with `IMessageWriter` as the service type. The second call to `AddSingleton` overrides the previous one when resolved as `IMessageWriter` and adds to the previous one when multiple services are resolved via `IEnumerable<IMessageWriter>`. Services appear in the order they were registered when resolved via `IEnumerable<{SERVICE}>`.

C#

```
using ConsoleDI.IEnumerableExample;
using Microsoft.Extensions.DependencyInjection;
using Microsoft.Extensions.Hosting;

HostApplicationBuilder builder = Host.CreateApplicationBuilder(args);

builder.Services.AddSingleton<IMessageWriter, ConsoleMessageWriter>();
builder.Services.AddSingleton<IMessageWriter, LoggingMessageWriter>();
builder.Services.AddSingleton<ExampleService>();

using IHost host = builder.Build();

_ = host.Services.GetService<ExampleService>();

await host.RunAsync();
```

The preceding sample source code registers two implementations of the `IMessageWriter`.

C#

```
using System.Diagnostics;

namespace ConsoleDI.IEnumerableExample;

public sealed class ExampleService
{
    public ExampleService(
        IMessageWriter messageWriter,
        IEnumerable<IMessageWriter> messageWriters)
    {
        Trace.Assert(messageWriter is LoggingMessageWriter);

        var dependencyArray = messageWriters.ToArray();
        Trace.Assert(dependencyArray[0] is ConsoleMessageWriter);
        Trace.Assert(dependencyArray[1] is LoggingMessageWriter);
    }
}
```

The `ExampleService` defines two constructor parameters; a single `IMessageWriter`, and an `IEnumerable<IMessageWriter>`. The single `IMessageWriter` is the last implementation to have been registered, whereas the `IEnumerable<IMessageWriter>` represents all registered implementations.

The framework also provides `TryAdd{LIFETIME}` extension methods, which register the service only if there isn't already an implementation registered.

In the following example, the call to `AddSingleton` registers `ConsoleMessageWriter` as an implementation for `IMessageWriter`. The call to `TryAddSingleton` has no effect because `IMessageWriter` already has a registered implementation:

C#

```
services.AddSingleton<IMessageWriter, ConsoleMessageWriter>();
services.TryAddSingleton<IMessageWriter, LoggingMessageWriter>();
```

The `TryAddSingleton` has no effect, as it was already added and the "try" will fail. The `ExampleService` would assert the following:

C#

```
public class ExampleService
{
    public ExampleService(
        IMessageWriter messageWriter,
        IEnumerable<IMessageWriter> messageWriters)
```

```
{  
    Trace.Assert(messageWriter is ConsoleMessageWriter);  
    Trace.Assert(messageWriters.Single() is ConsoleMessageWriter);  
}  
}
```

For more information, see:

- [TryAdd](#)
- [TryAddTransient](#)
- [TryAddScoped](#)
- [TryAddSingleton](#)

The [TryAddEnumerable\(ServiceDescriptor\)](#) methods register the service only if there isn't already an implementation of *the same type*. Multiple services are resolved via `IEnumerable<{SERVICE}>`. When registering services, add an instance if one of the same types hasn't already been added. Library authors use `TryAddEnumerable` to avoid registering multiple copies of an implementation in the container.

In the following example, the first call to `TryAddEnumerable` registers `MessageWriter` as an implementation for `IMessageWriter1`. The second call registers `MessageWriter` for `IMessageWriter2`. The third call has no effect because `IMessageWriter1` already has a registered implementation of `MessageWriter`:

C#

```
public interface IMessageWriter1 { }  
public interface IMessageWriter2 { }  
  
public class MessageWriter : IMessageWriter1, IMessageWriter2  
{  
}  
  
services.TryAddEnumerable(ServiceDescriptor.Singleton<IMessageWriter1,  
MessageWriter>());  
services.TryAddEnumerable(ServiceDescriptor.Singleton<IMessageWriter2,  
MessageWriter>());  
services.TryAddEnumerable(ServiceDescriptor.Singleton<IMessageWriter1,  
MessageWriter>());
```

Service registration is generally order-independent except when registering multiple implementations of the same type.

`IServiceCollection` is a collection of `ServiceDescriptor` objects. The following example shows how to register a service by creating and adding a `ServiceDescriptor`:

C#

```
string secretKey = Configuration["SecretKey"];
var descriptor = new ServiceDescriptor(
    typeof(IMessageWriter),
    _ => new DefaultMessageWriter(secretKey),
    ServiceLifetime.Transient);

services.Add(descriptor);
```

The built-in `Add{LIFETIME}` methods use the same approach. For example, see the [AddScoped source code](#).

Constructor injection behavior

Services can be resolved by using:

- [IServiceProvider](#)
- [ActivatorUtilities](#):
 - Creates objects that aren't registered in the container.
 - Used with some framework features.

Constructors can accept arguments that aren't provided by dependency injection, but the arguments must assign default values.

When services are resolved by `IServiceProvider` or `ActivatorUtilities`, constructor injection requires a *public* constructor.

When services are resolved by `ActivatorUtilities`, constructor injection requires that only one applicable constructor exists. Constructor overloads are supported, but only one overload can exist whose arguments can all be fulfilled by dependency injection.

Scope validation

When the app runs in the `Development` environment and calls [CreateApplicationBuilder](#) to build the host, the default service provider performs checks to verify that:

- Scoped services aren't resolved from the root service provider.
- Scoped services aren't injected into singletons.

The root service provider is created when [BuildServiceProvider](#) is called. The root service provider's lifetime corresponds to the app's lifetime when the provider starts with the app and is disposed when the app shuts down.

Scoped services are disposed by the container that created them. If a scoped service is created in the root container, the service's lifetime is effectively promoted to singleton because it's only disposed by the root container when the app shuts down. Validating service scopes catches these situations when `BuildServiceProvider` is called.

Scope scenarios

The `IServiceScopeFactory` is always registered as a singleton, but the `IServiceProvider` can vary based on the lifetime of the containing class. For example, if you resolve services from a scope, and any of those services take an `IServiceProvider`, it'll be a scoped instance.

To achieve scoping services within implementations of `IHostedService`, such as the `BackgroundService`, do *not* inject the service dependencies via constructor injection. Instead, inject `IServiceScopeFactory`, create a scope, then resolve dependencies from the scope to use the appropriate service lifetime.

C#

```
namespace WorkerScope.Example;

public sealed class Worker(
    ILogger<Worker> logger,
    IServiceProvider serviceScopeFactory)
    : BackgroundService
{
    protected override async Task ExecuteAsync(CancellationToken
stoppingToken)
    {
        while (!stoppingToken.IsCancellationRequested)
        {
            using (IServiceScope scope = serviceScopeFactory.CreateScope())
            {
                try
                {
                    logger.LogInformation(
                        "Starting scoped work, provider hash: {hash}.",
                        scope.ServiceProvider.GetHashCode());

                    var store =
scope.ServiceProvider.GetRequiredService<IObjectStore>();
                    var next = await store.GetNextAsync();
                    logger.LogInformation("{next}", next);

                    var processor =
scope.ServiceProvider.GetRequiredService<IObjectProcessor>();
                    await processor.ProcessAsync(next);
                    logger.LogInformation("Processing {name}.", next.Name);
                }
            }
        }
    }
}
```

```
        var relay =
scope.ServiceProvider.GetRequiredService<IObjectRelay>();
        await relay.RelayAsync(next);
        logger.LogInformation("Processed results have been
 relayed.");
    }

    var marked = await store.MarkAsync(next);
    logger.LogInformation("Marked as processed: {next}",
 marked);
}

finally
{
    logger.LogInformation(
        "Finished scoped work, provider hash: {hash}.{nl}",
        scope.ServiceProvider.GetHashCode(),
Environment.NewLine);
}
}
}
}
```

In the preceding code, while the app is running, the background service:

- Depends on the `IServiceScopeFactory`.
 - Creates an `IServiceScope` for resolving additional services.
 - Resolves scoped services for consumption.
 - Works on processing objects and then relaying them, and finally marks them as processed.

From the sample source code, you can see how implementations of [IHostedService](#) can benefit from scoped service lifetimes.

Keyed services

.NET also supports service registrations and lookups based on a key, meaning it's possible to register multiple services with a different key, and use this key for the lookup.

For example, consider the case where you have different implementations of the interface `IMessageWriter`: `MemoryMessageWriter` and `QueueMessageWriter`.

You can register these services using the overload of the service registration methods (seen earlier) that supports a key as a parameter:

C#

```
services.AddKeyedSingleton<IMessageWriter, MemoryMessageWriter>("memory");
services.AddKeyedSingleton<IMessageWriter, QueueMessageWriter>("queue");
```

The `key` isn't limited to `string`, it can be any `object` you want, as long as the type correctly implements `Equals`.

In the constructor of the class that uses `IMessageWriter`, you add the `FromKeyedServicesAttribute` to specify the key of the service to resolve:

C#

```
public class ExampleService
{
    public ExampleService(
        [FromKeyedServices("queue")] IMessageWriter writer)
    {
        // Omitted for brevity...
    }
}
```

Tutorial: Use dependency injection in .NET

Article • 12/11/2023

This tutorial shows how to use [dependency injection \(DI\) in .NET](#). With *Microsoft.Extensions*, DI is managed by adding services and configuring them in an [IServiceCollection](#). The [IHost](#) interface exposes the [IServiceProvider](#) instance, which acts as a container of all the registered services.

In this tutorial, you learn how to:

- ✓ Create a .NET console app that uses dependency injection
- ✓ Build and configure a [Generic Host](#)
- ✓ Write several interfaces and corresponding implementations
- ✓ Use service lifetime and scoping for DI

Prerequisites

- [.NET Core 3.1 SDK](#) or later.
- Familiarity with creating new .NET applications and installing NuGet packages.

Create a new console application

Using either the [dotnet new](#) command or an IDE new project wizard, create a new .NET console application named **ConsoleDI.Example**. Add the [Microsoft.Extensions.Hosting](#) NuGet package to the project.

Your new console app project file should resemble the following:

```
XML

<Project Sdk="Microsoft.NET.Sdk">

  <PropertyGroup>
    <OutputType>Exe</OutputType>
    <TargetFramework>net8.0</TargetFramework>
    <Nullable>enable</Nullable>
    <ImplicitUsings>true</ImplicitUsings>
    <RootNamespace>ConsoleDI.Example</RootNamespace>
  </PropertyGroup>

  <ItemGroup>
    <PackageReference Include="Microsoft.Extensions.Hosting" Version="8.0.0" />
  </ItemGroup>
</Project>
```

```
/>  
  </ItemGroup>  
  
</Project>
```

ⓘ Important

In this example, the [Microsoft.Extensions.Hosting](#) NuGet package is required to build and run the app. Some metapackages might contain the `Microsoft.Extensions.Hosting` package, in which case an explicit package reference isn't required.

Add interfaces

In this sample app, you'll learn how dependency injection handles service lifetime. You'll create several interfaces that represent different service lifetimes. Add the following interfaces to the project root directory:

IReportServiceLifetime.cs

C#

```
using Microsoft.Extensions.DependencyInjection;  
  
namespace ConsoleDI.Example;  
  
public interface IReportServiceLifetime  
{  
    Guid Id { get; }  
  
    ServiceLifetime Lifetime { get; }  
}
```

The `IReportServiceLifetime` interface defines:

- A `Guid Id` property that represents the unique identifier of the service.
- A `ServiceLifetime` property that represents the service lifetime.

ExampleTransientService.cs

C#

```
using Microsoft.Extensions.DependencyInjection;  
  
namespace ConsoleDI.Example;
```

```
public interface IExampleTransientService : IReportServiceLifetime
{
    ServiceLifetime IReportServiceLifetime.Lifetime =>
    ServiceLifetime.Transient;
}
```

IExampleScopedService.cs

C#

```
using Microsoft.Extensions.DependencyInjection;

namespace ConsoleDI.Example;

public interface IExampleScopedService : IReportServiceLifetime
{
    ServiceLifetime IReportServiceLifetime.Lifetime =>
    ServiceLifetime.Scoped;
}
```

IExampleSingletonService.cs

C#

```
using Microsoft.Extensions.DependencyInjection;

namespace ConsoleDI.Example;

public interface IExampleSingletonService : IReportServiceLifetime
{
    ServiceLifetime IReportServiceLifetime.Lifetime =>
    ServiceLifetime.Singleton;
}
```

All of the subinterfaces of `IReportServiceLifetime` explicitly implement the `IReportServiceLifetime.Lifetime` with a default. For example, `IExampleTransientService` explicitly implements `IReportServiceLifetime.Lifetime` with the `ServiceLifetime.Transient` value.

Add default implementations

The example implementations all initialize their `Id` property with the result of `Guid.NewGuid()`. Add the following default implementation classes for the various services to the project root directory:

ExampleTransientService.cs

C#

```
namespace ConsoleDI.Example;

internal sealed class ExampleTransientService : IExampleTransientService
{
    Guid IReportServiceLifetime.Id { get; } = Guid.NewGuid();
}
```

ExampleScopedService.cs

C#

```
namespace ConsoleDI.Example;

internal sealed class ExampleScopedService : IExampleScopedService
{
    Guid IReportServiceLifetime.Id { get; } = Guid.NewGuid();
}
```

ExampleSingletonService.cs

C#

```
namespace ConsoleDI.Example;

internal sealed class ExampleSingletonService : IExampleSingletonService
{
    Guid IReportServiceLifetime.Id { get; } = Guid.NewGuid();
}
```

Each implementation is defined as `internal sealed` and implements its corresponding interface. For example, `ExampleSingletonService` implements `IExampleSingletonService`.

Add a service that requires DI

Add the following service lifetime reporter class, which acts as a service to the console app:

ServiceLifetimeReporter.cs

C#

```

namespace ConsoleDI.Example;

internal sealed class ServiceLifetimeReporter(
    IExampleTransientService transientService,
    IExampleScopedService scopedService,
    IExampleSingletonService singletonService)
{
    public void ReportServiceLifetimeDetails(string lifetimeDetails)
    {
        Console.WriteLine(lifetimeDetails);

        LogService(transientService, "Always different");
        LogService(scopedService, "Changes only with lifetime");
        LogService(singletonService, "Always the same");
    }

    private static void LogService<T>(T service, string message)
        where T : IReportServiceLifetime =>
        Console.WriteLine(
            $"    {typeof(T).Name}: {service.Id} ({message})");
}

```

The `ServiceLifetimeReporter` defines a constructor that requires each of the aforementioned service interfaces, that is, `IExampleTransientService`, `IExampleScopedService`, and `IExampleSingletonService`. The object exposes a single method that allows the consumer to report on the service with a given `lifetimeDetails` parameter. When invoked, the `ReportServiceLifetimeDetails` method logs each service's unique identifier with the service lifetime message. The log messages help to visualize the service lifetime.

Register services for DI

Update `Program.cs` with the following code:

C#

```

using Microsoft.Extensions.DependencyInjection;
using Microsoft.Extensions.Hosting;
using ConsoleDI.Example;

HostApplicationBuilder builder = Host.CreateApplicationBuilder(args);

builder.Services.AddTransient<IExampleTransientService,
ExampleTransientService>();
builder.Services.AddScoped<IExampleScopedService, ExampleScopedService>();
builder.Services.AddSingleton<IExampleSingletonService,
ExampleSingletonService>();
builder.Services.AddTransient<ServiceLifetimeReporter>();

```

```

using IHost host = builder.Build();

ExemplifyServiceLifetime(host.Services, "Lifetime 1");
ExemplifyServiceLifetime(host.Services, "Lifetime 2");

await host.RunAsync();

static void ExemplifyServiceLifetime(IServiceProvider hostProvider, string
lifetime)
{
    using IServiceScope serviceScope = hostProvider.CreateScope();
    IServiceProvider provider = serviceScope.ServiceProvider;
    ServiceLifetimeReporter logger =
provider.GetRequiredService<ServiceLifetimeReporter>();
    logger.ReportServiceLifetimeDetails(
        $"{lifetime}: Call 1 to
provider.GetRequiredService<ServiceLifetimeReporter>()");

    Console.WriteLine("...");

    logger = provider.GetRequiredService<ServiceLifetimeReporter>();
    logger.ReportServiceLifetimeDetails(
        $"{lifetime}: Call 2 to
provider.GetRequiredService<ServiceLifetimeReporter>()");

    Console.WriteLine();
}

```

Each `services.Add{LIFETIME}<{SERVICE}>` extension method adds (and potentially configures) services. We recommend that apps follow this convention. Place extension methods in the [Microsoft.Extensions.DependencyInjection](#) namespace to encapsulate groups of service registrations. Including the namespace portion

[Microsoft.Extensions.DependencyInjection](#) for DI extension methods also:

- Allows them to be displayed in [IntelliSense](#) without adding additional `using` blocks.
- Prevents excessive `using` statements in the `Program` or `Startup` classes where these extension methods are typically called.

The app:

- Creates an [IHostBuilder](#) instance with [host builder settings](#).
- Configures services and adds them with their corresponding service lifetime.
- Calls [Build\(\)](#) and assigns an instance of [IHost](#).
- Calls [ExemplifyScoping](#), passing in the [IHost.Services](#).

Conclusion

In this sample app, you created several interfaces and corresponding implementations. Each of these services is uniquely identified and paired with a [ServiceLifetime](#). The sample app demonstrates registering service implementations against an interface, and how to register pure classes without backing interfaces. The sample app then demonstrates how dependencies defined as constructor parameters are resolved at run time.

When you run the app, it displays output similar to the following:

C#

```
// Sample output:  
// Lifetime 1: Call 1 to  
provider.GetRequiredService<ServiceLifetimeReporter>()  
//      IExampleTransientService: d08a27fa-87d2-4a06-98d7-2773af886125  
(Always different)  
//      IExampleScopedService: 402c83c9-b4ed-4be1-b78c-86be1b1d908d (Changes  
only with lifetime)  
//      IExampleSingletonService: a61f1ff4-0b14-4508-bd41-21d852484a7b  
(Always the same)  
// ...  
// Lifetime 1: Call 2 to  
provider.GetRequiredService<ServiceLifetimeReporter>()  
//      IExampleTransientService: b43d68fb-2c7b-4a9b-8f02-fc507c164326  
(Always different)  
//      IExampleScopedService: 402c83c9-b4ed-4be1-b78c-86be1b1d908d (Changes  
only with lifetime)  
//      IExampleSingletonService: a61f1ff4-0b14-4508-bd41-21d852484a7b  
(Always the same)  
//  
// Lifetime 2: Call 1 to  
provider.GetRequiredService<ServiceLifetimeReporter>()  
//      IExampleTransientService: f3856b59-ab3f-4bbd-876f-7bab0013d392  
(Always different)  
//      IExampleScopedService: bba80089-1157-4041-936d-e96d81dd9d1c (Changes  
only with lifetime)  
//      IExampleSingletonService: a61f1ff4-0b14-4508-bd41-21d852484a7b  
(Always the same)  
// ...  
// Lifetime 2: Call 2 to  
provider.GetRequiredService<ServiceLifetimeReporter>()  
//      IExampleTransientService: a8015c6a-08cd-4799-9ec3-2f2af9cbbfd2  
(Always different)  
//      IExampleScopedService: bba80089-1157-4041-936d-e96d81dd9d1c (Changes  
only with lifetime)  
//      IExampleSingletonService: a61f1ff4-0b14-4508-bd41-21d852484a7b  
(Always the same)
```

From the app output, you can see that:

- Transient services are always different, a new instance is created with every retrieval of the service.
- Scoped services change only with a new scope, but are the same instance within a scope.
- Singleton services are always the same, a new instance is only created once.

Dependency injection guidelines

Article • 06/23/2023

This article provides general guidelines and best practices for implementing dependency injection in .NET applications.

Design services for dependency injection

When designing services for dependency injection:

- Avoid stateful, static classes and members. Avoid creating global state by designing apps to use singleton services instead.
- Avoid direct instantiation of dependent classes within services. Direct instantiation couples the code to a particular implementation.
- Make services small, well-factored, and easily tested.

If a class has many injected dependencies, it might be a sign that the class has too many responsibilities and violates the [Single Responsibility Principle \(SRP\)](#). Attempt to refactor the class by moving some of its responsibilities into new classes.

Disposal of services

The container is responsible for cleanup of types it creates, and calls [Dispose](#) on [IDisposable](#) instances. Services resolved from the container should never be disposed by the developer. If a type or factory is registered as a singleton, the container disposes the singleton automatically.

In the following example, the services are created by the service container and disposed automatically:

```
C#  
  
namespace ConsoleDisposable.Example;  
  
public sealed class TransientDisposable : IDisposable  
{  
    public void Dispose() => Console.WriteLine($"  
{nameof(TransientDisposable)}.Dispose()");  
}
```

The preceding disposable is intended to have a transient lifetime.

C#

```
namespace ConsoleDisposable.Example;

public sealed class ScopedDisposable : IDisposable
{
    public void Dispose() => Console.WriteLine($""
{nameof(ScopedDisposable)}.Dispose()");
}
```

The preceding disposable is intended to have a scoped lifetime.

C#

```
namespace ConsoleDisposable.Example;

public sealed class SingletonDisposable : IDisposable
{
    public void Dispose() => Console.WriteLine($""
{nameof(SingletonDisposable)}.Dispose()");
}
```

The preceding disposable is intended to have a singleton lifetime.

C#

```
using ConsoleDisposable.Example;
using Microsoft.Extensions.DependencyInjection;
using Microsoft.Extensions.Hosting;

HostApplicationBuilder builder = Host.CreateApplicationBuilder(args);
builder.Services.AddTransient<TransientDisposable>();
builder.Services.AddScoped<ScopedDisposable>();
builder.Services.AddSingleton<SingletonDisposable>();

using IHost host = builder.Build();

ExemplifyDisposableScoping(host.Services, "Scope 1");
Console.WriteLine();

ExemplifyDisposableScoping(host.Services, "Scope 2");
Console.WriteLine();

await host.RunAsync();

static void ExemplifyDisposableScoping(IServiceProvider services, string
scope)
{
    Console.WriteLine($"{scope}...");

    using IServiceScope serviceScope = services.CreateScope();
```

```
    IServiceProvider provider = serviceScope.ServiceProvider;

    _ = provider.GetRequiredService<TransientDisposable>();
    _ = provider.GetRequiredService<ScopedDisposable>();
    _ = provider.GetRequiredService<SingletonDisposable>();
}
```

The debug console shows the following sample output after running:

```
Console

Scope 1...
ScopedDisposable.Dispose()
TransientDisposable.Dispose()

Scope 2...
ScopedDisposable.Dispose()
TransientDisposable.Dispose()

info: Microsoft.Hosting.Lifetime[0]
      Application started. Press Ctrl+C to shut down.
info: Microsoft.Hosting.Lifetime[0]
      Hosting environment: Production
info: Microsoft.Hosting.Lifetime[0]
      Content root path: .\configuration\console-di-
disposable\bin\Debug\net5.0
info: Microsoft.Hosting.Lifetime[0]
      Application is shutting down...
SingletonDisposable.Dispose()
```

Services not created by the service container

Consider the following code:

```
C#

// Register example service in IServiceCollection
builder.Services.AddSingleton(new ExampleService());
```

In the preceding code:

- The `ExampleService` instance is **not** created by the service container.
- The framework does **not** dispose of the services automatically.
- The developer is responsible for disposing the services.

IDisposable guidance for transient and shared instances

Transient, limited lifetime

Scenario

The app requires an [IDisposable](#) instance with a transient lifetime for either of the following scenarios:

- The instance is resolved in the root scope (root container).
- The instance should be disposed before the scope ends.

Solution

Use the factory pattern to create an instance outside of the parent scope. In this situation, the app would generally have a `Create` method that calls the final type's constructor directly. If the final type has other dependencies, the factory can:

- Receive an [IServiceProvider](#) in its constructor.
- Use [ActivatorUtilities.CreateInstance](#) to instantiate the instance outside of the container, while using the container for its dependencies.

Shared instance, limited lifetime

Scenario

The app requires a shared [IDisposable](#) instance across multiple services, but the [IDisposable](#) instance should have a limited lifetime.

Solution

Register the instance with a scoped lifetime. Use [IServiceScopeFactory.CreateScope](#) to create a new [IServiceScope](#). Use the scope's [IServiceProvider](#) to get required services. Dispose the scope when it's no longer needed.

General [IDisposable](#) guidelines

- Don't register [IDisposable](#) instances with a transient lifetime. Use the factory pattern instead.
- Don't resolve [IDisposable](#) instances with a transient or scoped lifetime in the root scope. The only exception to this is if the app creates/recreates and disposes [IServiceProvider](#), but this isn't an ideal pattern.
- Receiving an [IDisposable](#) dependency via DI doesn't require that the receiver implement [IDisposable](#) itself. The receiver of the [IDisposable](#) dependency shouldn't call [Dispose](#) on that dependency.

- Use scopes to control the lifetimes of services. Scopes aren't hierarchical, and there's no special connection among scopes.

For more information on resource cleanup, see [Implement a Dispose method](#), or [Implement a DisposeAsync method](#). Additionally, consider the [Disposable transient services captured by container](#) scenario as it relates to resource cleanup.

Default service container replacement

The built-in service container is designed to serve the needs of the framework and most consumer apps. We recommend using the built-in container unless you need a specific feature that it doesn't support, such as:

- Property injection
- Injection based on name
- Child containers
- Custom lifetime management
- `Func<T>` support for lazy initialization
- Convention-based registration

The following third-party containers can be used with ASP.NET Core apps:

- [Autofac ↗](#)
- [Dryloc ↗](#)
- [Grace ↗](#)
- [LightInject ↗](#)
- [Lamar ↗](#)
- [Stashbox ↗](#)
- [Simple Injector ↗](#)

Thread safety

Create thread-safe singleton services. If a singleton service has a dependency on a transient service, the transient service may also require thread safety depending on how it's used by the singleton.

The factory method of a singleton service, such as the second argument to `AddSingleton<TService>(IServiceCollection, Func<IServiceProvider, TService>)`, doesn't need to be thread-safe. Like a type (`static`) constructor, it's guaranteed to be called only once by a single thread.

Recommendations

- `async/await` and `Task` based service resolution isn't supported. Because C# doesn't support asynchronous constructors, use asynchronous methods after synchronously resolving the service.
- Avoid storing data and configuration directly in the service container. For example, a user's shopping cart shouldn't typically be added to the service container. Configuration should use the options pattern. Similarly, avoid "data holder" objects that only exist to allow access to another object. It's better to request the actual item via DI.
- Avoid static access to services. For example, avoid capturing `IApplicationBuilder.ApplicationServices` as a static field or property for use elsewhere.
- Keep **DI factories** fast and synchronous.
- Avoid using the *service locator pattern*. For example, don't invoke `GetService` to obtain a service instance when you can use DI instead.
- Another service locator variation to avoid is injecting a factory that resolves dependencies at run time. Both of these practices mix **Inversion of Control** strategies.
- Avoid calls to `BuildServiceProvider` when configuring services. Calling `BuildServiceProvider` typically happens when the developer wants to resolve a service when registering another service. Instead, use an overload that includes the `IServiceProvider` for this reason.
- **Disposable transient services are captured** by the container for disposal. This can turn into a memory leak if resolved from the top-level container.
- Enable scope validation to make sure the app doesn't have singletons that capture scoped services. For more information, see [Scope validation](#).

Like all sets of recommendations, you may encounter situations where ignoring a recommendation is required. Exceptions are rare, mostly special cases within the framework itself.

DI is an *alternative* to static/global object access patterns. You may not be able to realize the benefits of DI if you mix it with static object access.

Example anti-patterns

In addition to the guidelines in this article, there are several anti-patterns *you should avoid*. Some of these anti-patterns are learnings from developing the runtimes themselves.

⚠ Warning

These are example anti-patterns, *do not* copy the code, *do not* use these patterns, and avoid these patterns at all costs.

Disposable transient services captured by container

When you register *Transient* services that implement [IDisposable](#), by default the DI container will hold onto these references, and not [Dispose\(\)](#) of them until the container is disposed when application stops if they were resolved from the container, or until the scope is disposed if they were resolved from a scope. This can turn into a memory leak if resolved from container level.

C#

```
static void TransientDisposablesWithoutDispose()
{
    var services = new ServiceCollection();
    services.AddTransient<ExampleDisposable>();
    ServiceProvider serviceProvider = services.BuildServiceProvider();

    for (int i = 0; i < 1000; ++ i)
    {
        _ = serviceProvider.GetRequiredService<ExampleDisposable>();
    }

    // serviceProvider.Dispose();
}
```

In the preceding anti-pattern, 1,000 `ExampleDisposable` objects are instantiated and rooted. They will not be disposed of until the `serviceProvider` instance is disposed.

For more information on debugging memory leaks, see [Debug a memory leak in .NET](#).

Async DI factories can cause deadlocks

The term "DI factories" refers to the overload methods that exist when calling `Add{LIFETIME}`. There are overloads accepting a `Func<IServiceProvider, T>` where `T` is the service being registered, and the parameter is named `implementationFactory`. The `implementationFactory` can be provided as a lambda expression, local function, or method. If the factory is asynchronous, and you use `Task<TResult>.Result`, this will cause a deadlock.

C#

```
static void DeadLockWithAsyncFactory()
{
    var services = new ServiceCollection();
    services.AddSingleton<Foo>(implementationFactory: provider =>
    {
        Bar bar = GetBarAsync(provider).Result;
        return new Foo(bar);
    });

    services.AddSingleton<Bar>();

    using ServiceProvider serviceProvider = services.BuildServiceProvider();
    _ = serviceProvider.GetRequiredService<Foo>();
}
```

In the preceding code, the `implementationFactory` is given a lambda expression where the body calls `Task<TResult>.Result` on a `Task<Bar>` returning method. This *causes a deadlock*. The `GetBarAsync` method simply emulates an asynchronous work operation with `Task.Delay`, and then calls `GetRequiredService<T>(IServiceProvider)`.

C#

```
static async Task<Bar> GetBarAsync(IServiceProvider serviceProvider)
{
    // Emulate asynchronous work operation
    await Task.Delay(1000);

    return serviceProvider.GetRequiredService<Bar>();
}
```

For more information on asynchronous guidance, see [Asynchronous programming: Important info and advice](#). For more information debugging deadlocks, see [Debug a deadlock in .NET](#).

When you're running this anti-pattern and the deadlock occurs, you can view the two threads waiting from Visual Studio's Parallel Stacks window. For more information, see [View threads and tasks in the Parallel Stacks window](#).

Captive dependency

The term "[captive dependency](#)" was coined by [Mark Seemann](#), and refers to the misconfiguration of service lifetimes, where a longer-lived service holds a shorter-lived service captive.

C#

```
static void CaptiveDependency()
{
    var services = new ServiceCollection();
    services.AddSingleton<Foo>();
    services.AddScoped<Bar>();

    using ServiceProvider serviceProvider = services.BuildServiceProvider();
    // Enable scope validation
    // using ServiceProvider serviceProvider =
    services.BuildServiceProvider(validateScopes: true);

    _ = serviceProvider.GetRequiredService<Foo>();
}
```

In the preceding code, `Foo` is registered as a singleton and `Bar` is scoped - which on the surface seems valid. However, consider the implementation of `Foo`.

C#

```
namespace DependencyInjection.AntiPatterns
{
    public class Foo
    {
        public Foo(Bar bar)
        {
        }
    }
}
```

The `Foo` object requires a `Bar` object, and since `Foo` is a singleton, and `Bar` is scoped - this is a misconfiguration. As is, `Foo` would only be instantiated once, and it would hold onto `Bar` for its lifetime, which is longer than the intended scoped lifetime of `Bar`. You should consider validating scopes, by passing `validateScopes: true` to the `BuildServiceProvider(IServiceCollection, Boolean)`. When you validate the scopes, you'd get an `InvalidOperationException` with a message similar to "Cannot consume scoped service 'Bar' from singleton 'Foo'.".

For more information, see [Scope validation](#).

Scoped service as singleton

When using scoped services, if you're not creating a scope or within an existing scope - the service becomes a singleton.

C#

```
static void ScopedServiceBecomesSingleton()
{
    var services = new ServiceCollection();
    services.AddScoped<Bar>();

    using ServiceProvider serviceProvider =
services.BuildServiceProvider(validateScopes: true);
    using (IServiceScope scope = serviceProvider.CreateScope())
    {
        // Correctly scoped resolution
        Bar correct = scope.ServiceProvider.GetRequiredService<Bar>();
    }

    // Not within a scope, becomes a singleton
    Bar avoid = serviceProvider.GetRequiredService<Bar>();
}
```

In the preceding code, `Bar` is retrieved within an `IServiceScope`, which is correct. The anti-pattern is the retrieval of `Bar` outside of the scope, and the variable is named `avoid` to show which example retrieval is incorrect.

Configuration in .NET

Article • 07/20/2023

Configuration in .NET is performed using one or more [configuration providers](#). Configuration providers read configuration data from key-value pairs using various configuration sources:

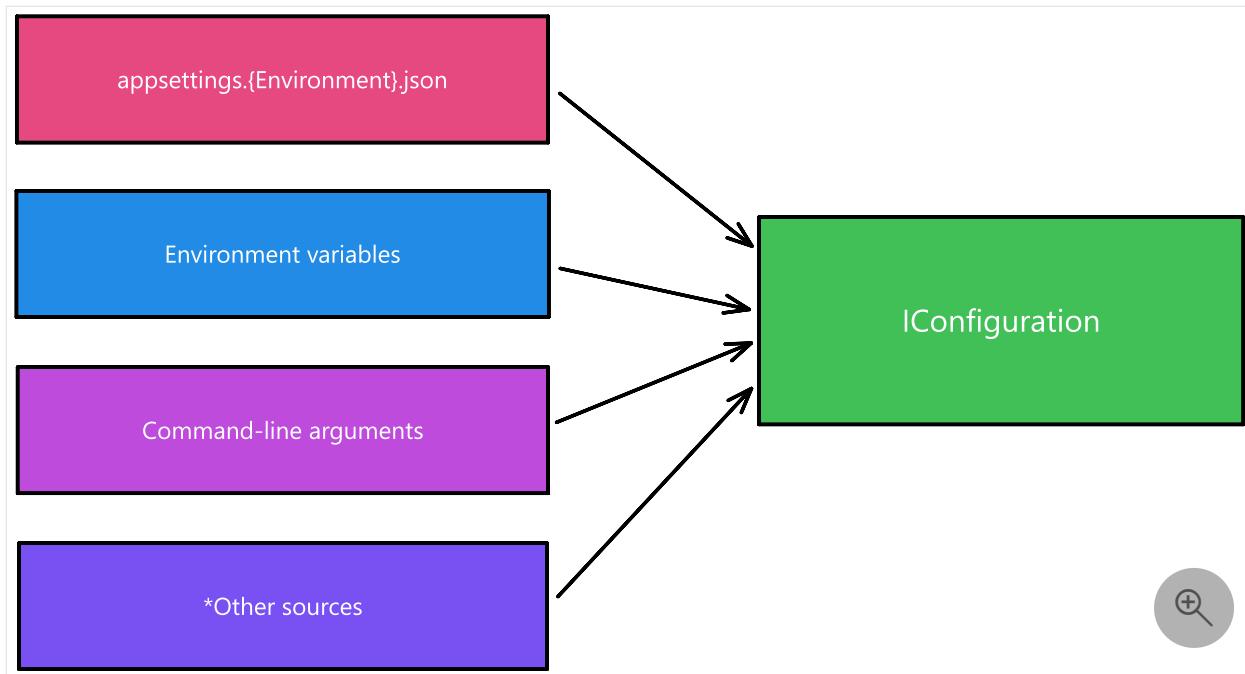

- Settings files, such as `appsettings.json`
- Environment variables
- [Azure Key Vault](#)
- [Azure App Configuration](#)
- Command-line arguments
- Custom providers, installed or created
- Directory files
- In-memory .NET objects
- Third-party providers

ⓘ Note

For information about configuring the .NET runtime itself, see [.NET Runtime configuration settings](#).

Concepts and abstractions

Given one or more configuration sources, the `IConfiguration` type provides a unified view of the configuration data. Configuration is read-only, and the configuration pattern isn't designed to be programmatically writable. The `IConfiguration` interface is a single representation of all the configuration sources, as shown in the following diagram:

Configure console apps

.NET console applications created using the [dotnet new](#) command template or Visual Studio by default *don't* expose configuration capabilities. To add configuration in a new .NET console application, [add a package reference to Microsoft.Extensions.Configuration](#). This package is the foundation for configuration in .NET apps. It provides the [ConfigurationBuilder](#) and related types.

C#

```

using Microsoft.Extensions.Configuration;

var configuration = new ConfigurationBuilder()
    .AddInMemoryCollection(new Dictionary<string, string?>()
{
    ["SomeKey"] = "SomeValue"
})
    .Build();

Console.WriteLine(configuration["SomeKey"]);

// Outputs:
// SomeValue

```

The preceding code:

- Creates a new [ConfigurationBuilder](#) instance.
- Adds an in-memory collection of key-value pairs to the configuration builder.
- Calls the [Build\(\)](#) method to create an [IConfiguration](#) instance.

- Writes the value of the `SomeKey` key to the console.

While this example uses an in-memory configuration, there are many configuration providers available, exposing functionality for file-based, environment variables, command line arguments, and other configuration sources. For more information, see [Configuration providers in .NET](#).

Alternative hosting approach

Commonly, your apps will do more than just read configuration. They'll likely use dependency injection, logging, and other services. The [.NET Generic Host](#) approach is recommended for apps that use these services. Instead, consider [adding a package reference](#) to [Microsoft.Extensions.Hosting](#). Modify the `Program.cs` file to match the following code:

C#

```
using Microsoft.Extensions.Hosting;

using IHost host = Host.CreateApplicationBuilder(args).Build();

// Application code should start here.

await host.RunAsync();
```

The `Host.CreateApplicationBuilder(String[])` method provides default configuration for the app in the following order, from highest to lowest priority:

1. Command-line arguments using the [Command-line configuration provider](#).
2. Environment variables using the [Environment Variables configuration provider](#).
3. [App secrets](#) when the app runs in the `Development` environment.
4. `appsettings.Environment.json` using the [JSON configuration provider](#). For example, `appsettings.Production.json` and `appsettings.Development.json`.
5. `appsettings.json` using the [JSON configuration provider](#).
6. [ChainedConfigurationProvider](#) : Adds an existing `IConfiguration` as a source.

Adding a configuration provider overrides previous configuration values. For example, the [Command-line configuration provider](#) overrides all values from other providers because it's added last. If `SomeKey` is set in both `appsettings.json` and the environment, the environment value is used because it was added after `appsettings.json`.

Binding

One of the key advantages of using the .NET configuration abstractions is the ability to bind configuration values to instances of .NET objects. For example, the JSON configuration provider can be used to map *appsettings.json* files to .NET objects and is used with [dependency injection](#). This enables the [options pattern](#), which uses classes to provide strongly typed access to groups of related settings. .NET configuration provides various abstractions. Consider the following interfaces:

- [IConfiguration](#): Represents a set of key/value application configuration properties.
- [IConfigurationRoot](#): Represents the root of an [IConfiguration](#) hierarchy.
- [IConfigurationSection](#): Represents a section of application configuration values.

These abstractions are agnostic to their underlying configuration provider ([IConfigurationProvider](#)). In other words, you can use an [IConfiguration](#) instance to access any configuration value from multiple providers.

The binder can use different approaches to process configuration values:

- Direct deserialization (using built-in converters) for primitive types.
- The [TypeConverter](#) for a complex type when the type has one.
- Reflection for a complex type that has properties.

① Note

The binder has a few limitations:

- Properties are ignored if they have private setters or their type can't be converted.
- Properties without corresponding configuration keys are ignored.

Binding hierarchies

Configuration values can contain hierarchical data. Hierarchical objects are represented with the use of the `:` delimiter in the configuration keys. To access a configuration value, use the `:` character to delimit a hierarchy. For example, consider the following configuration values:

JSON

```
{  
  "Parent": {  
    "FavoriteNumber": 7,  
    "Child": {  
      "Name": "Example",  
    }  
  }  
}
```

```

        "GrandChild": {
            "Age": 3
        }
    }
}

```

The following table represents example keys and their corresponding values for the preceding example JSON:

| Key | Value |
|-------------------------------|-----------|
| "Parent:FavoriteNumber" | 7 |
| "Parent:Child:Name" | "Example" |
| "Parent:Child:GrandChild:Age" | 3 |

Basic example

To access configuration values in their basic form, without the assistance of the *generic host* approach, use the [ConfigurationBuilder](#) type directly.

Tip

The [System.Configuration.ConfigurationBuilder](#) type is different to the [Microsoft.Extensions.Configuration.ConfigurationBuilder](#) type. All of this content is specific to the `Microsoft.Extensions.*` NuGet packages and namespaces.

Consider the following C# project:

XML

```

<Project Sdk="Microsoft.NET.Sdk">

    <PropertyGroup>
        <OutputType>Exe</OutputType>
        <TargetFramework>net7.0</TargetFramework>
        <Nullable>enable</Nullable>
        <ImplicitUsings>true</ImplicitUsings>
    </PropertyGroup>

    <ItemGroup>
        <Content Include="appsettings.json">
            <CopyToOutputDirectory>Always</CopyToOutputDirectory>
        </Content>
    </ItemGroup>

```

```

<ItemGroup>
    <PackageReference Include="Microsoft.Extensions.Configuration.Binder"
Version="8.0.0" />
    <PackageReference Include="Microsoft.Extensions.Configuration.Json"
Version="8.0.0" />
    <PackageReference
Include="Microsoft.Extensions.Configuration.EnvironmentVariables"
Version="8.0.0" />
</ItemGroup>

</Project>

```

The preceding project file references several configuration NuGet packages:

- [Microsoft.Extensions.Configuration.Binder](#): Functionality to bind an object to data in configuration providers for `Microsoft.Extensions.Configuration`.
- [Microsoft.Extensions.Configuration.Json](#): JSON configuration provider implementation for `Microsoft.Extensions.Configuration`.
- [Microsoft.Extensions.Configuration.EnvironmentVariables](#): Environment variables configuration provider implementation for `Microsoft.Extensions.Configuration`.

Consider an example `appsettings.json` file:

JSON

```
{
  "Settings": {
    "KeyOne": 1,
    "KeyTwo": true,
    "KeyThree": {
      "Message": "Oh, that's nice...",
      "SupportedVersions": {
        "v1": "1.0.0",
        "v3": "3.0.7"
      }
    },
    "IPAddressRange": [
      "46.36.198.121",
      "46.36.198.122",
      "46.36.198.123",
      "46.36.198.124",
      "46.36.198.125"
    ]
  }
}
```

Now, given this JSON file, here's an example consumption pattern using the configuration builder directly:

C#

```
using Microsoft.Extensions.Configuration;

// Build a config object, using env vars and JSON providers.
IConfigurationRoot config = new ConfigurationBuilder()
    .AddJsonFile("appsettings.json")
    .AddEnvironmentVariables()
    .Build();

// Get values from the config given their key and their target type.
Settings? settings = config.GetRequiredSection("Settings").Get<Settings>();

// Write the values to the console.
Console.WriteLine($"KeyOne = {settings?.KeyOne}");
Console.WriteLine($"KeyTwo = {settings?.KeyTwo}");
Console.WriteLine($"KeyThree:Message = {settings?.KeyThree?.Message}");

// Application code which might rely on the config could start here.

// This will output the following:
// KeyOne = 1
// KeyTwo = True
// KeyThree:Message = Oh, that's nice...
```

The preceding C# code:

- Instantiates a [ConfigurationBuilder](#).
- Adds the "appsettings.json" file to be recognized by the JSON configuration provider.
- Adds environment variables as being recognized by the Environment Variable configuration provider.
- Gets the required "Settings" section and the corresponding `Settings` instance by using the `config` instance.

The `Settings` object is shaped as follows:

C#

```
public sealed class Settings
{
    public required int KeyOne { get; set; }
    public required bool KeyTwo { get; set; }
    public required NestedSettings KeyThree { get; set; } = null!;
}
```

C#

```
public sealed class NestedSettings
{
    public required string Message { get; set; } = null!;
}
```

Basic example with hosting

To access the `IConfiguration` value, you can rely again on the [Microsoft.Extensions.Hosting](#) NuGet package. Create a new console application, and paste the following project file contents into it:

XML

```
<Project Sdk="Microsoft.NET.Sdk">

<PropertyGroup>
    <OutputType>Exe</OutputType>
    <TargetFramework>net7.0</TargetFramework>
    <Nullable>enable</Nullable>
    <ImplicitUsings>true</ImplicitUsings>
</PropertyGroup>

<ItemGroup>
    <Content Include="appsettings.json">
        <CopyToOutputDirectory>Always</CopyToOutputDirectory>
    </Content>
</ItemGroup>

<ItemGroup>
    <PackageReference Include="Microsoft.Extensions.Hosting" Version="8.0.0" />
</ItemGroup>

</Project>
```

The preceding project file defines that:

- The application is an executable.
- An *appsettings.json* file is to be copied to the output directory when the project is compiled.
- The `Microsoft.Extensions.Hosting` NuGet package reference is added.

Add the *appsettings.json* file at the root of the project with the following contents:

JSON

```
{  
    "KeyOne": 1,  
    "KeyTwo": true,  
    "KeyThree": {  
        "Message": "Thanks for checking this out!"  
    }  
}
```

Replace the contents of the `Program.cs` file with the following C# code:

C#

```
using Microsoft.Extensions.Configuration;  
using Microsoft.Extensions.DependencyInjection;  
using Microsoft.Extensions.Hosting;  
  
using IHost host = Host.CreateApplicationBuilder(args).Build();  
  
// Ask the service provider for the configuration abstraction.  
IConfiguration config = host.Services.GetRequiredService< IConfiguration>();  
  
// Get values from the config given their key and their target type.  
int keyOneValue = config.GetValue< int >("KeyOne");  
bool keyTwoValue = config.GetValue< bool >("KeyTwo");  
string? keyThreeNestedValue = config.GetValue< string >("KeyThree:Message");  
  
// Write the values to the console.  
Console.WriteLine($"KeyOne = {keyOneValue}");  
Console.WriteLine($"KeyTwo = {keyTwoValue}");  
Console.WriteLine($"KeyThree:Message = {keyThreeNestedValue}");  
  
// Application code which might rely on the config could start here.  
  
await host.RunAsync();  
  
// This will output the following:  
// KeyOne = 1  
// KeyTwo = True  
// KeyThree:Message = Thanks for checking this out!
```

When you run this application, the `Host.CreateApplicationBuilder` defines the behavior to discover the JSON configuration and expose it through the `IConfiguration` instance. From the `host` instance, you can ask the service provider for the `IConfiguration` instance and then ask it for values.

 Tip

Using the raw `IConfiguration` instance in this way, while convenient, doesn't scale very well. When applications grow in complexity, and their corresponding configurations become more complex, we recommend that you use the ***options pattern*** as an alternative.

Basic example with hosting and using the indexer API

Consider the same `appsettings.json` file contents from the previous example:

JSON

```
{  
  "SupportedVersions": {  
    "v1": "1.0.0",  
    "v3": "3.0.7"  
  },  
  "IPAddressRange": [  
    "46.36.198.123",  
    "46.36.198.124",  
    "46.36.198.125"  
  ]  
}
```

Replace the contents of the `Program.cs` file with the following C# code:

C#

```
using Microsoft.Extensions.Configuration;  
using Microsoft.Extensions.DependencyInjection;  
using Microsoft.Extensions.Hosting;  
  
using IHost host = Host.CreateApplicationBuilder(args).Build();  
  
// Ask the service provider for the configuration abstraction.  
IConfiguration config = host.Services.GetRequiredService<IConfiguration>();  
  
// Get values from the config given their key and their target type.  
string? ipOne = config["IPAddressRange:0"];  
string? ipTwo = config["IPAddressRange:1"];  
string? ipThree = config["IPAddressRange:2"];  
string? versionOne = config["SupportedVersions:v1"];  
string? versionThree = config["SupportedVersions:v3"];  
  
// Write the values to the console.  
Console.WriteLine($"IPAddressRange:0 = {ipOne}");  
Console.WriteLine($"IPAddressRange:1 = {ipTwo}");  
Console.WriteLine($"IPAddressRange:2 = {ipThree}");  
Console.WriteLine($"SupportedVersions:v1 = {versionOne}");  
Console.WriteLine($"SupportedVersions:v3 = {versionThree}");
```

```
// Application code which might rely on the config could start here.

await host.RunAsync();

// This will output the following:
//     IPAddressRange:0 = 46.36.198.123
//     IPAddressRange:1 = 46.36.198.124
//     IPAddressRange:2 = 46.36.198.125
//     SupportedVersions:v1 = 1.0.0
//     SupportedVersions:v3 = 3.0.7
```

The values are accessed using the indexer API where each key is a string, and the value is a string. Configuration supports properties, objects, arrays, and dictionaries.

Configuration providers

The following table shows the configuration providers available to .NET Core apps.

| Provider | Provides configuration from |
|--|------------------------------------|
| Azure App configuration provider | Azure App Configuration |
| Azure Key Vault configuration provider | Azure Key Vault |
| Command-line configuration provider | Command-line parameters |
| Custom configuration provider | Custom source |
| Environment Variables configuration provider | Environment variables |
| File configuration provider | JSON, XML, and INI files |
| Key-per-file configuration provider | Directory files |
| Memory configuration provider | In-memory collections |
| App secrets (Secret Manager) | File in the user profile directory |

Tip

The order in which configuration providers are added matters. When multiple configuration providers are used and more than one provider specifies the same key, the last one added is used.

For more information on various configuration providers, see [Configuration providers in .NET](#).

Configuration providers in .NET

Article • 06/23/2023

Configuration in .NET is possible with configuration providers. Several types of providers rely on various configuration sources. This article details all of the different configuration providers and their corresponding sources.

- File configuration provider
- Environment variable configuration provider
- Command-line configuration provider
- Key-per-file configuration provider
- Memory configuration provider

File configuration provider

[FileConfigurationProvider](#) is the base class for loading configuration from the file system. The following configuration providers derive from `FileConfigurationProvider`:

- JSON configuration provider
- XML configuration provider
- INI configuration provider

Keys are case-insensitive. All of the file configuration providers throw the [FormatException](#) when duplicate keys are found in a single provider.

JSON configuration provider

The [JsonConfigurationProvider](#) class loads configuration from a JSON file. Install the [Microsoft.Extensions.Configuration.Json](#) NuGet package.

Overloads can specify:

- Whether the file is optional.
- Whether the configuration is reloaded if the file changes.

Consider the following code:

C#

```
using Microsoft.Extensions.Configuration;
using Microsoft.Extensions.Hosting;
using ConsoleJson.Example;
```

```

HostApplicationBuilder builder = Host.CreateApplicationBuilder(args);

builder.Configuration.Sources.Clear();

IHostEnvironment env = builder.Environment;

builder.Configuration
    .AddJsonFile("appsettings.json", optional: true, reloadOnChange: true)
    .AddJsonFile($"appsettings.{env.EnvironmentName}.json", true, true);

TransientFaultHandlingOptions options = new();
builder.Configuration.GetSection(nameof(TransientFaultHandlingOptions))
    .Bind(options);

Console.WriteLine($"TransientFaultHandlingOptions.Enabled= {options.Enabled}");
Console.WriteLine($"TransientFaultHandlingOptions.AutoRetryDelay= {options.AutoRetryDelay}");

using IHost host = builder.Build();

// Application code should start here.

await host.RunAsync();

```

The preceding code:

- Clears all existing configuration providers that were added by default in the `CreateApplicationBuilder(String[])` method.
- Configures the JSON configuration provider to load the `appsettings.json` and `appsettings.Environment.json` files with the following options:
 - `optional: true`: The file is optional.
 - `reloadOnChange: true`: The file is reloaded when changes are saved.

ⓘ Important

When [adding configuration providers](#) with `IConfigurationBuilder.Add`, the added configuration provider is added to the end of the end of the `IConfigurationSource` list. When keys are found by multiple providers, the last provider to read the key overrides previous providers.

An example `appsettings.json` file with various configuration settings follows:

JSON

```
{
  "SecretKey": "Secret key value",
```

```
"TransientFaultHandlingOptions": {  
    "Enabled": true,  
    "AutoRetryDelay": "00:00:07"  
},  
"Logging": {  
    "LogLevel": {  
        "Default": "Information",  
        "Microsoft": "Warning",  
        "Microsoft.Hosting.Lifetime": "Information"  
    }  
}  
}
```

From the [IConfigurationBuilder](#) instance, after configuration providers have been added, you can call [IConfigurationBuilder.Build\(\)](#) to get the [IConfigurationRoot](#) object. The configuration root represents the root of a configuration hierarchy. Sections from the configuration can be bound to instances of .NET objects and later provided as [IOptions<TOptions>](#) through dependency injection.

ⓘ Note

The *Build Action* and *Copy to Output Directory* properties of the JSON file must be set to *Content* and *Copy if newer (or Copy always)*, respectively.

Consider the `TransientFaultHandlingOptions` class defined as follows:

```
C#  
  
namespace ConsoleJson.Example;  
  
public sealed class TransientFaultHandlingOptions  
{  
    public bool Enabled { get; set; }  
    public TimeSpan AutoRetryDelay { get; set; }  
}
```

The following code builds the configuration root, binds a section to the `TransientFaultHandlingOptions` class type, and prints the bound values to the console window:

```
C#  
  
TransientFaultHandlingOptions options = new();  
builder.Configuration.GetSection(nameof(TransientFaultHandlingOptions))  
    .Bind(options);  
  
Console.WriteLine($"TransientFaultHandlingOptions.Enabled=
```

```
{options.Enabled}");  
Console.WriteLine($"TransientFaultHandlingOptions.AutoRetryDelay=  
{options.AutoRetryDelay}");
```

The application writes the following sample output:

C#

```
// Sample output:  
//     TransientFaultHandlingOptions.Enabled=True  
//     TransientFaultHandlingOptions.AutoRetryDelay=00:00:07
```

XML configuration provider

The [XmlConfigurationProvider](#) class loads configuration from an XML file at run time. Install the [Microsoft.Extensions.Configuration.Xml](#) NuGet package.

The following code demonstrates the configuration of XML files using the XML configuration provider.

C#

```
using Microsoft.Extensions.Configuration;  
using Microsoft.Extensions.Hosting;  
  
HostApplicationBuilder builder = Host.CreateApplicationBuilder(args);  
  
builder.Configuration.Sources.Clear();  
  
builder.Configuration  
    .AddXmlFile("appsettings.xml", optional: true, reloadOnChange: true)  
    .AddXmlFile("repeating-example.xml", optional: true, reloadOnChange:  
true);  
  
builder.Configuration.AddEnvironmentVariables();  
  
if (args is { Length: > 0 })  
{  
    builder.Configuration.AddCommandLine(args);  
}  
  
using IHost host = builder.Build();  
  
// Application code should start here.  
  
await host.RunAsync();
```

The preceding code:

- Clears all existing configuration providers that were added by default in the `CreateApplicationBuilder(String[])` method.
- Configures the XML configuration provider to load the `appsettings.xml` and `repeating-example.xml` files with the following options:
 - `optional: true`: The file is optional.
 - `reloadOnChange: true`: The file is reloaded when changes are saved.
- Configures the environment variables configuration provider.
- Configures the command-line configuration provider if the given `args` contain arguments.

The XML settings are overridden by settings in the [Environment variables configuration provider](#) and the [Command-line configuration provider](#).

An example `appsettings.xml` file with various configuration settings follows:

XML

```
<?xml version="1.0" encoding="utf-8" ?>
<configuration>
  <SecretKey>Secret key value</SecretKey>
  <TransientFaultHandlingOptions>
    <Enabled>true</Enabled>
    <AutoRetryDelay>00:00:07</AutoRetryDelay>
  </TransientFaultHandlingOptions>
  <Logging>
    <LogLevel>
      <Default>Information</Default>
      <Microsoft>Warning</Microsoft>
    </LogLevel>
  </Logging>
</configuration>
```

Tip

To use the `IConfiguration` type in WinForms apps, add a reference to the [Microsoft.Extensions.Configuration.Xml](#) NuGet package. Instantiate the `ConfigurationBuilder` and chain calls to `AddXmlFile` and `Build()`. For more information, see [.NET Docs Issue #29679](#).

In .NET 5 and earlier versions, add the `name` attribute to distinguish repeating elements that use the same element name. In .NET 6 and later versions, the XML configuration provider automatically indexes repeating elements. That means you don't have to specify the `name` attribute, except if you want the "0" index in the key and there's only one element. (If you're upgrading to .NET 6 or later, you may encounter a break

resulting from this change in behavior. For more information, see [Repeated XML elements include index](#).)

XML

```
<?xml version="1.0" encoding="UTF-8"?>
<configuration>
    <section name="section0">
        <key name="key0">value 00</key>
        <key name="key1">value 01</key>
    </section>
    <section name="section1">
        <key name="key0">value 10</key>
        <key name="key1">value 11</key>
    </section>
</configuration>
```

The following code reads the previous configuration file and displays the keys and values:

C#

```
IConfigurationRoot configurationRoot = builder.Configuration;

string key00 = "section:section0:key:key0";
string key01 = "section:section0:key:key1";
string key10 = "section:section1:key:key0";
string key11 = "section:section1:key:key1";

string? val00 = configurationRoot[key00];
string? val01 = configurationRoot[key01];
string? val10 = configurationRoot[key10];
string? val11 = configurationRoot[key11];

Console.WriteLine($"{key00} = {val00}");
Console.WriteLine($"{key01} = {val01}");
Console.WriteLine($"{key10} = {val10}");
Console.WriteLine($"{key11} = {val11}");
```

The application would write the following sample output:

C#

```
// Sample output:
//    section:section0:key:key0 = value 00
//    section:section0:key:key1 = value 01
//    section:section1:key:key0 = value 10
//    section:section1:key:key1 = value 11
```

Attributes can be used to supply values:

XML

```
<?xml version="1.0" encoding="UTF-8"?>
<configuration>
  <key attribute="value" />
  <section>
    <key attribute="value" />
  </section>
</configuration>
```

The previous configuration file loads the following keys with `value`:

- `key:attribute`
- `section:key:attribute`

INI configuration provider

The `IniConfigurationProvider` class loads configuration from an INI file at run time. Install the [Microsoft.Extensions.Configuration.Ini](#) NuGet package.

The following code clears all the configuration providers and adds the `IniConfigurationProvider` with two INI files as the source:

C#

```
using Microsoft.Extensions.Configuration;
using Microsoft.Extensions.Hosting;

HostApplicationBuilder builder = Host.CreateApplicationBuilder(args);
builder.Configuration.Sources.Clear();

IHostEnvironment env = builder.Environment;

builder.Configuration
  .AddIniFile("appsettings.ini", optional: true, reloadOnChange: true)
  .AddIniFile($"appsettings.{env.EnvironmentName}.ini", true, true);

using IHost host = builder.Build();

// Application code should start here.

await host.RunAsync();
```

An example `appsettings.ini` file with various configuration settings follows:

ini

```
SecretKey="Secret key value"

[TransientFaultHandlingOptions]
Enabled=True
AutoRetryDelay="00:00:07"

[Logging:LogLevel]
Default=Information
Microsoft=Warning
```

The following code displays the preceding configuration settings by writing them to the console window:

C#

```
foreach ((string key, string? value) in
    builder.Configuration.AsEnumerable().Where(t => t.Value is not null))
{
    Console.WriteLine($"{key}={value}");
}
```

The application would write the following sample output:

C#

```
// Sample output:
// TransientFaultHandlingOptions:Enabled=True
// TransientFaultHandlingOptions:AutoRetryDelay=00:00:07
// SecretKey=Secret key value
// Logging:LogLevel:Microsoft=Warning
// Logging:LogLevel:Default=Information
```

Environment variable configuration provider

Using the default configuration, the [EnvironmentVariablesConfigurationProvider](#) loads configuration from environment variable key-value pairs after reading *appsettings.json*, *appsettings.Environment.json*, and Secret manager. Therefore, key values read from the environment override values read from *appsettings.json*, *appsettings.Environment.json*, and Secret manager.

The `:` delimiter doesn't work with environment variable hierarchical keys on all platforms. For example, the `:` delimiter is not supported by [Bash](#). The double underscore (`__`), which is supported on all platforms, automatically replaces any `:` delimiters in environment variables.

Consider the `TransientFaultHandlingOptions` class:

C#

```
public class TransientFaultHandlingOptions
{
    public bool Enabled { get; set; }
    public TimeSpan AutoRetryDelay { get; set; }
}
```

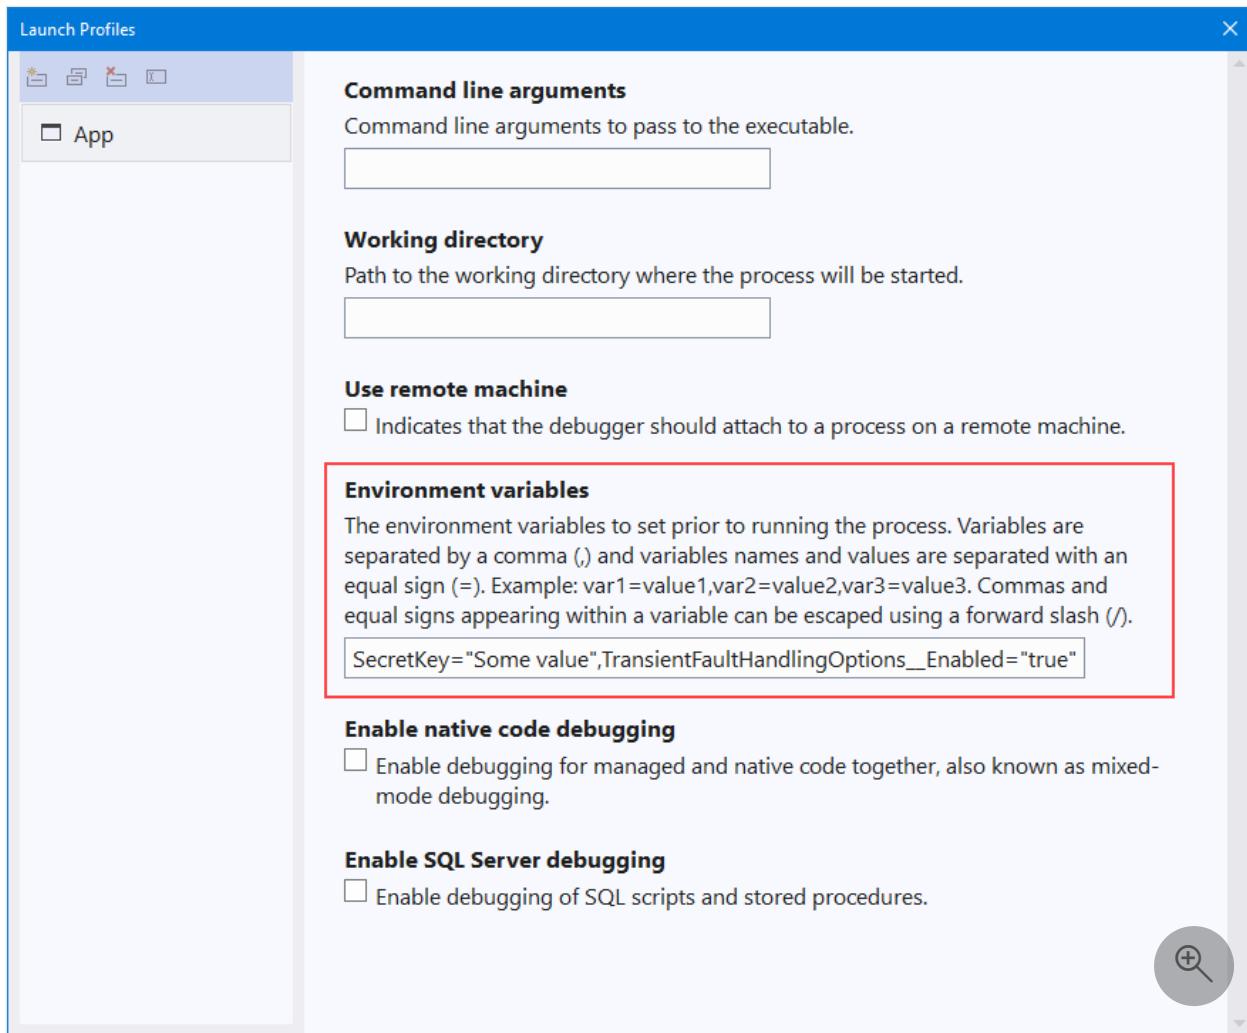

The following `set` commands set the environment keys and values of `SecretKey` and `TransientFaultHandlingOptions`.

.NET CLI

```
set SecretKey="Secret key from environment"
set TransientFaultHandlingOptions__Enabled="true"
set TransientFaultHandlingOptions__AutoRetryDelay="00:00:13"
```

These environment settings are only set in processes launched from the command window they were set in. They aren't read by web apps launched with Visual Studio.

With Visual Studio 2019 and later, you can specify environment variables using the **Launch Profiles** dialog.

The following `setx` commands can be used to set the environment keys and values on Windows. Unlike `set`, `setx` settings are persisted. `/M` sets the variable in the system environment. If the `/M` switch isn't used, a user environment variable is set.

.NET CLI

```
setx SecretKey "Secret key from setx environment" /M
setx TransientFaultHandlingOptions__Enabled "true" /M
setx TransientFaultHandlingOptions__AutoRetryDelay "00:00:05" /M
```

To test that the preceding commands override any `appsettings.json` and `appsettings.Environment.json` settings:

- With Visual Studio: Exit and restart Visual Studio.
- With the CLI: Start a new command window and enter `dotnet run`.

Prefixes

To specify a prefix for environment variables, call `AddEnvironmentVariables` with a string:

C#

```

using Microsoft.Extensions.Configuration;
using Microsoft.Extensions.Hosting;

HostApplicationBuilder builder = Host.CreateApplicationBuilder(args);

builder.Configuration.AddEnvironmentVariables(prefix: "CustomPrefix_");
using IHost host = builder.Build();

// Application code should start here.

await host.RunAsync();

```

In the preceding code:

- `config.AddEnvironmentVariables(prefix: "CustomPrefix_")` is added after the default configuration providers. For an example of ordering the configuration providers, see [XML configuration provider](#).
- Environment variables set with the `CustomPrefix_` prefix override the default configuration providers. This includes environment variables without the prefix.

The prefix is stripped off when the configuration key-value pairs are read.

The default configuration loads environment variables and command-line arguments prefixed with `DOTNET_`. The `DOTNET_` prefix is used by .NET for [host](#) and [app configuration](#), but not for user configuration.

For more information on host and app configuration, see [.NET Generic Host](#).

Connection string prefixes

The Configuration API has special processing rules for four connection string environment variables. These connection strings are involved in configuring Azure connection strings for the app environment. Environment variables with the prefixes shown in the table are loaded into the app with the default configuration or when no prefix is supplied to `AddEnvironmentVariables`.

| Connection string prefix | Provider |
|-------------------------------|------------------------------------|
| <code>CUSTOMCONNSTR_</code> | Custom provider |
| <code>MYSQLCONNSTR_</code> | MySQL |
| <code>SQLAZURECONNSTR_</code> | Azure SQL Database |
| <code>SQLCONNSTR_</code> | SQL Server |

When an environment variable is discovered and loaded into configuration with any of the four prefixes shown in the table:

- The configuration key is created by removing the environment variable prefix and adding a configuration key section (`ConnectionStrings`).
- A new configuration key-value pair is created that represents the database connection provider (except for `CUSTOMCONNSTR_`, which has no stated provider).

| Environment variable key | Converted configuration key | Provider configuration entry |
|------------------------------------|--------------------------------------|---|
| <code>CUSTOMCONNSTR_{KEY}</code> | <code>ConnectionStrings:{KEY}</code> | Configuration entry not created. |
| <code>MYSQLCONNSTR_{KEY}</code> | <code>ConnectionStrings:{KEY}</code> | Key: <code>ConnectionStrings:{KEY}_ProviderName:</code> Value: <code>MySql.Data.MySqlClient</code> |
| <code>SQLAZURECONNSTR_{KEY}</code> | <code>ConnectionStrings:{KEY}</code> | Key: <code>ConnectionStrings:{KEY}_ProviderName:</code> Value: <code>System.Data.SqlClient</code> |
| <code>SQLCONNSTR_{KEY}</code> | <code>ConnectionStrings:{KEY}</code> | Key: <code>ConnectionStrings:{KEY}_ProviderName:</code> Value: <code>System.Data.SqlClient</code> |

Environment variables set in `launchSettings.json`

Environment variables set in `launchSettings.json` override those set in the system environment.

Azure App Service settings

On [Azure App Service](#), select **New application setting** on the **Settings > Configuration** page. Azure App Service application settings are:

- Encrypted at rest and transmitted over an encrypted channel.
- Exposed as environment variables.

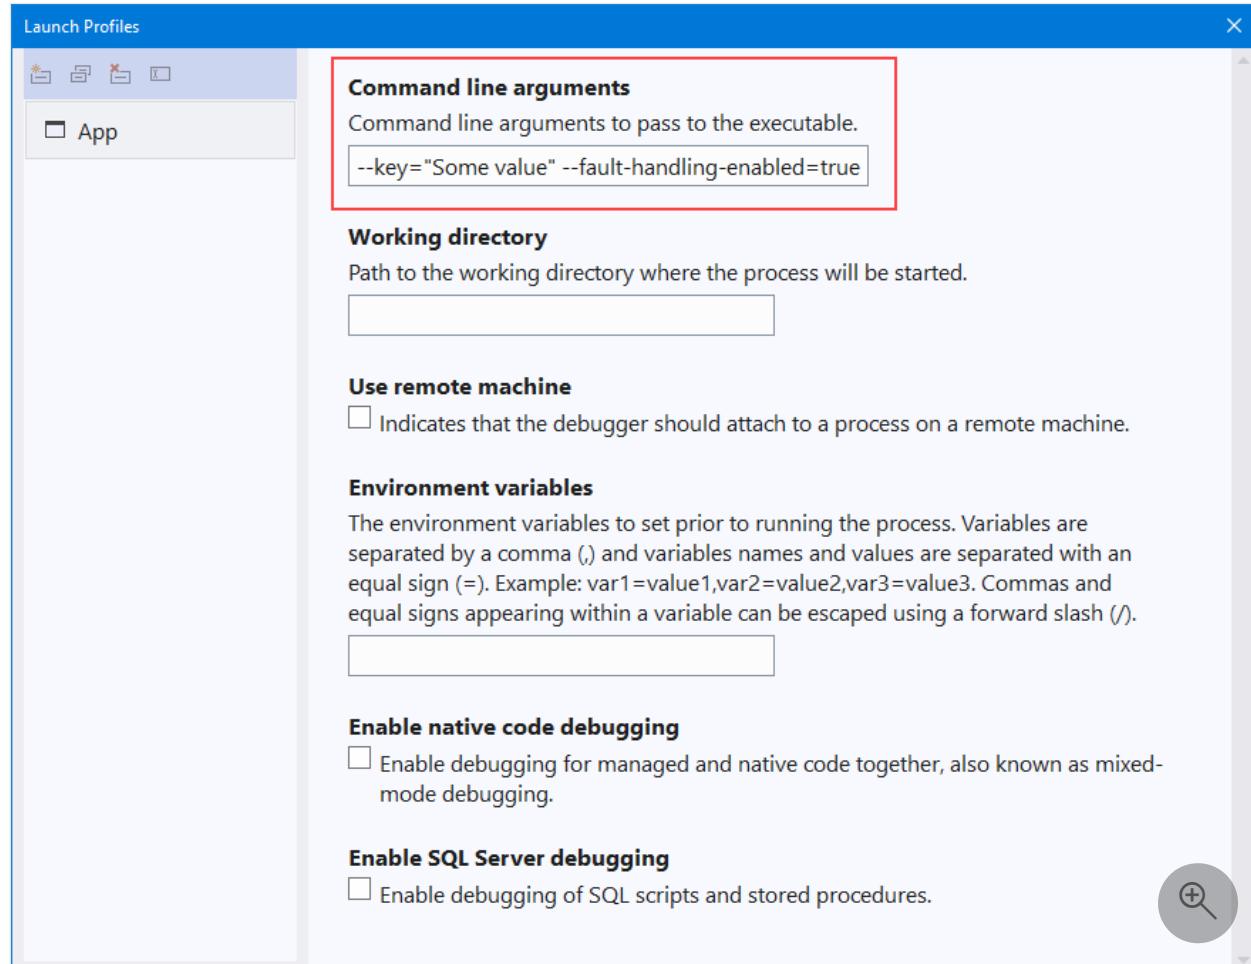

Command-line configuration provider

Using the default configuration, the [CommandLineConfigurationProvider](#) loads configuration from command-line argument key-value pairs after the following configuration sources:

- *appsettings.json* and *appsettings.Environment.json* files.
- App secrets (Secret Manager) in the `Development` environment.
- Environment variables.

By default, configuration values set on the command line override configuration values set with all the other configuration providers.

With Visual Studio 2019 and later, you can specify command-line arguments using the **Launch Profiles** dialog.

Command-line arguments

The following command sets keys and values using `=`:

```
.NET CLI
dotnet run SecretKey="Secret key from command line"
```

The following command sets keys and values using `/`:

```
.NET CLI
```

```
dotnet run /SecretKey "Secret key set from forward slash"
```

The following command sets keys and values using `--`:

.NET CLI

```
dotnet run --SecretKey "Secret key set from double hyphen"
```

The key value:

- Must follow `=`, or the key must have a prefix of `--` or `/` when the value follows a space.
- Isn't required if `=` is used. For example, `SomeKey=`.

Within the same command, don't mix command-line argument key-value pairs that use `=` with key-value pairs that use a space.

Key-per-file configuration provider

The [KeyPerFileConfigurationProvider](#) uses a directory's files as configuration key-value pairs. The key is the file name. The value is the file's contents. The Key-per-file configuration provider is used in Docker hosting scenarios.

To activate key-per-file configuration, call the [AddKeyPerFile](#) extension method on an instance of [ConfigurationBuilder](#). The `directoryPath` to the files must be an absolute path.

Overloads permit specifying:

- An `Action<KeyPerFileConfigurationSource>` delegate that configures the source.
- Whether the directory is optional and the path to the directory.

The double-underscore (`__`) is used as a configuration key delimiter in file names. For example, the file name `Logging__LogLevel__System` produces the configuration key `Logging:LogLevel:System`.

Call `ConfigureAppConfiguration` when building the host to specify the app's configuration:

C#

```
.ConfigureAppConfiguration((_, configuration) =>
{
```

```
    var path = Path.Combine(
        Directory.GetCurrentDirectory(), "path/to/files");

    configuration.AddKeyPerFile(directoryPath: path, optional: true);
}
```

Memory configuration provider

The [MemoryConfigurationProvider](#) uses an in-memory collection as configuration key-value pairs.

The following code adds a memory collection to the configuration system:

C#

```
using Microsoft.Extensions.Configuration;
using Microsoft.Extensions.Hosting;

HostApplicationBuilder builder = Host.CreateApplicationBuilder(args);

builder.Configuration.AddInMemoryCollection(
    new Dictionary<string, string?>
{
    ["SecretKey"] = "Dictionary MyKey Value",
    ["TransientFaultHandlingOptions:Enabled"] = bool.TrueString,
    ["TransientFaultHandlingOptions:AutoRetryDelay"] = "00:00:07",
    ["Logging:LogLevel:Default"] = "Warning"
});

using IHost host = builder.Build();

// Application code should start here.

await host.RunAsync();
```

In the preceding code,

[MemoryConfigurationBuilderExtensions.AddInMemoryCollection\(IConfigurationBuilder, IEnumerable<KeyValuePair<String, String>>\)](#) adds the memory provider after the default configuration providers. For an example of ordering the configuration providers, see [XML configuration provider](#).

Implement a custom configuration provider in .NET

Article • 06/23/2023

There are many [configuration providers](#) available for common configuration sources such as JSON, XML, and INI files. You may need to implement a custom configuration provider when one of the available providers doesn't suit your application needs. In this article, you'll learn how to implement a custom configuration provider that relies on a database as its configuration source.

Custom configuration provider

The sample app demonstrates how to create a basic configuration provider that reads configuration key-value pairs from a database using [Entity Framework \(EF\) Core](#).

The provider has the following characteristics:

- The EF in-memory database is used for demonstration purposes.
 - To use a database that requires a connection string, get a connection string from an interim configuration.
- The provider reads a database table into configuration at startup. The provider doesn't query the database on a per-key basis.
- Reload-on-change isn't implemented, so updating the database after the app has started will not affect the app's configuration.

Define a `Settings` record type entity for storing configuration values in the database.

For example, you could add a `Settings.cs` file in your `Models` folder:

```
C#  
  
namespace CustomProvider.Example.Models;  
  
public record Settings(string Id, string? Value);
```

For information on record types, see [Record types in C#](#).

Add an `EntityConfigurationContext` to store and access the configured values.

Providers/EntityConfigurationContext.cs:

```
C#
```

```

using CustomProvider.Example.Models;
using Microsoft.EntityFrameworkCore;

namespace CustomProvider.Example.Providers;

public class EntityConfigurationContext : DbContext
{
    private readonly string _connectionString;

    public DbSet<Settings> Settings => Set<Settings>();

    public EntityConfigurationContext(string? connectionString) =>
        _connectionString = connectionString ?? "";

    protected override void OnConfiguring(DbContextOptionsBuilder
optionsBuilder)
    {
        _ = _connectionString switch
        {
            { Length: > 0 } =>
optionsBuilder.UseSqlServer(_connectionString),
            _ => optionsBuilder.UseInMemoryDatabase("InMemoryDatabase")
        };
    }
}

```

By overriding [OnConfiguring\(DbContextOptionsBuilder\)](#) you can use the appropriate database connection. For example, if a connection string was provided you could connect to SQL Server, otherwise you could rely on an in-memory database.

Create a class that implements [IConfigurationSource](#).

Providers/EntityConfigurationSource.cs:

C#

```

using Microsoft.Extensions.Configuration;

namespace CustomProvider.Example.Providers;

public class EntityConfigurationSource : IConfigurationSource
{
    private readonly string? _connectionString;

    public EntityConfigurationSource(string? connectionString) =>
        _connectionString = connectionString;

    public IConfigurationProvider Build(IConfigurationBuilder builder) =>
        new EntityConfigurationProvider(_connectionString);
}

```

Create the custom configuration provider by inheriting from [ConfigurationProvider](#). The configuration provider initializes the database when it's empty. Since configuration keys are case-insensitive, the dictionary used to initialize the database is created with the case-insensitive comparer ([StringComparer.OrdinalIgnoreCase](#)).

Providers/EntityConfigurationProvider.cs:

C#

```
using CustomProvider.Example.Models;
using Microsoft.Extensions.Configuration;

namespace CustomProvider.Example.Providers;

public class EntityConfigurationProvider : ConfigurationProvider
{
    private readonly string? _connectionString;

    public EntityConfigurationProvider(string? connectionString) =>
        _connectionString = connectionString;

    public override void Load()
    {
        using var dbContext = new
EntityConfigurationContext(_connectionString);

        dbContext.Database.EnsureCreated();

        Data = dbContext.Settings.Any()
            ? dbContext.Settings.ToDictionary<Settings, string, string?>(c
=> c.Id, c => c.Value, StringComparer.OrdinalIgnoreCase)
            : CreateAndSaveDefaultValues(dbContext);
    }

    static IDictionary<string, string?> CreateAndSaveDefaultValues(
        EntityConfigurationContext context)
    {
        var settings = new Dictionary<string, string?>(
            StringComparer.OrdinalIgnoreCase)
        {
            ["WidgetOptions:EndpointId"] = "b3da3c4c-9c4e-4411-bc4d-
609e2dcc5c67",
            ["WidgetOptions:DisplayLabel"] = "Widgets Incorporated, LLC.",
            ["WidgetOptions:WidgetRoute"] = "api/widgets"
        };

        context.Settings.AddRange(
            settings.Select(kvp => new Settings(kvp.Key, kvp.Value))
                .ToArray());
    }

    context.SaveChanges();

    return settings;
}
```

```
    }  
}
```

An `AddEntityConfiguration` extension method permits adding the configuration source to a `IConfigurationBuilder` instance.

Extensions/ConfigurationBuilderExtensions.cs:

C#

```
using CustomProvider.Example.Providers;  
  
namespace Microsoft.Extensions.Configuration;  
  
public static class ConfigurationBuilderExtensions  
{  
    public static IApplicationBuilder AddEntityConfiguration(  
        this IApplicationBuilder builder)  
    {  
        var tempConfig = builder.Build();  
        var connectionString =  
            tempConfig.GetConnectionString("WidgetConnectionString");  
  
        return builder.Add(new EntityConfigurationSource(connectionString));  
    }  
}
```

ⓘ Important

The use of a temporary configuration source to acquire the connection string is important. The current `builder` has its configuration constructed temporarily by calling `IApplicationBuilder.Build()`, and `GetConnectionString`. After obtaining the connection string, the `builder` adds the `EntityConfigurationSource` given the `connectionString`.

The following code shows how to use the custom `EntityConfigurationProvider` in `Program.cs`:

C#

```
using Microsoft.Extensions.Configuration;  
using Microsoft.Extensions.DependencyInjection;  
using Microsoft.Extensions.Hosting;  
using Microsoft.Extensions.Options;  
using CustomProvider.Example;  
  
HostApplicationBuilder builder = Host.CreateApplicationBuilder(args);
```

```
builder.Configuration.Sources.Clear();
builder.Configuration.AddEntityConfiguration();
builder.Services.Configure<WidgetOptions>(
    builder.Configuration.GetSection("WidgetOptions"));

using IHost host = builder.Build();

WidgetOptions options =
host.Services.GetRequiredService<IOptions<WidgetOptions>>().Value;
Console.WriteLine($"DisplayLabel={options.DisplayLabel}");
Console.WriteLine($"EndpointId={options.EndpointId}");
Console.WriteLine($"WidgetRoute={options.WidgetRoute}");

await host.RunAsync();
// Sample output:
//   WidgetRoute=api/widgets
//   EndpointId=b3da3c4c-9c4e-4411-bc4d-609e2dcc5c67
//   DisplayLabel=Widgets Incorporated, LLC.
```

Consume provider

To consume the custom configuration provider, you can use the [options pattern](#). With the sample app in place, define an options object to represent the widget settings.

C#

```
namespace CustomProvider.Example;

public class WidgetOptions
{
    public required Guid EndpointId { get; set; }

    public required string DisplayLabel { get; set; } = null!;

    public required string WidgetRoute { get; set; } = null!;
}
```

A call to [Configure](#) registers a configuration instance, which `IOptions<WidgetOptions>` binds against.

C#

```
using Microsoft.Extensions.Configuration;
using Microsoft.Extensions.DependencyInjection;
using Microsoft.Extensions.Hosting;
using Microsoft.Extensions.Options;
using CustomProvider.Example;

HostApplicationBuilder builder = Host.CreateApplicationBuilder(args);
```

```

builder.Configuration.Sources.Clear();
builder.Configuration.AddEntityConfiguration();
builder.Services.Configure<WidgetOptions>(
    builder.Configuration.GetSection("WidgetOptions"));

using IHost host = builder.Build();

WidgetOptions options =
host.Services.GetRequiredService<IOptions<WidgetOptions>>().Value;
Console.WriteLine($"DisplayLabel={options.DisplayLabel}");
Console.WriteLine($"EndpointId={options.EndpointId}");
Console.WriteLine($"WidgetRoute={options.WidgetRoute}");

await host.RunAsync();
// Sample output:
//   WidgetRoute=api/widgets
//   EndpointId=b3da3c4c-9c4e-4411-bc4d-609e2dcc5c67
//   DisplayLabel=Widgets Incorporated, LLC.

```

The preceding code configures the `WidgetOptions` object from the "WidgetOptions" section of the configuration. This enables the options pattern, exposing a dependency injection-ready `IOptions<WidgetOptions>` representation of the EF settings. The options are ultimately provided from the custom configuration provider.

Options pattern in .NET

Article • 06/23/2023

The options pattern uses classes to provide strongly-typed access to groups of related settings. When [configuration settings](#) are isolated by scenario into separate classes, the app adheres to two important software engineering principles:

- The [Interface Segregation Principle \(ISP\)](#) or [Encapsulation](#): Scenarios (classes) that depend on configuration settings depend only on the configuration settings that they use.
- [Separation of Concerns](#): Settings for different parts of the app aren't dependent or coupled with one another.

Options also provide a mechanism to validate configuration data. For more information, see the [Options validation](#) section.

Bind hierarchical configuration

The preferred way to read related configuration values is using the options pattern. The options pattern is possible through the `IOptions<TOptions>` interface, where the generic type parameter `TOptions` is constrained to a `class`. The `IOptions<TOptions>` can later be provided through dependency injection. For more information, see [Dependency injection in .NET](#).

For example, to read the highlighted configuration values from an `appsettings.json` file:

```
JSON

{
    "SecretKey": "Secret key value",
    "TransientFaultHandlingOptions": {
        "Enabled": true,
        "AutoRetryDelay": "00:00:07"
    },
    "Logging": {
        "LogLevel": {
            "Default": "Information",
            "Microsoft": "Warning",
            "Microsoft.Hosting.Lifetime": "Information"
        }
    }
}
```

Create the following `TransientFaultHandlingOptions` class:

C#

```
public sealed class TransientFaultHandlingOptions
{
    public bool Enabled { get; set; }
    public TimeSpan AutoRetryDelay { get; set; }
}
```

When using the options pattern, an options class:

- Must be non-abstract with a public parameterless constructor
- Contain public read-write properties to bind (fields are **not** bound)

The following code is part of the *Program.cs* C# file and:

- Calls [ConfigurationBinder.Bind](#) to bind the `TransientFaultHandlingOptions` class to the `"TransientFaultHandlingOptions"` section.
- Displays the configuration data.

C#

```
using Microsoft.Extensions.Configuration;
using Microsoft.Extensions.Hosting;
using ConsoleJson.Example;

HostApplicationBuilder builder = Host.CreateApplicationBuilder(args);

builder.Configuration.Sources.Clear();

IHostEnvironment env = builder.Environment;

builder.Configuration
    .AddJsonFile("appsettings.json", optional: true, reloadOnChange: true)
    .AddJsonFile($"appsettings.{env.EnvironmentName}.json", true, true);

TransientFaultHandlingOptions options = new();
builder.Configuration.GetSection(nameof(TransientFaultHandlingOptions))
    .Bind(options);

Console.WriteLine($"TransientFaultHandlingOptions.Enabled={options.Enabled}");
Console.WriteLine($"TransientFaultHandlingOptions.AutoRetryDelay={options.AutoRetryDelay}");

using IHost host = builder.Build();

// Application code should start here.

await host.RunAsync();
```

```
// <Output>
// Sample output:
```

In the preceding code, the JSON configuration file has its `"TransientFaultHandlingOptions"` section bound to the `TransientFaultHandlingOptions` instance. This hydrates the C# objects properties with those corresponding values from the configuration.

`ConfigurationBinder.Get<T>` binds and returns the specified type. `ConfigurationBinder.Get<T>` may be more convenient than using `ConfigurationBinder.Bind`. The following code shows how to use `ConfigurationBinder.Get<T>` with the `TransientFaultHandlingOptions` class:

C#

```
var options =
    builder.Configuration.GetSection(nameof(TransientFaultHandlingOptions))
    .Get<TransientFaultHandlingOptions>();

Console.WriteLine($"TransientFaultHandlingOptions.Enabled=
{options.Enabled}");
Console.WriteLine($"TransientFaultHandlingOptions.AutoRetryDelay=
{options.AutoRetryDelay}");
```

In the preceding code, the `ConfigurationBinder.Get<T>` is used to acquire an instance of the `TransientFaultHandlingOptions` object with its property values populated from the underlying configuration.

ⓘ Important

The `ConfigurationBinder` class exposes several APIs, such as `.Bind(object instance)` and `.Get<T>()` that are *not* constrained to `class`. When using any of the **Options interfaces**, you must adhere to aforementioned **options class constraints**.

An alternative approach when using the options pattern is to bind the `"TransientFaultHandlingOptions"` section and add it to the [dependency injection service container](#). In the following code, `TransientFaultHandlingOptions` is added to the service container with `Configure` and bound to configuration:

C#

```
HostApplicationBuilder builder = Host.CreateApplicationBuilder(args);
```

```
builder.Services.Configure<TransientFaultHandlingOptions>(
    builder.Configuration.GetSection(
        key: nameof(TransientFaultHandlingOptions)));
```

The `builder` in the preceding example is an instance of [HostApplicationBuilder](#).

💡 Tip

The `key` parameter is the name of the configuration section to search for. It does *not* have to match the name of the type that represents it. For example, you could have a section named `"FaultHandling"` and it could be represented by the `TransientFaultHandlingOptions` class. In this instance, you'd pass `"FaultHandling"` to the `GetSection` function instead. The `nameof` operator is used as a convenience when the named section matches the type it corresponds to.

Using the preceding code, the following code reads the position options:

C#

```
using Microsoft.Extensions.Options;

namespace ConsoleJson.Example;

public sealed class ExampleService
{
    private readonly TransientFaultHandlingOptions _options;

    public ExampleService(IOptions<TransientFaultHandlingOptions> options)
=>
    _options = options.Value;

    public void DisplayValues()
    {
        Console.WriteLine($"TransientFaultHandlingOptions.Enabled={_
            _options.Enabled}");
        Console.WriteLine($"TransientFaultHandlingOptions.AutoRetryDelay=_
            {_options.AutoRetryDelay}");
    }
}
```

In the preceding code, changes to the JSON configuration file after the app has started are *not* read. To read changes after the app has started, use [IOptionsSnapshot](#) or [IOptionsMonitor](#) to monitor changes as they occur, and react accordingly.

Options interfaces

[IOptions<TOptions>:](#)

- Does **not** support:
 - Reading of configuration data after the app has started.
 - [Named options](#)
- Is registered as a [Singleton](#) and can be injected into any [service lifetime](#).

[IOptionsSnapshot<TOptions>:](#)

- Is useful in scenarios where options should be recomputed on every injection resolution, in [scoped or transient lifetimes](#). For more information, see [Use IOptionsSnapshot to read updated data](#).
- Is registered as [Scoped](#) and therefore cannot be injected into a Singleton service.
- Supports [named options](#)

[IOptionsMonitor<TOptions>:](#)

- Is used to retrieve options and manage options notifications for `TOptions` instances.
- Is registered as a [Singleton](#) and can be injected into any [service lifetime](#).
- Supports:
 - Change notifications
 - [Named options](#)
 - [Reloadable configuration](#)
 - Selective options invalidation ([IOptionsMonitorCache<TOptions>](#))

[IOptionsFactory<TOptions>](#) is responsible for creating new options instances. It has a single [Create](#) method. The default implementation takes all registered [IConfigureOptions<TOptions>](#) and [IPostConfigureOptions<TOptions>](#) and runs all the configurations first, followed by the post-configuration. It distinguishes between [IConfigureNamedOptions<TOptions>](#) and [IConfigureOptions<TOptions>](#) and only calls the appropriate interface.

[IOptionsMonitorCache<TOptions>](#) is used by [IOptionsMonitor<TOptions>](#) to cache `TOptions` instances. The [IOptionsMonitorCache<TOptions>](#) invalidates options instances in the monitor so that the value is recomputed ([TryRemove](#)). Values can be manually introduced with [TryAdd](#). The [Clear](#) method is used when all named instances should be recreated on demand.

[IOptionsChangeTokenSource<TOptions>](#) is used to fetch the [IChangeToken](#) that tracks changes to the underlying `TOptions` instance. For more information on change-token primitives, see [Change notifications](#).

Options interfaces benefits

Using a generic wrapper type gives you the ability to decouple the lifetime of the option from the DI container. The `IOptions<TOptions>.Value` interface provides a layer of abstraction, including generic constraints, on your options type. This provides the following benefits:

- The evaluation of the `T` configuration instance is deferred to the accessing of `IOptions<TOptions>.Value`, rather than when it is injected. This is important because you can consume the `T` option from various places and choose the lifetime semantics without changing anything about `T`.
- When registering options of type `T`, you do not need to explicitly register the `T` type. This is a convenience when you're [authoring a library](#) with simple defaults, and you don't want to force the caller to register options into the DI container with a specific lifetime.
- From the perspective of the API, it allows for constraints on the type `T` (in this case, `T` is constrained to a reference type).

Use `IOptionsSnapshot` to read updated data

When you use `IOptionsSnapshot<TOptions>`, options are computed once per request when accessed and are cached for the lifetime of the request. Changes to the configuration are read after the app starts when using configuration providers that support reading updated configuration values.

The difference between `IOptionsMonitor` and `IOptionsSnapshot` is that:

- `IOptionsMonitor` is a [singleton service](#) that retrieves current option values at any time, which is especially useful in singleton dependencies.
- `IOptionsSnapshot` is a [scoped service](#) and provides a snapshot of the options at the time the `IOptionsSnapshot<T>` object is constructed. Options snapshots are designed for use with transient and scoped dependencies.

The following code uses `IOptionsSnapshot<TOptions>`.

C#

```
using Microsoft.Extensions.Options;

namespace ConsoleJson.Example;

public sealed class ScopedService
{
```

```
private readonly TransientFaultHandlingOptions _options;

public ScopedService(IOptionsSnapshot<TransientFaultHandlingOptions>
options) =>
    _options = options.Value;

public void DisplayValues()
{
    Console.WriteLine($"TransientFaultHandlingOptions.Enabled={_
options.Enabled}");
    Console.WriteLine($"TransientFaultHandlingOptions.AutoRetryDelay=_
options.AutoRetryDelay");
}

}
```

The following code registers a configuration instance which `TransientFaultHandlingOptions` binds against:

C#

```
builder.Services
    .Configure<TransientFaultHandlingOptions>(
        configurationRoot.GetSection(
            nameof(TransientFaultHandlingOptions)));
```

In the preceding code, the `Configure<TOptions>` method is used to register a configuration instance that `TOptions` will bind against, and updates the options when the configuration changes.

IOptionsMonitor

To use the options monitor, options objects are configured in the same way from a configuration section.

C#

```
builder.Services
    .Configure<TransientFaultHandlingOptions>(
        configurationRoot.GetSection(
            nameof(TransientFaultHandlingOptions)));
```

The following example uses `IOptionsMonitor<TOptions>`:

C#

```
using Microsoft.Extensions.Options;
```

```

namespace ConsoleJson.Example;

public sealed class MonitorService
{
    private readonly IOptionsMonitor<TransientFaultHandlingOptions>
    _monitor;

    public MonitorService(IOptionsMonitor<TransientFaultHandlingOptions>
    monitor) =>
        _monitor = monitor;

    public void DisplayValues()
    {
        TransientFaultHandlingOptions options = _monitor.CurrentValue;

        Console.WriteLine($"TransientFaultHandlingOptions.Enabled=
{options.Enabled}");
        Console.WriteLine($"TransientFaultHandlingOptions.AutoRetryDelay=
{options.AutoRetryDelay}");
    }
}

```

In the preceding code, changes to the JSON configuration file after the app has started are read.

Tip

Some file systems, such as Docker containers and network shares, may not reliably send change notifications. When using the `IOptionsMonitor<TOptions>` interface in these environments, set the `DOTNET_USE_POLLING_FILE_WATCHER` environment variable to `1` or `true` to poll the file system for changes. The interval at which changes are polled is every four seconds and is not configurable.

For more information on Docker containers, see [Containerize a .NET app](#).

Named options support using `IConfigureNamedOptions`

Named options:

- Are useful when multiple configuration sections bind to the same properties.
- Are case-sensitive.

Consider the following `appsettings.json` file:

JSON

```
{  
    "Features": {  
        "Personalize": {  
            "Enabled": true,  
            "ApiKey":  
                "aGEgaGEgeW91IHRob3VnaHQgdGhhCB3YXMgcwVhbGx5IHNvbW0aGluZw=="  
        },  
        "WeatherStation": {  
            "Enabled": true,  
            "ApiKey": "QXJlIH1vdSBhdHR1bXB0aW5nIHRvIGhhY2sgdXM/"  
        }  
    }  
}
```

Rather than creating two classes to bind `Features:Personalize` and `Features:WeatherStation`, the following class is used for each section:

C#

```
public class Features  
{  
    public const string Personalize = nameof(Personalize);  
    public const string WeatherStation = nameof(WeatherStation);  
  
    public bool Enabled { get; set; }  
    public string ApiKey { get; set; }  
}
```

The following code configures the named options:

C#

```
HostApplicationBuilder builder = Host.CreateApplicationBuilder(args);  
  
// Omitted for brevity...  
  
builder.Services.Configure<Features>(  
    Features.Personalize,  
    builder.Configuration.GetSection("Features:Personalize"));  
  
builder.Services.Configure<Features>(  
    Features.WeatherStation,  
    builder.Configuration.GetSection("Features:WeatherStation"));
```

The following code displays the named options:

C#

```

public class sealed Service
{
    private readonly Features _personalizeFeature;
    private readonly Features _weatherStationFeature;

    public Service(IOptionsSnapshot<Features> namedOptionsAccessor)
    {
        _personalizeFeature =
            namedOptionsAccessor.Get(Features.Personalize);
        _weatherStationFeature =
            namedOptionsAccessor.Get(Features.WeatherStation);
    }
}

```

All options are named instances. `IConfigureOptions<TOptions>` instances are treated as targeting the `Options.DefaultName` instance, which is `string.Empty`.

`IConfigureNamedOptions<TOptions>` also implements `IConfigureOptions<TOptions>`. The default implementation of the `IOptionsFactory<TOptions>` has logic to use each appropriately. The `null` named option is used to target all of the named instances instead of a specific named instance. `ConfigureAll` and `PostConfigureAll` use this convention.

OptionsBuilder API

`OptionsBuilder<TOptions>` is used to configure `TOptions` instances. `OptionsBuilder` streamlines creating named options as it's only a single parameter to the initial `AddOptions<TOptions>(string optionsName)` call instead of appearing in all of the subsequent calls. Options validation and the `ConfigureOptions` overloads that accept service dependencies are only available via `OptionsBuilder`.

`OptionsBuilder` is used in the [Options validation](#) section.

Use DI services to configure options

Services can be accessed from dependency injection while configuring options in two ways:

- Pass a configuration delegate to `Configure` on `OptionsBuilder<TOptions>`. `OptionsBuilder<TOptions>` provides overloads of `Configure` that allow use of up to five services to configure options:

C#

```
builder.Services
    .AddOptions<MyOptions>("optionalName")
    .Configure<ExampleService, ScopedService, MonitorService>(
        (options, es, ss, ms) =>
            options.Property = DoSomethingWith(es, ss, ms));
```

- Create a type that implements [IConfigureOptions<TOptions>](#) or [IConfigureNamedOptions<TOptions>](#) and register the type as a service.

We recommend passing a configuration delegate to [Configure](#), since creating a service is more complex. Creating a type is equivalent to what the framework does when calling [Configure](#). Calling [Configure](#) registers a transient generic [IConfigureNamedOptions<TOptions>](#), which has a constructor that accepts the generic service types specified.

Options validation

Options validation enables option values to be validated.

Consider the following *appsettings.json* file:

JSON

```
{  
    "MyCustomSettingsSection": {  
        "SiteTitle": "Amazing docs from Awesome people!",  
        "Scale": 10,  
        "VerbosityLevel": 32  
    }  
}
```

The following class binds to the `"MyCustomSettingsSection"` configuration section and applies a couple of `DataAnnotations` rules:

C#

```
using System.ComponentModel.DataAnnotations;  
  
namespace ConsoleJson.Example;  
  
public sealed class SettingsOptions  
{  
    public const string ConfigurationSectionName =  
        "MyCustomSettingsSection";  
  
    [RegularExpression(@"^[\w\W]{1,40}$")]
```

```
    public required string SiteTitle { get; set; } = null!;

    [Range(0, 1000,
        ErrorMessage = "Value for {0} must be between {1} and {2}.")]
    public required int Scale { get; set; }

    public required int VerbosityLevel { get; set; }
}
```

In the preceding `SettingsOptions` class, the `ConfigurationSectionName` property contains the name of the configuration section to bind to. In this scenario, the options object provides the name of its configuration section.

💡 Tip

The configuration section name is independent of the configuration object that it's binding to. In other words, a configuration section named `"FooBarOptions"` can be bound to an options object named `ZedOptions`. Although it might be common to name them the same, it's *not* necessary and can actually cause name conflicts.

The following code:

- Calls `AddOptions` to get an `OptionsResolver<TOptions>` that binds to the `SettingsOptions` class.
- Calls `ValidateDataAnnotations` to enable validation using `DataAnnotations`.

C#

```
builder.Services
    .AddOptions<SettingsOptions>()

    .Bind(Configuration.GetSection(SettingsOptions.ConfigurationSectionName))
    .ValidateDataAnnotations();
```

The `ValidateDataAnnotations` extension method is defined in the [Microsoft.Extensions.Options.DataAnnotations](#) NuGet package.

The following code displays the configuration values or the validation errors:

C#

```
using Microsoft.Extensions.Logging;
using Microsoft.Extensions.Options;

namespace ConsoleJson.Example;
```

```

public sealed class ValidationService
{
    private readonly ILogger<ValidationService> _logger;
    private readonly IOptions<SettingsOptions> _config;

    public ValidationService(
        ILogger<ValidationService> logger,
        IOptions<SettingsOptions> config)
    {
        _config = config;
        _logger = logger;

        try
        {
            SettingsOptions options = _config.Value;
        }
        catch (OptionsValidationException ex)
        {
            foreach (string failure in ex.Failures)
            {
                _logger.LogError(failure);
            }
        }
    }
}

```

The following code applies a more complex validation rule using a delegate:

```

C#

builder.Services
    .AddOptions<SettingsOptions>()

    .Bind(Configuration.GetSection(SettingsOptions.ConfigurationSectionName))
        .ValidateDataAnnotations()
        .Validate(config =>
    {
        if (config.Scale != 0)
        {
            return config.VerboseLevel > config.Scale;
        }

        return true;
    }, "VerboseLevel must be > than Scale.");

```

IValidateOptions for complex validation

The following class implements [IValidateOptions<TOptions>](#):

C#

```
using System.Text;
using System.Text.RegularExpressions;
using Microsoft.Extensions.Configuration;
using Microsoft.Extensions.Options;

namespace ConsoleJson.Example;

sealed partial class ValidateSettingsOptions : 
IValidateOptions<SettingsOptions>
{
    public SettingsOptions? _settings { get; private set; }

    public ValidateSettingsOptions(IConfiguration config) =>
        _settings =
config.GetSection(SettingsOptions.ConfigurationSectionName)
            .Get<SettingsOptions>();

    public ValidateOptionsResult Validate(string? name, SettingsOptions options)
    {
        StringBuilder? failure = null;

        if (!ValidationRegex().IsMatch(options.SiteTitle))
        {
            (failure ??= new()).AppendLine($"{options.SiteTitle} doesn't
match RegEx");
        }

        if (options.Scale is < 0 or > 1_000)
        {
            (failure ??= new()).AppendLine($"{options.Scale} isn't within
Range 0 - 1000");
        }

        if (_settings is { Scale: 0 } && _settings.VerboseLevel <=
_settings.Scale)
        {
            (failure ??= new()).AppendLine("VerboseLevel must be > than
Scale.");
        }

        return failure is not null ?
            ? ValidateOptionsResult.Fail(failure.ToString())
            : ValidateOptionsResult.Success;
    }

    [GeneratedRegex("^[a-zA-Z'-'\\s]{1,40}$")]
    private static partial Regex ValidationRegex();
}
```

IValidateOptions enables moving the validation code into a class.

ⓘ Note

This example code relies on the [Microsoft.Extensions.Configuration.Json](#) NuGet package.

Using the preceding code, validation is enabled when configuring services with the following code:

C#

```
HostApplicationBuilder builder = Host.CreateApplicationBuilder(args);

// Omitted for brevity...

builder.Services.Configure<SettingsOptions>(
    builder.Configuration.GetSection(
        SettingsOptions.ConfigurationSectionName));

builder.Services.TryAddEnumerable(
    ServiceDescriptor.Singleton
    <IValidateOptions<SettingsOptions>, ValidateSettingsOptions>());
```

Options post-configuration

Set post-configuration with [IPostConfigureOptions<TOptions>](#). Post-configuration runs after all [IConfigureOptions<TOptions>](#) configuration occurs, and can be useful in scenarios when you need to override configuration:

C#

```
builder.Services.PostConfigure<CustomOptions>(customOptions =>
{
    customOptions.Option1 = "post_configured_option1_value";
});
```

[PostConfigure](#) is available to post-configure named options:

C#

```
builder.Services.PostConfigure<CustomOptions>("named_options_1",
customOptions =>
{
    customOptions.Option1 = "post_configured_option1_value";
});
```

Use `PostConfigureAll` to post-configure all configuration instances:

C#

```
builder.Services.PostConfigureAll<CustomOptions>(customOptions =>
{
    customOptions.Option1 = "post_configured_option1_value";
});
```

Compile-time options validation source generation

Article • 12/20/2023

In the [options pattern](#), various methods for validating options are presented. These methods include using data annotation attributes or employing a custom validator. Data annotation attributes are validated at run time and can incur performance costs. This article demonstrates how to utilize the options validation source generator to produce optimized validation code at compile time.

Automatic `IValidateOptions` implementation generation

The [options pattern](#) article illustrates how to implement the `IValidateOptions<TOptions>` interface for validating options. The options validation source generator can automatically create the `IValidateOptions` interface implementation by leveraging data annotation attributes on the options class.

The content that follows takes the annotation attributes example that's shown in [Options pattern](#) and converts it to use the options validation source generator.

Consider the following `appsettings.json` file:

```
JSON

{
  "MyCustomSettingsSection": {
    "SiteTitle": "Amazing docs from awesome people!",
    "Scale": 10,
    "VerbosityLevel": 32
  }
}
```

The following class binds to the `"MyCustomSettingsSection"` configuration section and applies a couple of `DataAnnotations` rules:

```
C#

using System.ComponentModel.DataAnnotations;

namespace ConsoleJson.Example;
```

```

public sealed class SettingsOptions
{
    public const string ConfigurationSectionName =
"MyCustomSettingsSection";

    [Required]
    [RegularExpression(@"^a-zA-Z'-'s]{1,40}$")]
    public required string SiteTitle { get; set; }

    [Required]
    [Range(0, 1_000,
        ErrorMessage = "Value for {0} must be between {1} and {2}.")]
    public required int? Scale { get; set; }

    [Required]
    public required int? VerbosityLevel { get; set; }
}

```

In the preceding `SettingsOptions` class, the `ConfigurationSectionName` property contains the name of the configuration section to bind to. In this scenario, the options object provides the name of its configuration section. The use of the following data annotation attributes are used:

- **RequiredAttribute**: Specifies that the property is required.
- **RegularExpressionAttribute**: Specifies that the property value must match the specified regular expression pattern.
- **RangeAttribute**: Specifies that the property value must be within a specified range.

Tip

In addition to the `RequiredAttribute`, the properties also use the `required` modifier. This helps to ensure that consumers of the options object don't forget to set the property value, although it doesn't relate to the validation source generation feature.

The following code exemplifies how to bind the configuration section to the options object and validate the data annotations:

C#

```

using ConsoleJson.Example;
using Microsoft.Extensions.Configuration;
using Microsoft.Extensions.DependencyInjection;
using Microsoft.Extensions.Hosting;
using Microsoft.Extensions.Options;

HostApplicationBuilder builder = Host.CreateApplicationBuilder(args);

```

```
builder.Services
    .AddOptions<SettingsOptions>()

    .Bind(builder.Configuration.GetSection(SettingsOptions.ConfigurationSectionName));

builder.Services
    .AddSingleton<IValidateOptions<SettingsOptions>,
    ValidateSettingsOptions>();

using IHost app = builder.Build();

var settingsOptions =
    app.Services.GetRequiredService<IOptions<SettingsOptions>>().Value;

await app.RunAsync();
```

By leveraging compile-time source generation for options validation, you can generate performance-optimized validation code and eliminate the need for reflection, resulting in smoother AOT-compatible app building. The following code demonstrates how to use the options validation source generator:

C#

```
using Microsoft.Extensions.Options;

namespace ConsoleJson.Example;

[OptionsValidator]
public partial class ValidateSettingsOptions :
    IValidateOptions<SettingsOptions>
{}
```

The presence of the [OptionsValidatorAttribute](#) on an empty partial class instructs the options validation source generator to create the `IValidateOptions` interface implementation that validates `SettingsOptions`. The code that's generated by the options validation source generator will resemble the following example:

C#

```
// <auto-generated/>
#pragma warning disable CS1591 // Compensate for
https://github.com/dotnet/roslyn/issues/54103
namespace ConsoleJson.Example
{
    partial class ValidateSettingsOptions
```

```

{
    /// <summary>
    /// Validates a specific named options instance (or all when
<paramref name="name"/> is <see langword="null" />).
    /// </summary>
    /// <param name="name">The name of the options instance being
validated.</param>
    /// <param name="options">The options instance.</param>
    /// <returns>Validation result.</returns>

            value = global::System.Convert.ChangeType(stringValue,
OperandType, formatProvider);
        }
        else
        {
            value = global::System.Convert.ChangeType(value,
OperandType, formatProvider);
        }
        return value;
    }
}

```

The generated code is optimized for performance and doesn't rely on reflection. It's also AOT-compatible. The generated code is placed in a file named `Validators.g.cs`.

ⓘ Note

You don't need to take any additional steps to enable the options validation source generator. It's automatically enabled by default when your project references `Microsoft.Extensions.Options` [↗] version 8 or later, or when building an ASP.NET application.

The only step you need to take is to add the following to the startup code:

C#

```
builder.Services
    .AddSingleton<IValidateOptions<SettingsOptions>,
    ValidateSettingsOptions>();
```

ⓘ Note

Calling `OptionsBuilderDataAnnotationsExtensions.ValidateDataAnnotations<TOptions>(OptionsBuilder<TOptions>)` isn't required when using the options validation source generator.

When the application attempts to access the options object, the generated code for options validation is executed to validate the options object. The following code snippet illustrates how to access the options object:

C#

```
var settingsOptions =
    app.Services.GetRequiredService<IOptions<SettingsOptions>>().Value;
```

Replaced data annotation attributes

Upon close examination of the generated code, you'll observe that the original data annotation attributes, such as `RangeAttribute`, that were initially applied to the property `SettingsOptions.Scale`, have been substituted with custom attributes like `__SourceGen__RangeAttribute`. This substitution is made because the `RangeAttribute`

relies on reflection for validation. In contrast, `_SourceGen_RangeAttribute` is a custom attribute optimized for performance and doesn't depend on reflection, making the code AOT-compatible. The same pattern of attribute replacement will be applied on [MaxLengthAttribute](#), [MinLengthAttribute](#), and [LengthAttribute](#) in addition to [RangeAttribute](#).

For anyone developing custom data annotation attributes, it's advisable to refrain from using reflection for validation. Instead, it's recommended to craft strongly typed code that doesn't rely on reflection. This approach ensures smooth compatibility with AOT builds.

Options pattern guidance for .NET library authors

Article • 06/23/2023

With the help of dependency injection, registering your services and their corresponding configurations can make use of the *options pattern*. The options pattern enables consumers of your library (and your services) to require instances of [options interfaces](#) where `TOptions` is your options class. Consuming configuration options through strongly-typed objects helps to ensure consistent value representation, enables validation with data annotations, and removes the burden of manually parsing string values. There are many [configuration providers](#) for consumers of your library to use. With these providers, consumers can configure your library in many ways.

As a .NET library author, you'll learn general guidance on how to correctly expose the options pattern to consumers of your library. There are various ways to achieve the same thing, and several considerations to make.

Naming conventions

By convention, extension methods responsible for registering services are named `Add{Service}`, where `{Service}` is a meaningful and descriptive name. `Add{Service}` extension methods are commonplace in [ASP.NET Core](#) and .NET alike.

- ✓ CONSIDER names that disambiguate your service from other offerings.
- ✗ DO NOT use names that are already part of the .NET ecosystem from official Microsoft packages.
- ✓ CONSIDER naming static classes that expose extension methods as `{Type}Extensions`, where `{Type}` is the type that you're extending.

Namespace guidance

Microsoft packages make use of the `Microsoft.Extensions.DependencyInjection` namespace to unify the registration of various service offerings.

- ✓ CONSIDER a namespace that clearly identifies your package offering.
- ✗ DO NOT use the `Microsoft.Extensions.DependencyInjection` namespace for non-official Microsoft packages.

Parameterless

If your service can work with minimal or no explicit configuration, consider a parameterless extension method.

C#

```
using Microsoft.Extensions.DependencyInjection;

namespace ExampleLibrary.Extensions.DependencyInjection;

public static class ServiceCollectionExtensions
{
    public static IServiceCollection AddMyLibraryService(
        this IServiceCollection services)
    {
        services.AddOptions<LibraryOptions>()
            .Configure(options =>
        {
            // Specify default option values
        });

        // Register lib services here...
        // services.AddScoped<ILibraryService, DefaultLibraryService>();

        return services;
    }
}
```

In the preceding code, the `AddMyLibraryService`:

- Extends an instance of `IServiceCollection`
- Calls `OptionsServiceCollectionExtensions.AddOptions<TOptions>(IServiceCollection)` with the type parameter of `LibraryOptions`
- Chains a call to `Configure`, which specifies the default option values

IConfiguration parameter

When you author a library that exposes many options to consumers, you may want to consider requiring an `IConfiguration` parameter extension method. The expected `IConfiguration` instance should be scoped to a named section of the configuration by using the `IConfiguration.GetSection` function.

C#

```
using Microsoft.Extensions.Configuration;
using Microsoft.Extensions.DependencyInjection;
```

```
namespace ExampleLibrary.Extensions.DependencyInjection;

public static class ServiceCollectionExtensions
{
    public static IServiceCollection AddMyLibraryService(
        this IServiceCollection services,
        IConfiguration namedConfigurationSection)
    {
        // Default library options are overridden
        // by bound configuration values.
        services.Configure<LibraryOptions>(namedConfigurationSection);

        // Register lib services here...
        // services.AddScoped<ILibraryService, DefaultLibraryService>();

        return services;
    }
}
```

💡 Tip

The `Configure<TOptions>(IServiceCollection, IConfiguration)` method is part of the [Microsoft.Extensions.Options.ConfigurationExtensions](#) NuGet package.

In the preceding code, the `AddMyLibraryService`:

- Extends an instance of `IServiceCollection`
- Defines an `IConfiguration` parameter `namedConfigurationSection`
- Calls `Configure<TOptions>(IServiceCollection, IConfiguration)` passing the generic type parameter of `LibraryOptions` and the `namedConfigurationSection` instance to configure

Consumers in this pattern provide the scoped `IConfiguration` instance of the named section:

C#

```
using ExampleLibrary.Extensions.DependencyInjection;
using Microsoft.Extensions.Hosting;

HostApplicationBuilder builder = Host.CreateApplicationBuilder(args);

builder.Services.AddMyLibraryService(
    builder.Configuration.GetSection("LibraryOptions"));

using IHost host = builder.Build();
```

```
// Application code should start here.  
  
await host.RunAsync();
```

The call to `.AddMyLibraryService` is made on the `IServiceCollection` type.

As the library author, specifying default values is up to you.

ⓘ Note

It is possible to bind configuration to an options instance. However, there is a risk of name collisions - which will cause errors. Additionally, when manually binding in this way, you limit the consumption of your options pattern to read-once. Changes to settings will not be re-bound, as such consumers will not be able to use the `IOptionsMonitor` interface.

C#

```
services.AddOptions<LibraryOptions>()  
    .Configure< IConfiguration>(  
        (options, configuration) =>  
            configuration.GetSection("LibraryOptions").Bind(options));
```

Instead, you should use the `BindConfiguration` extension method. This extension method binds the configuration to the options instance, and also registers a change token source for the configuration section. This allows consumers to use the `IOptionsMonitor` interface.

Configuration section path parameter

Consumers of your library may want to specify the configuration section path to bind your underlying `IOptions` type. In this scenario, you define a `string` parameter in your extension method.

C#

```
using Microsoft.Extensions.DependencyInjection;  
  
namespace ExampleLibrary.Extensions.DependencyInjection;  
  
public static class ServiceCollectionExtensions  
{  
    public static IServiceCollection AddMyLibraryService(  
        this IServiceCollection services,
```

```

        string configSectionPath)
    {
        services.AddOptions<SupportOptions>()
            .BindConfiguration(configSectionPath)
            .ValidateDataAnnotations()
            .ValidateOnStart();

        // Register lib services here...
        // services.AddScoped<ILibraryService, DefaultLibraryService>();

        return services;
    }
}

```

In the preceding code, the `AddMyLibraryService`:

- Extends an instance of `IServiceCollection`
- Defines a `string` parameter `configSectionPath`
- Calls:
 - `AddOptions` with the generic type parameter of `SupportOptions`
 - `BindConfiguration` with the given `configSectionPath` parameter
 - `ValidateDataAnnotations` to enable data annotation validation
 - `ValidateOnStart` to enforce validation on start rather than in runtime

In the next example, the [Microsoft.Extensions.Options.DataAnnotations](#) NuGet package is used to enable data annotation validation. The `SupportOptions` class is defined as follows:

C#

```

using System.ComponentModel.DataAnnotations;

public sealed class SupportOptions
{
    [Url]
    public string? Url { get; set; }

    [Required, EmailAddress]
    public required string Email { get; set; }

    [Required, DataType(DataType.PhoneNumber)]
    public required string PhoneNumber { get; set; }
}

```

Imagine that the following JSON `appsettings.json` file is used:

JavaScript

```
{  
    "Support": {  
        "Url": "https://support.example.com",  
        "Email": "help@support.example.com",  
        "PhoneNumber": "+1(888)-SUPPORT"  
    }  
}
```

Action<TOptions> parameter

Consumers of your library may be interested in providing a lambda expression that yields an instance of your options class. In this scenario, you define an `Action<LibraryOptions>` parameter in your extension method.

C#

```
using Microsoft.Extensions.DependencyInjection;  
  
namespace ExampleLibrary.Extensions.DependencyInjection;  
  
public static class ServiceCollectionExtensions  
{  
    public static IServiceCollection AddMyLibraryService(  
        this IServiceCollection services,  
        Action<LibraryOptions> configureOptions)  
    {  
        services.Configure(configureOptions);  
  
        // Register lib services here...  
        // services.AddScoped<ILibraryService, DefaultLibraryService>();  
  
        return services;  
    }  
}
```

In the preceding code, the `AddMyLibraryService`:

- Extends an instance of `IServiceCollection`
- Defines an `Action<T>` parameter `configureOptions` where `T` is `LibraryOptions`
- Calls `Configure` given the `configureOptions` action

Consumers in this pattern provide a lambda expression (or a delegate that satisfies the `Action<LibraryOptions>` parameter):

C#

```
using ExampleLibrary.Extensions.DependencyInjection;
using Microsoft.Extensions.Hosting;

HostApplicationBuilder builder = Host.CreateApplicationBuilder(args);

builder.Services.AddMyLibraryService(options =>
{
    // User defined option values
    // options.SomePropertyValue = ...
});

using IHost host = builder.Build();

// Application code should start here.

await host.RunAsync();
```

Options instance parameter

Consumers of your library might prefer to provide an inlined options instance. In this scenario, you expose an extension method that takes an instance of your options object, `LibraryOptions`.

C#

```
using Microsoft.Extensions.DependencyInjection;

namespace ExampleLibrary.Extensions.DependencyInjection;

public static class ServiceCollectionExtensions
{
    public static IServiceCollection AddMyLibraryService(
        this IServiceCollection services,
        LibraryOptions userOptions)
    {
        services.AddOptions<LibraryOptions>()
            .Configure(options =>
            {
                // Overwrite default option values
                // with the user provided options.
                // options.SomeValue = userOptions.SomeValue;
            });

        // Register lib services here...
        // services.AddScoped<ILibraryService, DefaultLibraryService>();

        return services;
    }
}
```

In the preceding code, the `AddMyLibraryService`:

- Extends an instance of `IServiceCollection`
- Calls `OptionsServiceCollectionExtensions.AddOptions<TOptions>(IServiceCollection)` with the type parameter of `LibraryOptions`
- Chains a call to `Configure`, which specifies default option values that can be overridden from the given `userOptions` instance

Consumers in this pattern provide an instance of the `LibraryOptions` class, defining desired property values inline:

C#

```
using ExampleLibrary.Extensions.DependencyInjection;
using Microsoft.Extensions.Hosting;

HostApplicationBuilder builder = Host.CreateApplicationBuilder(args);

builder.Services.AddMyLibraryService(new LibraryOptions
{
    // Specify option values
    // SomePropertyValue = ...
});

using IHost host = builder.Build();

// Application code should start here.

await host.RunAsync();
```

Post configuration

After all configuration option values are bound or specified, post configuration functionality is available. Exposing the same `Action<TOptions>` parameter detailed earlier, you could choose to call `PostConfigure`. Post configure runs after all `.Configure` calls. There are few reasons why you'd want to consider using `PostConfigure`:

- **Execution order:** You can override any configuration values that were set in the `.Configure` calls.
- **Validation:** You can validate the default values have been set after all other configurations have been applied.

C#

```
using Microsoft.Extensions.DependencyInjection;
```

```
namespace ExampleLibrary.Extensions.DependencyInjection;

public static class ServiceCollectionExtensions
{
    public static IServiceCollection AddMyLibraryService(
        this IServiceCollection services,
        Action<LibraryOptions> configureOptions)
    {
        services.PostConfigure(configureOptions);

        // Register lib services here...
        // services.AddScoped<ILibraryService, DefaultLibraryService>();

        return services;
    }
}
```

In the preceding code, the `AddMyLibraryService`:

- Extends an instance of `IServiceCollection`
- Defines an `Action<T>` parameter `configureOptions` where `T` is `LibraryOptions`
- Calls `PostConfigure` given the `configureOptions` action

Consumers in this pattern provide a lambda expression (or a delegate that satisfies the `Action<LibraryOptions>` parameter), just as they would with the `Action<TOptions>` parameter in a non-post configuration scenario:

C#

```
using ExampleLibrary.Extensions.DependencyInjection;
using Microsoft.Extensions.Hosting;

HostApplicationBuilder builder = Host.CreateApplicationBuilder(args);

builder.Services.AddMyLibraryService(options =>
{
    // Specify option values
    // options.SomePropertyValue = ...
});

using IHost host = builder.Build();

// Application code should start here.

await host.RunAsync();
```

Logging in C# and .NET

Article • 12/11/2023

.NET supports high performance, structured logging via the [ILogger](#) API to help monitor application behavior and diagnose issues. Logs can be written to different destinations by configuring different [logging providers](#). Basic logging providers are built-in and there are many third-party providers available as well.

Get started

This first example shows the basics, but it is only suitable for a trivial console app. In the next section you see how to improve the code considering scale, performance, configuration and typical programming patterns.

C#

```
using Microsoft.Extensions.Logging;

using ILoggerFactory factory = LoggerFactory.Create(builder =>
builder.AddConsole());
ILogger logger = factory.CreateLogger("Program");
logger.LogInformation("Hello World! Logging is {Description}.", "fun");
```

The preceding example:

- Creates an [ILoggerFactory](#). The `ILoggerFactory` stores all the configuration that determines where log messages are sent. In this case, you configure the console [logging provider](#) so that log messages are written to the console.
- Creates an [ILogger](#) with a category named "Program". The `category` is a `string` that is associated with each message logged by the `ILogger` object. It's used to group log messages from the same class (or category) together when searching or filtering logs.
- Calls [.LogInformation](#) to log a message at the `Information` level. The [log level](#) indicates the severity of the logged event and is used to filter out less important log messages. The log entry also includes a [message template](#) `"Hello World! Logging is {Description}."` and a key-value pair `Description = fun`. The key name (or placeholder) comes from the word inside the curly braces in the template and the value comes from the remaining method argument.

💡 Tip

All of the logging example source code is available in the [Samples Browser](#) for download. For more information, see [Browse code samples: Logging in .NET](#).

Logging in a non-trivial app

There are several changes you should consider making to the previous example when logging in a less trivial scenario:

- If your application is using [Dependency Injection \(DI\)](#) or a host such as ASP.NET's [WebApplication](#) or [Generic Host](#) then you should use `ILoggerFactory` and `ILogger` objects from their respective DI containers rather than creating them directly. For more information, see [Integration with DI and Hosts](#).
- Logging [compile-time source generation](#) is usually a better alternative to `ILogger` extension methods like `LogInformation`. Logging source generation offers better performance, stronger typing, and avoids spreading `string` constants throughout your methods. The tradeoff is that using this technique requires a bit more code.

C#

```
using Microsoft.Extensions.Logging;

internal partial class Program
{
    static void Main(string[] args)
    {
        using ILoggerFactory factory = LoggerFactory.Create(builder =>
builder.AddConsole());
        ILogger logger = factory.CreateLogger("Program");
        LogStartupMessage(logger, "fun");
    }

    [LoggerMessage(Level = LogLevel.Information, Message = "Hello World!
Logging is {Description}.")]
    static partial void LogStartupMessage	ILogger logger, string
description);
}
```

- The recommended practice for log category names is to use the fully qualified name of the class that's creating the log message. This helps relate log messages back to the code which produced them and offers a good level of control when filtering logs. `CreateLogger` accepts a `Type` to make this naming easy to do.

C#

```
using Microsoft.Extensions.Logging;

internal class Program
{
    static void Main(string[] args)
    {
        using ILoggerFactory factory = LoggerFactory.Create(builder =>
builder.AddConsole());
        ILogger logger = factory.CreateLogger<Program>();
        logger.LogInformation("Hello World! Logging is {Description}.",
"fun");
    }
}
```

- If you don't use console logs as your sole production monitoring solution, add the [logging providers](#) you plan to use. For example, you could use [OpenTelemetry](#) to send logs over [OTLP \(OpenTelemetry protocol\)](#):

C#

```
using Microsoft.Extensions.Logging;
using OpenTelemetry.Logs;

using ILoggerFactory factory = LoggerFactory.Create(builder =>
{
    builder.AddOpenTelemetry(logging =>
    {
        logging.AddOtlpExporter();
    });
});
ILogger logger = factory.CreateLogger("Program");
logger.LogInformation("Hello World! Logging is {Description}.", "fun");
```

Integration with hosts and dependency injection

If your application is using [Dependency Injection \(DI\)](#) or a host such as ASP.NET's [WebApplication](#) or [Generic Host](#) then you should use `ILoggerFactory` and `ILogger` objects from the DI container rather than creating them directly.

Get an `ILogger` from DI

This example gets an `ILogger` object in a hosted app using [ASP.NET Minimal APIs](#):

C#

```

var builder = WebApplication.CreateBuilder(args);

builder.Services.AddSingleton<ExampleHandler>();

var app = builder.Build();

var handler = app.Services.GetRequiredService<ExampleHandler>();
app.MapGet("/", handler.HandleRequest);

app.Run();

partial class ExampleHandler(ILogger<ExampleHandler> logger)
{
    public string HandleRequest()
    {
        LogHandleRequest(logger);
        return "Hello World";
    }

    [LoggerMessage(LogLevel.Information, "ExampleHandler.HandleRequest was
called")]
    public static partial void LogHandleRequest(ILogger logger);
}

```

The preceding example:

- Created a singleton service called `ExampleHandler` and mapped incoming web requests to run the `ExampleHandler.HandleRequest` function.
- Line 8 defines a [primary constructor](#) for the `ExampleHandler`, a feature added in C# 12. Using the older style C# constructor would work equally well but is a little more verbose.
- The constructor defines a parameter of type `ILogger<ExampleHandler>`. `ILogger<TCategoriesName>` derives from `ILogger` and indicates which category the `ILogger` object has. The DI container locates an `ILogger` with the correct category and supplies it as the constructor argument. If no `ILogger` with that category exists yet, the DI container automatically creates it from the `ILoggerFactory` in the service provider.
- The `logger` parameter received in the constructor was used for logging in the `HandleRequest` function.

Host-provided `ILoggerFactory`

Host builders initialize [default configuration](#), then add a configured `ILoggerFactory` object to the host's DI container when the host is built. Before the host is built you can adjust the logging configuration via [HostApplicationBuilder.Logging](#),

`WebApplicationBuilder.Logging`, or similar APIs on other hosts. Hosts also apply logging configuration from default configuration sources as `appsettings.json` and environment variables. For more information, see [Configuration in .NET](#).

This example expands on the previous one to customize the `ILoggerFactory` provided by `WebApplicationBuilder`. It adds [OpenTelemetry](#) as a logging provider transmitting the logs over [OTLP \(OpenTelemetry protocol\)](#):

C#

```
var builder = WebApplication.CreateBuilder(args);
builder.Logging.AddOpenTelemetry(logging => logging.AddOtlpExporter());
builder.Services.AddSingleton<ExampleHandler>();
var app = builder.Build();
```

Create an `ILoggerFactory` with DI

If you're using a DI container without a host, use [AddLogging](#) to configure and add `ILoggerFactory` to the container.

C#

```
using Microsoft.Extensions.DependencyInjection;
using Microsoft.Extensions.Logging;

// Add services to the container including logging
var services = new ServiceCollection();
services.AddLogging(builder => builder.AddConsole());
services.AddSingleton<ExampleService>();
IServiceProvider serviceProvider = services.BuildServiceProvider();

// Get the ExampleService object from the container
ExampleService service = serviceProvider.GetRequiredService<ExampleService>();

// Do some pretend work
service.DoSomeWork(10, 20);

class ExampleService(ILogger<ExampleService> logger)
{
    public void DoSomeWork(int x, int y)
    {
        logger.LogInformation("DoSomeWork was called. x={X}, y={Y}", x, y);
    }
}
```

The preceding example:

- Created a DI service container containing an `ILoggerFactory` configured to write to the console
- Added a singleton `ExampleService` to the container
- Created an instance of the `ExampleService` from the DI container which also automatically created an `ILogger<ExampleService>` to use as the constructor argument.
- Invoked `ExampleService.DoSomeWork` which used the `ILogger<ExampleService>` to log a message to the console.

Configure logging

Logging configuration is set in code or via external sources, such as, config files and environment variables. Using external configuration is beneficial when possible because it can be changed without rebuilding the application. However, some tasks, such as setting logging providers, can only be configured from code.

Configure logging without code

For apps that [use a host](#), logging configuration is commonly provided by the `"Logging"` section of `appsettings.{Environment}.json` files. For apps that don't use a host, external configuration sources are [set up explicitly](#) or [configured in code](#) instead.

The following `appsettings.Development.json` file is generated by the .NET Worker service templates:

```
JSON

{
  "Logging": {
    "LogLevel": {
      "Default": "Information",
      "Microsoft": "Warning",
      "Microsoft.Hosting.Lifetime": "Information"
    }
  }
}
```

In the preceding JSON:

- The `"Default"`, `"Microsoft"`, and `"Microsoft.Hosting.Lifetime"` log level categories are specified.

- The "Default" value is applied to all categories that aren't otherwise specified, effectively making all default values for all categories "Information". You can override this behavior by specifying a value for a category.
- The "Microsoft" category applies to all categories that start with "Microsoft".
- The "Microsoft" category logs at a log level of Warning and higher.
- The "Microsoft.Hosting.Lifetime" category is more specific than the "Microsoft" category, so the "Microsoft.Hosting.Lifetime" category logs at log level "Information" and higher.
- A specific log provider is not specified, so LogLevel applies to all the enabled logging providers except for the [Windows EventLog](#).

The Logging property can have LogLevel and log provider properties. The LogLevel specifies the minimum level to log for selected categories. In the preceding JSON, Information and Warning log levels are specified. LogLevel indicates the severity of the log and ranges from 0 to 6:

Trace = 0, Debug = 1, Information = 2, Warning = 3, Error = 4, Critical = 5, and None = 6.

When a LogLevel is specified, logging is enabled for messages at the specified level and higher. In the preceding JSON, the Default category is logged for Information and higher. For example, Information, Warning, Error, and Critical messages are logged. If no LogLevel is specified, logging defaults to the Information level. For more information, see [Log levels](#).

A provider property can specify a LogLevel property. LogLevel under a provider specifies levels to log for that provider, and overrides the non-provider log settings. Consider the following *appsettings.json* file:

```
JSON
{
  "Logging": {
    "LogLevel": {
      "Default": "Error",
      "Microsoft": "Warning"
    },
    "Debug": {
      "LogLevel": {
        "Default": "Information",
        "Microsoft.Hosting": "Trace"
      }
    },
    "EventSource": {
      "LogLevel": {
        "Default": "Information"
      }
    }
  }
}
```

```
        "Default": "Warning"
    }
}
}
```

Settings in `Logging.{ProviderName}.LogLevel` override settings in `Logging.LogLevel`. In the preceding JSON, the `Debug` provider's default log level is set to `Information`:

```
Logging:Debug:LogLevel:Default:Information
```

The preceding setting specifies the `Information` log level for every `Logging:Debug:` category except `Microsoft.Hosting`. When a specific category is listed, the specific category overrides the default category. In the preceding JSON, the `Logging:Debug:LogLevel` categories `"Microsoft.Hosting"` and `"Default"` override the settings in `Logging:LogLevel`.

The minimum log level can be specified for any of:

- Specific providers: For example,
`Logging:EventSource:LogLevel:Default:Information`
- Specific categories: For example, `Logging:LogLevel:Microsoft:Warning`
- All providers and all categories: `Logging:LogLevel:Default:Warning`

Any logs below the minimum level are *not*:

- Passed to the provider.
- Logged or displayed.

To suppress all logs, specify `LogLevel.None`. `LogLevel.None` has a value of 6, which is higher than `LogLevel.Critical` (5).

If a provider supports [log scopes](#), `IncludeScopes` indicates whether they're enabled. For more information, see [log scopes](#)

The following `appsettings.json` file contains settings for all of the built-in providers:

JSON

```
{
  "Logging": {
    "LogLevel": {
      "Default": "Error",
      "Microsoft": "Warning",
      "Microsoft.Hosting.Lifetime": "Warning"
    },
  }
```

```

    "Debug": {
        "LogLevel": {
            "Default": "Information"
        }
    },
    "Console": {
        "IncludeScopes": true,
        "LogLevel": {
            "Microsoft.Extensions.Hosting": "Warning",
            "Default": "Information"
        }
    },
    "EventSource": {
        "LogLevel": {
            "Microsoft": "Information"
        }
    },
    "EventLog": {
        "LogLevel": {
            "Microsoft": "Information"
        }
    },
    "AzureAppServicesFile": {
        "IncludeScopes": true,
        "LogLevel": {
            "Default": "Warning"
        }
    },
    "AzureAppServicesBlob": {
        "IncludeScopes": true,
        "LogLevel": {
            "Microsoft": "Information"
        }
    },
    "ApplicationInsights": {
        "LogLevel": {
            "Default": "Information"
        }
    }
}
}

```

In the preceding sample:

- The categories and levels are not suggested values. The sample is provided to show all the default providers.
- Settings in `Logging.{ProviderName}.LogLevel` override settings in `Logging.LogLevel`. For example, the level in `Debug(LogLevel.Default)` overrides the level in `LogLevel.Default`.
- Each provider's *alias* is used. Each provider defines an *alias* that can be used in configuration in place of the fully qualified type name. The built-in providers'

aliases are:

- `Console`
- `Debug`
- `EventSource`
- `EventLog`
- `AzureAppServicesFile`
- `AzureAppServicesBlob`
- `ApplicationInsights`

Set log level by command line, environment variables, and other configuration

Log level can be set by any of the [configuration providers](#). For example, you can create a persisted environment variable named `Logging:LogLevel:Microsoft` with a value of `Information`.

Command Line

Create and assign persisted environment variable, given the log level value.

CMD

```
:: Assigns the env var to the value  
setx "Logging__LogLevel__Microsoft" "Information" /M
```

In a *new* instance of the **Command Prompt**, read the environment variable.

CMD

```
:: Prints the env var value  
echo %Logging__LogLevel__Microsoft%
```

The preceding environment setting is persisted in the environment. To test the settings when using an app created with the .NET Worker service templates, use the `dotnet run` command in the project directory after the environment variable is assigned.

.NET CLI

```
dotnet run
```

Tip

After setting an environment variable, restart your integrated development environment (IDE) to ensure that newly added environment variables are available.

On [Azure App Service](#), select **New application setting** on the **Settings > Configuration** page. Azure App Service application settings are:

- Encrypted at rest and transmitted over an encrypted channel.
- Exposed as environment variables.

For more information on setting .NET configuration values using environment variables, see [environment variables](#).

Configure logging with code

To configure logging in code, use the [ILoggingBuilder](#) API. This can be accessed from different places:

- When creating the `ILoggerFactory` directly, configure in [LoggerFactory.Create](#).
- When using DI without a host, configure in [LoggingServiceCollectionExtensions.AddLogging](#).
- When using a host, configure with [HostApplicationBuilder.Logging](#), [WebApplicationBuilder.Logging](#) or other host specific APIs.

This example shows setting the console [logging provider](#) and several [filters](#).

C#

```
using Microsoft.Extensions.Logging;

using var loggerFactory = LoggerFactory.Create(static builder =>
{
    builder
        .AddFilter("Microsoft", LogLevel.Warning)
        .AddFilter("System", LogLevel.Warning)
        .AddFilter("LoggingConsoleApp.Program", LogLevel.Debug)
        .AddConsole();
});

	ILogger logger = loggerFactory.CreateLogger<Program>();
	logger.LogDebug("Hello {Target}", "Everyone");
```

In the preceding example `AddFilter` is used to [adjust the log level](#) that's enabled for various categories. `AddConsole` is used to add the console logging provider. By default,

logs with `Debug` severity aren't enabled, but because the configuration adjusted the filters, the debug message "Hello Everyone" is displayed on the console.

How filtering rules are applied

When an `ILogger<TCategories>` object is created, the `ILoggerFactory` object selects a single rule per provider to apply to that logger. All messages written by an `ILogger` instance are filtered based on the selected rules. The most specific rule for each provider and category pair is selected from the available rules.

The following algorithm is used for each provider when an `ILogger` is created for a given category:

- Select all rules that match the provider or its alias. If no match is found, select all rules with an empty provider.
- From the result of the preceding step, select rules with longest matching category prefix. If no match is found, select all rules that don't specify a category.
- If multiple rules are selected, take the **last** one.
- If no rules are selected, use `LoggingBuilderExtensions.SetMinimumLevel(ILoggingBuilder, LogLevel)` to specify the minimum logging level.

Log category

When an `ILogger` object is created, a *category* is specified. That category is included with each log message created by that instance of `ILogger`. The category string is arbitrary, but the convention is to use the class name. For example, in an application with a service defined like the following object, the category might be

`"Example.DefaultService"`:

C#

```
namespace Example
{
    public class DefaultService : IService
    {
        private readonly ILogger<DefaultService> _logger;

        public DefaultService(ILogger<DefaultService> logger) =>
            _logger = logger;

        // ...
    }
}
```

```
    }  
}
```

To explicitly specify the category, call [LoggerFactory.CreateLogger](#):

C#

```
namespace Example  
{  
    public class DefaultService : IService  
    {  
        private readonly ILogger _logger;  
  
        public DefaultService	ILoggerFactory loggerFactory) =>  
            _logger = loggerFactory.CreateLogger("CustomCategory");  
  
        // ...  
    }  
}
```

Calling `CreateLogger` with a fixed name can be useful when used in multiple classes/types so the events can be organized by category.

`ILogger<T>` is equivalent to calling `CreateLogger` with the fully qualified type name of `T`.

Log level

The following table lists the [LogLevel](#) values, the convenience `Log{LogLevel}` extension method, and the suggested usage:

[+] [Expand table](#)

| LogLevel | Value | Method | Description |
|-------------|-------|---------------------------------|---|
| Trace | 0 | LogTrace | Contain the most detailed messages. These messages may contain sensitive app data. These messages are disabled by default and should not be enabled in production. |
| Debug | 1 | LogDebug | For debugging and development. Use with caution in production due to the high volume. |
| Information | 2 | .LogInformation | Tracks the general flow of the app. May have long-term value. |
| Warning | 3 | .LogWarning | For abnormal or unexpected events. Typically includes errors or conditions that don't cause the app to fail. |

| LogLevel | Value | Method | Description |
|----------|-------|-------------|---|
| Error | 4 | LogError | For errors and exceptions that cannot be handled. These messages indicate a failure in the current operation or request, not an app-wide failure. |
| Critical | 5 | LogCritical | For failures that require immediate attention. Examples: data loss scenarios, out of disk space. |
| None | 6 | | Specifies that no messages should be written. |

In the previous table, the `LogLevel` is listed from lowest to highest severity.

The `Log` method's first parameter, `LogLevel`, indicates the severity of the log. Rather than calling `Log(LogLevel, ...)`, most developers call the `Log{LogLevel}` extension methods. The `Log{LogLevel}` extension methods [call the Log method and specify the LogLevel ↗](#). For example, the following two logging calls are functionally equivalent and produce the same log:

C#

```
public void LogDetails()
{
    var logMessage = "Details for log.";

    _logger.Log(LogLevel.Information, AppLogEvents.Details, logMessage);
    _logger.LogInformation(AppLogEvents.Details, logMessage);
}
```

`AppLogEvents.Details` is the event ID, and is implicitly represented by a constant `Int32` value. `AppLogEvents` is a class that exposes various named identifier constants and is displayed in the [Log event ID](#) section.

The following code creates `Information` and `Warning` logs:

C#

```
public async Task<T> GetAsync<T>(string id)
{
    _logger.LogInformation(AppLogEvents.Read, "Reading value for {Id}", id);

    var result = await _repository.GetAsync(id);
    if (result is null)
    {
        _logger.LogWarning(AppLogEvents.ReadNotFound, "GetAsync({Id}) not found", id);
    }
}
```

```
    return result;  
}
```

In the preceding code, the first `Log{LogLevel}` parameter, `AppLogEvents.Read`, is the [Log event ID](#). The second parameter is a message template with placeholders for argument values provided by the remaining method parameters. The method parameters are explained in the [message template](#) section later in this article.

Configure the appropriate log level and call the correct `Log{LogLevel}` methods to control how much log output is written to a particular storage medium. For example:

- In production:
 - Logging at the `Trace` or `Debug` levels produces a high-volume of detailed log messages. To control costs and not exceed data storage limits, log `Trace` and `Debug` level messages to a high-volume, low-cost data store. Consider limiting `Trace` and `Debug` to specific categories.
 - Logging at `Warning` through `Critical` levels should produce few log messages.
 - Costs and storage limits usually aren't a concern.
 - Few logs allow more flexibility in data store choices.
- In development:
 - Set to `Warning`.
 - Add `Trace` or `Debug` messages when troubleshooting. To limit output, set `Trace` or `Debug` only for the categories under investigation.

The following JSON sets `Logging:Console:LogLevel:Microsoft:Information`:

JSON

```
{  
  "Logging": {  
    "LogLevel": {  
      "Microsoft": "Warning"  
    },  
    "Console": {  
      "LogLevel": {  
        "Microsoft": "Information"  
      }  
    }  
  }  
}
```

Log event ID

Each log can specify an *event identifier*, the `EventId` is a structure with an `Id` and optional `Name` readonly properties. The sample source code uses the `AppLogEvents` class to define event IDs:

C#

```
using Microsoft.Extensions.Logging;

internal static class AppLogEvents
{
    internal EventId Create = new(1000, "Created");
    internal EventId Read = new(1001, "Read");
    internal EventId Update = new(1002, "Updated");
    internal EventId Delete = new(1003, "Deleted");

    // These are also valid EventId instances, as there's
    // an implicit conversion from int to an EventId
    internal const int Details = 3000;
    internal const int Error = 3001;

    internal EventId ReadNotFound = 4000;
    internal EventId UpdateNotFound = 4001;

    // ...
}
```

Tip

For more information on converting an `int` to an `EventId`, see [EventId.Implicit\(Int32 to EventId\) Operator](#).

An event ID associates a set of events. For example, all logs related to reading values from a repository might be `1001`.

The logging provider may log the event ID in an ID field, in the logging message, or not at all. The Debug provider doesn't show event IDs. The console provider shows event IDs in brackets after the category:

Console

```
info: Example.DefaultService.GetAsync[1001]
      Reading value for a1b2c3
warn: Example.DefaultService.GetAsync[4000]
      GetAsync(a1b2c3) not found
```

Some logging providers store the event ID in a field, which allows for filtering on the ID.

Log message template

Each log API uses a message template. The message template can contain placeholders for which arguments are provided. Use names for the placeholders, not numbers. The order of placeholders, not their names, determines which parameters are used to provide their values. In the following code, the parameter names are out of sequence in the message template:

```
C#
```

```
string p1 = "param1";
string p2 = "param2";
_logger.LogInformation("Parameter values: {p2}, {p1}", p1, p2);
```

The preceding code creates a log message with the parameter values in sequence:

```
text
```

```
Parameter values: param1, param2
```

ⓘ Note

Be mindful when using multiple placeholders within a single message template, as they're ordinal-based. The names are *not* used to align the arguments to the placeholders.

This approach allows logging providers to implement [semantic or structured logging](#). The arguments themselves are passed to the logging system, not just the formatted message template. This enables logging providers to store the parameter values as fields. Consider the following logger method:

```
C#
```

```
_logger.LogInformation("Getting item {Id} at {RunTime}", id, DateTime.Now);
```

For example, when logging to Azure Table Storage:

- Each Azure Table entity can have `ID` and `RunTime` properties.
- Tables with properties simplify queries on logged data. For example, a query can find all logs within a particular `RunTime` range without having to parse the time out of the text message.

Log message template formatting

Log message templates support placeholder formatting. Templates are free to specify [any valid format](#) for the given type argument. For example, consider the following `Information` logger message template:

C#

```
_logger.LogInformation("Logged on {PlaceHolderName:MMMM dd, yyyy}",  
DateTimeOffset.UtcNow);  
// Logged on January 06, 2022
```

In the preceding example, the `DateTimeOffset` instance is the type that corresponds to the `PlaceHolderName` in the logger message template. This name can be anything as the values are ordinal-based. The `MMMM dd, yyyy` format is valid for the `DateTimeOffset` type.

For more information on `DateTime` and `DateTimeOffset` formatting, see [Custom date and time format strings](#).

Examples

The following examples show how to format a message template using the `{}` placeholder syntax. Additionally, an example of escaping the `{}` placeholder syntax is shown with its output. Finally, string interpolation with templating placeholders is also shown:

C#

```
logger.LogInformation("Number: {Number}", 1); // Number: 1  
logger.LogInformation("{Number}): {Number}", 3); // {Number}: 3  
logger.LogInformation($"{{{Number}}}: {{Number}}", 5); // {Number}: 5
```

Tip

- In most cases, you should use log message template formatting when logging. Use of string interpolation can cause performance issues.
- Code analysis rule [CA2254: Template should be a static expression](#) helps alert you to places where your log messages don't use proper formatting.

Log exceptions

The logger methods have overloads that take an exception parameter:

C#

```
public void Test(string id)
{
    try
    {
        if (id is "none")
        {
            throw new Exception("Default Id detected.");
        }
    }
    catch (Exception ex)
    {
        _logger.LogWarning(
            AppLogEvents.Error, ex,
            "Failed to process iteration: {Id}", id);
    }
}
```

Exception logging is provider-specific.

Default log level

If the default log level is not set, the default log level value is `Information`.

For example, consider the following worker service app:

- Created with the .NET Worker templates.
- `appsettings.json` and `appsettings.Development.json` deleted or renamed.

With the preceding setup, navigating to the privacy or home page produces many `Trace`, `Debug`, and `Information` messages with `Microsoft` in the category name.

The following code sets the default log level when the default log level is not set in configuration:

C#

```
HostApplicationBuilder builder = Host.CreateApplicationBuilder(args);

builder.Logging.SetMinimumLevel(LogLevel.Warning);

using IHost host = builder.Build();

await host.RunAsync();
```

Filter function

A filter function is invoked for all providers and categories that don't have rules assigned to them by configuration or code:

```
C#  
  
HostApplicationBuilder builder = Host.CreateApplicationBuilder(args);  
  
builder.Logging.AddFilter((provider, category, logLevel) =>  
{  
    return provider.Contains("ConsoleLoggerProvider")  
    && (category.Contains("Example") || category.Contains("Microsoft"))  
    && logLevel >= LogLevel.Information;  
});  
  
using IHost host = builder.Build();  
  
await host.RunAsync();
```

The preceding code displays console logs when the category contains `Example` or `Microsoft` and the log level is `Information` or higher.

Log scopes

A scope groups a set of logical operations. This grouping can be used to attach the same data to each log that's created as part of a set. For example, every log created as part of processing a transaction can include the transaction ID.

A scope:

- Is an [IDisposable](#) type that's returned by the [BeginScope](#) method.
- Lasts until it's disposed.

The following providers support scopes:

- [Console](#)
- [AzureAppServicesFile](#) and [AzureAppServicesBlob](#)

Use a scope by wrapping logger calls in a `using` block:

```
C#  
  
public async Task<T> GetAsync<T>(string id)  
{  
    T result;  
    var transactionId = Guid.NewGuid().ToString();
```

```

    using (_logger.BeginScope(new List<KeyValuePair<string, object>>
    {
        new KeyValuePair<string, object>("TransactionId",
transactionId),
    }))
{
    _logger.LogInformation(
        AppLogEvents.Read, "Reading value for {Id}", id);

    var result = await _repository.GetAsync(id);
    if (result is null)
    {
        _logger.LogWarning(
            AppLogEvents.ReadNotFound, "GetAsync({Id}) not found", id);
    }
}

return result;
}

```

The following JSON enables scopes for the console provider:

JSON

```
{
    "Logging": {
        "Debug": {
            "LogLevel": {
                "Default": "Information"
            }
        },
        "Console": {
            "IncludeScopes": true,
            "LogLevel": {
                "Microsoft": "Warning",
                "Default": "Information"
            }
        },
        "LogLevel": {
            "Default": "Debug"
        }
    }
}
```

The following code enables scopes for the console provider:

C#

```

HostApplicationBuilder builder = Host.CreateApplicationBuilder(args);

builder.Logging.ClearProviders();

```

```
builder.Logging.AddConsole(options => options.IncludeScopes = true);

using IHost host = builder.Build();

await host.RunAsync();
```

Create logs in Main

The following code logs in `Main` by getting an `ILogger` instance from DI after building the host:

C#

```
using Microsoft.Extensions.DependencyInjection;
using Microsoft.Extensions.Hosting;
using Microsoft.Extensions.Logging;

using IHost host = Host.CreateApplicationBuilder(args).Build();

var logger = host.Services.GetRequiredService<ILogger<Program>>();
logger.LogInformation("Host created.");

await host.RunAsync();
```

The preceding code relies on two NuGet packages:

- [Microsoft.Extensions.Hosting](#)
- [Microsoft.Extensions.Logging](#)

Its project file would look similar to the following:

XML

```
<Project Sdk="Microsoft.NET.Sdk">

  <PropertyGroup>
    <OutputType>Exe</OutputType>
    <TargetFramework>net7.0</TargetFramework>
    <ImplicitUsings>enable</ImplicitUsings>
    <Nullable>enable</Nullable>
  </PropertyGroup>

  <ItemGroup>
    <PackageReference Include="Microsoft.Extensions.Hosting" Version="7.0.1" />
    <PackageReference Include="Microsoft.Extensions.Logging" Version="7.0.0" />
  </ItemGroup>
```

```
</Project>
```

No asynchronous logger methods

Logging should be so fast that it isn't worth the performance cost of asynchronous code. If a logging datastore is slow, don't write to it directly. Consider writing the log messages to a fast store initially, then moving them to the slow store later. For example, when logging to SQL Server, don't do so directly in a `Log` method, since the `Log` methods are synchronous. Instead, synchronously add log messages to an in-memory queue and have a background worker pull the messages out of the queue to do the asynchronous work of pushing data to SQL Server.

Change log levels in a running app

The Logging API doesn't include a scenario to change log levels while an app is running. However, some configuration providers are capable of reloading configuration, which takes immediate effect on logging configuration. For example, the [File Configuration Provider](#) reloads logging configuration by default. If the configuration is changed in code while an app is running, the app can call [IConfigurationRoot.Reload](#) to update the app's logging configuration.

NuGet packages

The [ILogger<TCategoryName>](#) and [ILoggerFactory](#) interfaces and implementations are included in the .NET SDK. They are also available in the following NuGet packages:

- The interfaces are in [Microsoft.Extensions.Logging.Abstractions](#).
- The default implementations are in [Microsoft.Extensions.Logging](#).

Logging providers in .NET

Article • 06/23/2023

Logging providers persist logs, except for the `Console` provider, which only displays logs as standard output. For example, the Azure Application Insights provider stores logs in Azure Application Insights. Multiple providers can be enabled.

The default .NET Worker app templates:

- Use the [Generic Host](#).
- Call [CreateApplicationBuilder](#), which adds the following logging providers:
 - [Console](#)
 - [Debug](#)
 - [EventSource](#)
 - [EventLog](#) (Windows only)

C#

```
using Microsoft.Extensions.Hosting;

using IHost host = Host.CreateApplicationBuilder(args).Build();

// Application code should start here.

await host.RunAsync();
```

The preceding code shows the `Program` class created with the .NET Worker app templates. The next several sections provide samples based on the .NET Worker app templates, which use the Generic Host.

To override the default set of logging providers added by

`Host.CreateApplicationBuilder`, call `ClearProviders` and add the logging providers you want. For example, the following code:

- Calls [ClearProviders](#) to remove all the `ILoggerProvider` instances from the builder.
- Adds the [Console](#) logging provider.

C#

```
HostApplicationBuilder builder = Host.CreateApplicationBuilder(args);

builder.Logging.ClearProviders();
builder.Logging.AddConsole();
```

For additional providers, see:

- [Built-in logging providers](#).
- [Third-party logging providers](#).

Configure a service that depends on `ILogger`

To configure a service that depends on `ILogger<T>`, use constructor injection or provide a factory method. The factory method approach is recommended only if there's no other option. For example, consider a service that needs an `ILogger<T>` instance provided by DI:

C#

```
HostApplicationBuilder builder = Host.CreateApplicationBuilder(args);

builder.Services.AddSingleton<IExampleService>(
    container => new DefaultExampleService
    {
        Logger = container.GetRequiredService<ILogger<IExampleService>>()
    });

```

The preceding code is a `Func<IServiceProvider, IExampleService>` that runs the first time the DI container needs to construct an instance of `IExampleService`. You can access any of the registered services in this way.

Built-in logging providers

Microsoft Extensions include the following logging providers as part of the runtime libraries:

- [Console](#)
- [Debug](#)
- [EventSource](#)
- [EventLog](#)

The following logging providers are shipped by Microsoft, but not as part of the runtime libraries. They must be installed as additional NuGet packages.

- [AzureAppServicesFile](#) and [AzureAppServicesBlob](#)
- [ApplicationInsights](#)

Console

The `Console` provider logs output to the console.

Debug

The `Debug` provider writes log output by using the `System.Diagnostics.Debug` class, specifically through the `Debug.WriteLine` method and only when the debugger is attached. The `DebugLoggerProvider` creates `DebugLogger` instances, which are implementations of the `ILogger` interface.

Event Source

The `EventSource` provider writes to a cross-platform event source with the name `Microsoft.Extensions.Logging`. On Windows, the provider uses `ETW`.

dotnet trace tooling

The `dotnet-trace` tool is a cross-platform CLI global tool that enables the collection of .NET Core traces of a running process. The tool collects `Microsoft.Extensions.Logging.EventSource` provider data using a `LoggingEventSource`.

See `dotnet-trace` for installation instructions. For a diagnostic tutorial using `dotnet-trace`, see [Debug high CPU usage in .NET Core](#).

Windows EventLog

The `EventLog` provider sends log output to the Windows Event Log. Unlike the other providers, the `EventLog` provider does **not** inherit the default non-provider settings. If `EventLog` log settings aren't specified, they default to `LogLevel.Warning`.

To log events lower than `LogLevel.Warning`, explicitly set the log level. The following example sets the Event Log default log level to `LogLevel.Information`:

JSON

```
"Logging": {  
    "EventLog": {  
        "LogLevel": {  
            "Default": "Information"  
        }  
    }  
}
```

`AddEventLog` overloads can pass in `EventLogSettings`. If `null` or not specified, the following default settings are used:

- `LogName`: "Application"
- `SourceName`: ".NET Runtime"
- `MachineName`: The local machine name is used.

The following code changes the `SourceName` from the default value of ".NET Runtime" to `CustomLogs`:

C#

```
HostApplicationBuilder builder = Host.CreateApplicationBuilder(args);

builder.Logging.AddEventLog(
    config => config.SourceName = "CustomLogs");

using IHost host = builder.Build();

host.Run();
```

Azure App Service

The [Microsoft.Extensions.Logging.AzureAppServices](#) provider package writes logs to text files in an Azure App Service app's file system and to [blob storage](#) in an Azure Storage account.

The provider package isn't included in the runtime libraries. To use the provider, add the provider package to the project.

To configure provider settings, use [AzureFileLoggerOptions](#) and [AzureBlobLoggerOptions](#), as shown in the following example:

C#

```
using Microsoft.Extensions.Logging.AzureAppServices;

HostApplicationBuilder builder = Host.CreateApplicationBuilder(args)

builder.Logging.AddAzureWebAppDiagnostics();
builder.Services.Configure<AzureFileLoggerOptions>(options =>
{
    options.FileName = "azure-diagnostics-";
    options.FileSizeLimit = 50 * 1024;
    options.RetainedFileCountLimit = 5;
});
builder.ServicesConfigure<AzureBlobLoggerOptions>(options =>
```

```
{  
    options.BlobName = "log.txt";  
});  
  
using IHost host = builder.Build();  
  
// Application code should start here.  
  
await host.RunAsync();
```

When deployed to Azure App Service, the app uses the settings in the [App Service logs](#) section of the [App Service](#) page of the Azure portal. When the following settings are updated, the changes take effect immediately without requiring a restart or redeployment of the app.

The default location for log files is in the *D:\home\LogFiles\Application* folder. Additional defaults vary by provider:

- **Application Logging (Filesystem):** The default filesystem file name is *diagnostics-yyyymmdd.txt*. The default file size limit is 10 MB, and the default maximum number of files retained is 2.
- **Application Logging (Blob):** The default blob name is *{app-name}/yyyy/mm/dd/hh/{guid}_applicationLog.txt*.

This provider only logs when the project runs in the Azure environment.

Azure log streaming

Azure log streaming supports viewing log activity in real-time from:

- The app server
- The web server
- Failed request tracing

To configure Azure log streaming:

- Navigate to the [App Service logs](#) page from the app's portal page.
- Set **Application Logging (Filesystem)** to **On**.
- Choose the log **Level**. This setting only applies to Azure log streaming.

Navigate to the [Log Stream](#) page to view logs. The logged messages are logged with the [ILogger](#) interface.

Azure Application Insights

The [Microsoft.Extensions.Logging.ApplicationInsights](#) provider package writes logs to [Azure Application Insights](#). Application Insights is a service that monitors a web app and provides tools for querying and analyzing the telemetry data. If you use this provider, you can query and analyze your logs by using the Application Insights tools.

For more information, see the following resources:

- [Application Insights overview](#)
- [ApplicationInsightsLoggerProvider for .NET Core ILogger logs](#) - Start here if you want to implement the logging provider without the rest of Application Insights telemetry.
- [Application Insights logging adapters](#).
- [Install, configure, and initialize the Application Insights SDK](#) - Interactive tutorial on the Microsoft Learn site.

Logging provider design considerations

If you plan to develop your own implementation of the [ILoggerProvider](#) interface and corresponding custom implementation of [ILogger](#), consider the following points:

- The [ILogger.Log](#) method is synchronous.
- The lifetime of log state and objects should *not* be assumed.

An implementation of [ILoggerProvider](#) will create an [ILogger](#) via its [ILoggerProvider.CreateLogger](#) method. If your implementation strives to queue logging messages in a non-blocking manner, the messages should first be materialized or the object state that's used to materialize a log entry should be serialized. Doing so avoids potential exceptions from disposed objects.

For more information, see [Implement a custom logging provider in .NET](#).

Third-party logging providers

Here are some third-party logging frameworks that work with various .NET workloads:

- [elmah.io](#) ([GitHub repo](#))
- [Gelf](#) ([GitHub repo](#))
- [JSNLog](#) ([GitHub repo](#))
- [KissLog.net](#) ([GitHub repo](#))
- [Log4Net](#) ([GitHub repo](#))
- [NLog](#) ([GitHub repo](#))
- [NReco.Logging](#) ([GitHub repo](#))

- [Sentry](#) ([GitHub repo](#))
- [Serilog](#) ([GitHub repo](#))
- [Stackdriver](#) ([GitHub repo](#))

Some third-party frameworks can perform [semantic logging, also known as structured logging](#).

Using a third-party framework is similar to using one of the built-in providers:

1. Add a NuGet package to your project.
2. Call an `ILoggerFactory` or `ILoggingBuilder` extension method provided by the logging framework.

For more information, see each provider's documentation. Third-party logging providers aren't supported by Microsoft.

Compile-time logging source generation

Article • 10/11/2023

.NET 6 introduces the `LoggerMessageAttribute` type. This attribute is part of the `Microsoft.Extensions.Logging` namespace, and when used, it source-generates performant logging APIs. The source-generation logging support is designed to deliver a highly usable and highly performant logging solution for modern .NET applications. The auto-generated source code relies on the `ILogger` interface in conjunction with `LoggerMessage.Define` functionality.

The source generator is triggered when `LoggerMessageAttribute` is used on `partial` logging methods. When triggered, it is either able to autogenerate the implementation of the `partial` methods it's decorating, or produce compile-time diagnostics with hints about proper usage. The compile-time logging solution is typically considerably faster at run time than existing logging approaches. It achieves this by eliminating boxing, temporary allocations, and copies to the maximum extent possible.

Basic usage

To use the `LoggerMessageAttribute`, the consuming class and method need to be `partial`. The code generator is triggered at compile time, and generates an implementation of the `partial` method.

C#

```
public static partial class Log
{
    [LoggerMessage(
        EventId = 0,
        Level = LogLevel.Critical,
        Message = "Could not open socket to `{HostName}`")]
    public static partial void CouldNotOpenSocket(
        ILogger logger, string hostName);
}
```

In the preceding example, the logging method is `static` and the log level is specified in the attribute definition. When using the attribute in a static context, either the `ILogger` instance is required as a parameter, or modify the definition to use the `this` keyword to define the method as an extension method.

C#

```
public static partial class Log
{
    [LoggerMessage(
        EventId = 0,
        Level = LogLevel.Critical,
        Message = "Could not open socket to `{HostName}`")]
    public static partial void CouldNotOpenSocket(
        this ILogger logger, string hostName);
}
```

You may choose to use the attribute in a non-static context as well. Consider the following example where the logging method is declared as an instance method. In this context, the logging method gets the logger by accessing an `ILogger` field in the containing class.

C#

```
public partial class InstanceLoggingExample
{
    private readonly ILogger _logger;

    public InstanceLoggingExample(ILogger logger)
    {
        _logger = logger;
    }

    [LoggerMessage(
        EventId = 0,
        Level = LogLevel.Critical,
        Message = "Could not open socket to `{HostName}`")]
    public partial void CouldNotOpenSocket(string hostName);
}
```

Sometimes, the log level needs to be dynamic rather than statically built into the code. You can do this by omitting the log level from the attribute and instead requiring it as a parameter to the logging method.

C#

```
public static partial class Log
{
    [LoggerMessage(
        EventId = 0,
        Message = "Could not open socket to `{HostName}`")]
    public static partial void CouldNotOpenSocket(
        ILogger logger,
        LogLevel level, /* Dynamic log level as parameter, rather than
```

```
defined in attribute. */
        string hostName);
}
```

You can omit the logging message and `String.Empty` will be provided for the message. The state will contain the arguments, formatted as key-value pairs.

C#

```
using System.Text.Json;
using Microsoft.Extensions.Logging;

using ILoggerFactory loggerFactory = LoggerFactory.Create(
    builder =>
    builder.AddJsonConsole(
        options =>
        options.JsonWriterOptions = new JsonWriterOptions()
        {
            Indented = true
        }));
    });

ILogger<SampleObject> logger = loggerFactory.CreateLogger<SampleObject>();
logger.PlaceOfResidence(logLevel: LogLevel.Information, name: "Liana", city:
    "Seattle");

readonly file record struct SampleObject { }

public static partial class Log
{
    [LoggerMessage(EventId = 23, Message = "{Name} lives in {City}.")]
    public static partial void PlaceOfResidence(
        this ILogger logger,
        LogLevel logLevel,
        string name,
        string city);
}
```

Consider the example logging output when using the `JsonConsole` formatter.

JSON

```
{
    "EventId": 23,
    "LogLevel": "Information",
    "Category": "\u003CProgram\u003EF...9CB42__SampleObject",
    "Message": "Liana lives in Seattle.",
    "State": {
        "Message": "Liana lives in Seattle.",
        "name": "Liana",
        "city": "Seattle",
        "{OriginalFormat)": "{Name} lives in {City}."}
```

```
}
```

Log method constraints

When using the `LoggerMessageAttribute` on logging methods, some constraints must be followed:

- Logging methods must be `partial` and return `void`.
- Logging method names must *not* start with an underscore.
- Parameter names of logging methods must *not* start with an underscore.
- Logging methods may *not* be defined in a nested type.
- Logging methods *cannot* be generic.
- If a logging method is `static`, the `ILogger` instance is required as a parameter.

The code-generation model depends on code being compiled with a modern C# compiler, version 9 or later. The C# 9.0 compiler became available with .NET 5. To upgrade to a modern C# compiler, edit your project file to target C# 9.0.

XML

```
<PropertyGroup>
  <LangVersion>9.0</LangVersion>
</PropertyGroup>
```

For more information, see [C# language versioning](#).

Log method anatomy

The `ILogger.Log` signature accepts the `LogLevel` and optionally an `Exception`, as shown below.

C#

```
public interface ILogger
{
    void Log<TState>(
        Microsoft.Extensions.Logging.LogLevel logLevel,
        Microsoft.Extensions.Logging.EventId eventId,
        TState state,
        System.Exception? exception,
        Func<TState, System.Exception?, string> formatter);
}
```

As a general rule, the first instance of `ILogger`, `LogLevel`, and `Exception` are treated specially in the log method signature of the source generator. Subsequent instances are treated like normal parameters to the message template:

C#

```
// This is a valid attribute usage
[LoggerMessage(
    EventId = 110, Level = LogLevel.Debug, Message = "M1 {Ex3} {Ex2}")]
public static partial void ValidLogMethod(
    ILogger logger,
    Exception ex,
    Exception ex2,
    Exception ex3);

// This causes a warning
[LoggerMessage(
    EventId = 0, Level = LogLevel.Debug, Message = "M1 {Ex} {Ex2}")]
public static partial void WarningLogMethod(
    ILogger logger,
    Exception ex,
    Exception ex2);
```

ⓘ Important

The warnings emitted provide details as to the correct usage of the `LoggerMessageAttribute`. In the preceding example, the `WarningLogMethod` will report a `DiagnosticSeverity.Warning` of `SYSLIB0025`.

Console

Don't include a template for `ex` in the logging message since it is implicitly taken care of.

Case-insensitive template name support

The generator does a case-insensitive comparison between items in the message template and argument names in the log message. This means that when the `ILogger` enumerates the state, the argument is picked up by the message template, which can make the logs nicer to consume:

C#

```
public partial class LoggingExample
{
```

```

private readonly ILogger _logger;

public LoggingExample(ILogger logger)
{
    _logger = logger;
}

[LoggerMessage(
    EventId = 10,
    Level = LogLevel.Information,
    Message = "Welcome to {City} {Province}!")]
public partial void LogMethodSupportsPascalCasingOfNames(
    string city, string province);

public void TestLogging()
{
    LogMethodSupportsPascalCasingOfNames("Vancouver", "BC");
}
}

```

Consider the example logging output when using the `JsonConsole` formatter:

JSON

```
{
    "EventId": 13,
    "LogLevel": "Information",
    "Category": "LoggingExample",
    "Message": "Welcome to Vancouver BC!",
    "State": {
        "Message": "Welcome to Vancouver BC!",
        "City": "Vancouver",
        "Province": "BC",
        "{OriginalFormat)": "Welcome to {City} {Province}!"
    }
}
```

Indeterminate parameter order

There are no constraints on the ordering of log method parameters. A developer could define the `ILogger` as the last parameter, although it may appear a bit awkward.

C#

```

[LoggerMessage(
    EventId = 110,
    Level = LogLevel.Debug,
    Message = "M1 {Ex3} {Ex2}")]
static partial void LogMethod(
    Exception ex,

```

```
Exception ex2,  
Exception ex3,  
ILogger logger);
```

💡 Tip

The order of the parameters on a log method is *not* required to correspond to the order of the template placeholders. Instead, the placeholder names in the template are expected to match the parameters. Consider the following `JsonConsole` output and the order of the errors.

JSON

```
{  
    "EventId": 110,  
    "LogLevel": "Debug",  
    "Category": "ConsoleApp.Program",  
    "Message": "M1 System.Exception: Third time's the charm.  
System.Exception: This is the second error.",  
    "State": {  
        "Message": "M1 System.Exception: Third time's the charm.  
System.Exception: This is the second error.",  
        "ex2": "System.Exception: This is the second error.",  
        "ex3": "System.Exception: Third time's the charm.",  
        "{OriginalFormat)": "M1 {Ex3} {Ex2}"  
    }  
}
```

Additional logging examples

The following samples demonstrate how to retrieve the event name, set the log level dynamically, and format logging parameters. The logging methods are:

- `LogWithCustomEventName`: Retrieve event name via `LoggerMessage` attribute.
- `LogWithDynamicLogLevel`: Set log level dynamically, to allow log level to be set based on configuration input.
- `UsingFormatSpecifier`: Use format specifiers to format logging parameters.

C#

```
public partial class LoggingSample  
{  
    private readonly ILogger _logger;  
  
    public LoggingSample(ILogger logger)
```

```

    {
        _logger = logger;
    }

    [LoggerMessage(
        EventId = 20,
        Level = LogLevel.Critical,
        Message = "Value is {Value:E}")]
    public static partial void UsingFormatSpecifier(
        ILogger logger, double value);

    [LoggerMessage(
        EventId = 9,
        Level = LogLevel.Trace,
        Message = "Fixed message",
        EventName = "CustomEventName")]
    public partial void LogWithCustomEventName();

    [LoggerMessage(
        EventId = 10,
        Message = "Welcome to {City} {Province}!")]
    public partial void LogWithDynamicLogLevel(
        string city, LogLevel level, string province);

    public void TestLogging()
    {
        LogWithCustomEventName();

        LogWithDynamicLogLevel("Vancouver", LogLevel.Warning, "BC");
        LogWithDynamicLogLevel("Vancouver", LogLevel.Information, "BC");

        UsingFormatSpecifier(logger, 12345.6789);
    }
}

```

Consider the example logging output when using the `SimpleConsole` formatter:

Console

```

trce: LoggingExample[9]
    Fixed message
warn: LoggingExample[10]
    Welcome to Vancouver BC!
info: LoggingExample[10]
    Welcome to Vancouver BC!
crit: LoggingExample[20]
    Value is 1.234568E+004

```

Consider the example logging output when using the `JsonConsole` formatter:

JSON

```
{
    "EventId": 9,
    "LogLevel": "Trace",
    "Category": "LoggingExample",
    "Message": "Fixed message",
    "State": {
        "Message": "Fixed message",
        "{OriginalFormat}": "Fixed message"
    }
}
{
    "EventId": 10,
    "LogLevel": "Warning",
    "Category": "LoggingExample",
    "Message": "Welcome to Vancouver BC!",
    "State": {
        "Message": "Welcome to Vancouver BC!",
        "city": "Vancouver",
        "province": "BC",
        "{OriginalFormat}": "Welcome to {City} {Province}!"
    }
}
{
    "EventId": 10,
    "LogLevel": "Information",
    "Category": "LoggingExample",
    "Message": "Welcome to Vancouver BC!",
    "State": {
        "Message": "Welcome to Vancouver BC!",
        "city": "Vancouver",
        "province": "BC",
        "{OriginalFormat}": "Welcome to {City} {Province}!"
    }
}
{
    "EventId": 20,
    "LogLevel": "Critical",
    "Category": "LoggingExample",
    "Message": "Value is 1.234568E+004",
    "State": {
        "Message": "Value is 1.234568E+004",
        "value": 12345.6789,
        "{OriginalFormat}": "Value is {Value:E}"
    }
}
}
```

Summary

With the advent of C# source generators, writing highly performant logging APIs is much easier. Using the source generator approach has several key benefits:

- Allows the logging structure to be preserved and enables the exact format syntax required by [Message Templates](#).
- Allows supplying alternative names for the template placeholders and using format specifiers.
- Allows the passing of all original data as-is, without any complication around how it's stored before something is done with it (other than creating a `string`).
- Provides logging-specific diagnostics, and emits warnings for duplicate event IDs.

Additionally, there are benefits over manually using `LoggerMessage.Define`:

- Shorter and simpler syntax: Declarative attribute usage rather than coding boilerplate.
- Guided developer experience: The generator gives warnings to help developers do the right thing.
- Support for an arbitrary number of logging parameters. `LoggerMessage.Define` supports a maximum of six.
- Support for dynamic log level. This is not possible with `LoggerMessage.Define` alone.

Logging guidance for .NET library authors

Article • 10/11/2023

As a library author, exposing logging is a great way to provide consumers with insight into the inner workings of your library. This guidance helps you expose logging in a way that is consistent with other .NET libraries and frameworks. It also helps you avoid common performance bottlenecks that may not be otherwise obvious.

When to use the `ILoggerFactory` interface

When writing a library that emits logs, you need an `ILogger` object to record the logs. To get that object, your API can either accept an `ILogger<TCategoriesName>` parameter, or it can accept an `ILoggerFactory` after which you call `ILoggerFactory.CreateLogger`. Which approach should be preferred?

- When you need a logging object that can be passed along to multiple classes so that all of them can emit logs, use `ILoggerFactory`. It's recommended that each class creates logs with a separate category, named the same as the class. To do this, you need the factory to create unique `ILogger<TCategoriesName>` objects for each class that emits logs. Common examples include public entry point APIs for a library or public constructors of types that might create helper classes internally.
- When you need a logging object that's only used inside one class and never shared, use `ILogger<TCategoriesName>`, where `TCategoriesName` is the type that produces the logs. A common example of this is a constructor for a class created by dependency injection.

If you're designing a public API that must remain stable over time, keep in mind that you might desire to refactor your internal implementation in the future. Even if a class doesn't create any internal helper types initially, that might change as the code evolves. Using `ILoggerFactory` accommodates creating new `ILogger<TCategoriesName>` objects for any new classes without changing the public API.

For more information, see [How filtering rules are applied](#).

Prefer source-generated logging

The `ILogger` API supports two approaches to using the API. You can either call methods such as `LoggerExtensions.LogError` and `LoggerExtensions.LogInformation`, or you can use the logging source generator to define strongly typed logging methods. For most situations, the source generator is recommended because it offers superior performance and stronger typing. It also isolates logging-specific concerns such as message templates, IDs, and log levels from the calling code. The non-source-generated approach is primarily useful for scenarios where you are willing to give up those advantages to make the code more concise.

C#

```
using Microsoft.Extensions.Logging;

namespace Logging.LibraryAuthors;

internal static partial class LogMessages
{
    [LoggerMessage(
        Message = "Sold {Quantity} of {Description}",
        Level = LogLevel.Information)]
    internal static partial void LogProductSaleDetails(
        this ILogger logger,
        int quantity,
        string description);
}
```

The preceding code:

- Defines a `partial class` named `LogMessages`, which is `static` so that it can be used to define extension methods on the `ILogger` type.
- Decorates a `LogProductSaleDetails` extension method with the `LoggerMessage` attribute and `Message` template.
- Declares `LogProductSaleDetails`, which extends the `ILogger` and accepts a `quantity` and `description`.

💡 Tip

You can step into the source-generated code during debugging, because it's part of the same assembly as the code that calls it.

Use `.IsEnabled` to avoid expensive parameter evaluation

There may be situations where evaluating parameters is expensive. Expanding upon the previous example, imagine the `description` parameter is a `string` that is expensive to compute. Perhaps the product being sold gets a friendly product description and relies on a database query, or reading from a file. In these situations, you can instruct the source generator to skip the `.IsEnabled` guard and manually add the `.IsEnabled` guard at the call site. This allows the user to determine where the guard is called and ensures that parameters that might be expensive to compute are only evaluated when truly needed. Consider the following code:

```
C#  
  
using Microsoft.Extensions.Logging;  
  
namespace Logging.LibraryAuthors;  
  
internal static partial class LogMessages  
{  
    [LoggerMessage(  
        Message = "Sold {Quantity} of {Description}",  
        Level = LogLevel.Information,  
        SkipEnabledCheck = true)]  
    internal static partial void LogProductSaleDetails(  
        this ILogger logger,  
        int quantity,  
        string description);  
}
```

When the `LogProductSaleDetails` extension method is called, the `.IsEnabled` guard is manually invoked and the expensive parameter evaluation is limited to when it's needed. Consider the following code:

```
C#  
  
if (_logger.IsEnabled(LogLevel.Information))  
{  
    // Expensive parameter evaluation  
    var description = product.GetFriendlyProductDescription();  
  
    _logger.LogProductSaleDetails(  
        quantity,  
        description);  
}
```

For more information, see [Compile-time logging source generation](#) and [High-performance logging in .NET](#).

Avoid string interpolation in logging

A common mistake is to use [string interpolation](#) to build log messages. String interpolation in logging is problematic for performance, as the string is evaluated even if the corresponding `LogLevel` isn't enabled. Instead of string interpolation, use the log message template, formatting, and argument list. For more information, see [Logging in .NET: Log message template](#).

Use no-op logging defaults

Libraries can default to *null logging* if no `ILoggerFactory` is provided. The use of *null logging* differs from defining types as nullable (`ILoggerFactory?`), as the types are non-null. These convenience-based types don't log anything and are essentially no-ops. Consider using any of the available abstraction types where applicable:

- [NullLogger.Instance](#)
- [NullLoggerFactory.Instance](#)
- [NullLoggerProvider.Instance](#)

Implement a custom logging provider in .NET

Article • 03/18/2023

There are many [logging providers](#) available for common logging needs. You may need to implement a custom [ILoggerProvider](#) when one of the available providers doesn't suit your application needs. In this article, you'll learn how to implement a custom logging provider that can be used to colorize logs in the console.

💡 Tip

The custom logging provider example source code is available in the [Docs Github repo](#). For more information, see [GitHub: .NET Docs - Console Custom Logging](#).

Sample custom logger configuration

The sample creates different color console entries per log level and event ID using the following configuration type:

C#

```
using Microsoft.Extensions.Logging;

public sealed class ColorConsoleLoggerConfiguration
{
    public int EventId { get; set; }

    public Dictionary<LogLevel, ConsoleColor> LogLevelToColorMap { get; set; }
} = new()
{
    [LogLevel.Information] = ConsoleColor.Green
};
```

The preceding code sets the default level to `Information`, the color to `Green`, and the `EventId` is implicitly `0`.

Create the custom logger

The `ILogger` implementation category name is typically the logging source. For example, the type where the logger is created:

C#

```
using Microsoft.Extensions.Logging;

public sealed class ColorConsoleLogger : ILogger
{
    private readonly string _name;
    private readonly Func<ColorConsoleLoggerConfiguration>
    _getCurrentConfig;

    public ColorConsoleLogger(
        string name,
        Func<ColorConsoleLoggerConfiguration> getCurrentConfig) =>
        (_name, _getCurrentConfig) = (name, getCurrentConfig);

    public IDisposable? BeginScope<TState>(TState state) where TState : notnull => default!;

    public bool IsEnabled(LogLevel logLevel) =>
        _getCurrentConfig().LogLevelToColorMap.ContainsKey(logLevel);

    public void Log<TState>(
        LogLevel logLevel,
        EventId eventId,
        TState state,
        Exception? exception,
        Func<TState, Exception?, string> formatter)
    {
        if (!IsEnabled(logLevel))
        {
            return;
        }

        ColorConsoleLoggerConfiguration config = _getCurrentConfig();
        if (config.EventId == 0 || config.EventId == eventId.Id)
        {
            ConsoleColor originalColor = Console.ForegroundColor;

            Console.ForegroundColor = config.LogLevelToColorMap[logLevel];
            Console.WriteLine($"[{eventId.Id,2}: {logLevel,-12}]");

            Console.ForegroundColor = originalColor;
            Console.Write($"{_name} - ");
        }

        Console.ForegroundColor = config.LogLevelToColorMap[logLevel];
        Console.Write($"{formatter(state, exception)}");

        Console.ForegroundColor = originalColor;
        Console.WriteLine();
    }
}
```

The preceding code:

- Creates a logger instance per category name.
- Checks `_getCurrentConfig().LogLevelToColorMap.ContainsKey(logLevel)` in `IsEnabled`, so each `logLevel` has a unique logger. In this implementation, each log level requires an explicit configuration entry to log.

It's a good practice to call `ILogger.IsEnabled` within `ILogger.Log` implementations since `Log` can be called by any consumer, and there are no guarantees that it was previously checked. The `IsEnabled` method should be very fast in most implementations.

C#

```
public bool IsEnabled(LogLevel logLevel) =>
    _getCurrentConfig().LogLevelToColorMap.ContainsKey(logLevel);
```

The logger is instantiated with the `name` and a `Func<ColorConsoleLoggerConfiguration>`, which returns the current config — this handles updates to the config values as monitored through the `IOptionsMonitor<TOptions>.OnChange` callback.

ⓘ Important

The `ILogger.Log` implementation checks if the `config.EventId` value is set. When `config.EventId` is not set or when it matches the exact `logEntry.EventId`, the logger logs in color.

Custom logger provider

The `ILoggerProvider` object is responsible for creating logger instances. It's not necessary to create a logger instance per category, but it makes sense for some loggers, like NLog or log4net. This strategy allows you to choose different logging output targets per category, as in the following example:

C#

```
using System.Collections.Concurrent;
using System.Runtime.Versioning;
using Microsoft.Extensions.Logging;
using Microsoft.Extensions.Options;

[UnsupportedOSPlatform("browser")]
[ProviderAlias("ColorConsole")]
public sealed class ColorConsoleLoggerProvider : ILoggerProvider
```

```

{
    private readonly IDisposable? _onChangeToken;
    private ColorConsoleLoggerConfiguration _currentConfig;
    private readonly ConcurrentDictionary<string, ColorConsoleLogger>
    _loggers =
        new(StringComparer.OrdinalIgnoreCase);

    public ColorConsoleLoggerProvider(
        IOptionsMonitor<ColorConsoleLoggerConfiguration> config)
    {
        _currentConfig = config.CurrentValue;
        _onChangeToken = config.OnChange(updatedConfig => _currentConfig =
updatedConfig);
    }

    public ILogger CreateLogger(string categoryName) =>
        _loggers.GetOrAdd(categoryName, name => new ColorConsoleLogger(name,
GetCurrentConfig()));

    private ColorConsoleLoggerConfiguration GetCurrentConfig() =>
        _currentConfig;

    public void Dispose()
    {
        _loggers.Clear();
        _onChangeToken?.Dispose();
    }
}

```

In the preceding code, `CreateLogger` creates a single instance of the `ColorConsoleLogger` per category name and stores it in the `ConcurrentDictionary< TKey, TValue >`. Additionally, the `IOptionsMonitor< TOptions >` interface is required to update changes to the underlying `ColorConsoleLoggerConfiguration` object.

To control the configuration of the `ColorConsoleLogger`, you define an alias on its provider:

C#

```

[UnsupportedOSPlatform("browser")]
[ProviderAlias("ColorConsole")]
public sealed class ColorConsoleLoggerProvider : ILoggerProvider

```

The `ColorConsoleLoggerProvider` class defines two class-scoped attributes:

- **UnsupportedOSPlatformAttribute**: The `ColorConsoleLogger` type is *not supported* in the "browser".

- **ProviderAliasAttribute**: Configuration sections can define options using the `"ColorConsole"` key.

The configuration can be specified with any valid [configuration provider](#). Consider the following `appsettings.json` file:

JSON

```
{  
  "Logging": {  
    "ColorConsole": {  
      "LogLevelToColorMap": {  
        "Information": "DarkGreen",  
        "Warning": "Cyan",  
        "Error": "Red"  
      }  
    }  
  }  
}
```

This configures the log levels to the following values:

- `LogLevel.Information`: `ConsoleColor.DarkGreen`
- `LogLevel.Warning`: `ConsoleColor.Cyan`
- `LogLevel.Error`: `ConsoleColor.Red`

The `Information` log level is set to `DarkGreen`, which overrides the default value set in the `ColorConsoleLoggerConfiguration` object.

Usage and registration of the custom logger

By convention, registering services for dependency injection happens as part of the startup routine of an application. The registration occurs in the `Program` class, or could be delegated to a `Startup` class. In this example, you'll register directly from the `Program.cs`.

To add the custom logging provider and corresponding logger, add an [`ILoggerProvider`](#) with [`ILoggingBuilder`](#) from the `HostingHostBuilderExtensions.ConfigureLogging(IHostBuilder, Action<ILoggingBuilder>)`:

C#

```
using Microsoft.Extensions.DependencyInjection;  
using Microsoft.Extensions.Hosting;  
using Microsoft.Extensions.Logging;
```

```

HostApplicationBuilder builder = Host.CreateApplicationBuilder(args);

builder.Logging.ClearProviders();
builder.Logging.AddColorConsoleLogger(configuration =>
{
    // Replace warning value from appsettings.json of "Cyan"
    configuration.LogLevelToColorMap[LogLevel.Warning] =
    ConsoleColor.DarkCyan;
    // Replace warning value from appsettings.json of "Red"
    configuration.LogLevelToColorMap[LogLevel.Error] = ConsoleColor.DarkRed;
});

using IHost host = builder.Build();

var logger = host.Services.GetRequiredService<ILogger<Program>>();

logger.LogDebug(1, "Does this line get hit?");      // Not logged
logger.LogInformation(3, "Nothing to see here."); // Logs in
ConsoleColor.DarkGreen
logger.LogWarning(5, "Warning... that was odd."); // Logs in
ConsoleColor.DarkCyan
logger.LogError(7, "Oops, there was an error."); // Logs in
ConsoleColor.DarkRed
logger.LogTrace(5, "== 120.");                      // Not logged

await host.RunAsync();

```

The `ILoggingBuilder` creates one or more `ILogger` instances. The `ILogger` instances are used by the framework to log the information.

The configuration from the `appsettings.json` file overrides the following values:

- `LogLevel.Warning`: `ConsoleColor.DarkCyan`
- `LogLevel.Error`: `ConsoleColor.DarkRed`

By convention, extension methods on `ILoggingBuilder` are used to register the custom provider:

C#

```

using Microsoft.Extensions.DependencyInjection;
using Microsoft.Extensions.DependencyInjection.Extensions;
using Microsoft.Extensions.Logging;
using Microsoft.Extensions.Logging.Configuration;

public static class ColorConsoleLoggerExtensions
{
    public static ILoggingBuilder AddColorConsoleLogger(
        this ILoggingBuilder builder)
    {

```

```

        builder.AddConfiguration();

        builder.Services.TryAddEnumerable(
            ServiceDescriptor.Singleton<ILoggerProvider,
ColorConsoleLoggerProvider>());

        LoggerProviderOptions.RegisterProviderOptions
            <ColorConsoleLoggerConfiguration, ColorConsoleLoggerProvider>
(builder.Services);

        return builder;
    }

    public static ILoggingBuilder AddColorConsoleLogger(
        this ILoggingBuilder builder,
        Action<ColorConsoleLoggerConfiguration> configure)
    {
        builder.AddColorConsoleLogger();
        builder.Services.Configure(configure);

        return builder;
    }
}

```

Running this simple application will render color output to the console window similar to the following image:

High-performance logging in .NET

Article • 03/14/2023

The [LoggerMessage](#) class exposes functionality to create cacheable delegates that require fewer object allocations and reduced computational overhead compared to [logger extension methods](#), such as [LogInformation](#) and [LogDebug](#). For high-performance logging scenarios, use the [LoggerMessage](#) pattern.

[LoggerMessage](#) provides the following performance advantages over Logger extension methods:

- Logger extension methods require "boxing" (converting) value types, such as `int`, into `object`. The [LoggerMessage](#) pattern avoids boxing by using static `Action` fields and extension methods with strongly typed parameters.
- Logger extension methods must parse the message template (named format string) every time a log message is written. [LoggerMessage](#) only requires parsing a template once when the message is defined.

ⓘ Important

Instead of using the [LoggerMessage class](#) to create high-performance logs, you can use the [LoggerMessage attribute](#) in .NET 6.0. The `LoggerMessageAttribute` provides source-generation logging support designed to deliver a highly usable and highly performant logging solution for modern .NET applications. For more information, see [Compile-time logging source generation \(.NET Fundamentals\)](#).

The sample app demonstrates [LoggerMessage](#) features with a priority queue processing worker service. The app processes work items in priority order. As these operations occur, log messages are generated using the [LoggerMessage](#) pattern.

ⓘ Tip

All of the logging example source code is available in the [Samples Browser](#) for download. For more information, see [Browse code samples: Logging in .NET](#).

Define a logger message

Use [Define\(LogLevel, EventId, String\)](#) to create an `Action` delegate for logging a message. [Define](#) overloads permit passing up to six type parameters to a named format

string (template).

The string provided to the [Define](#) method is a template and not an interpolated string. Placeholders are filled in the order that the types are specified. Placeholder names in the template should be descriptive and consistent across templates. They serve as property names within structured log data. We recommend [Pascal casing](#) for placeholder names. For example, `{Item}`, `{DateTime}`.

Each log message is an [Action](#) held in a static field created by [LoggerMessage.Define](#). For example, the sample app creates a field to describe a log message for the processing of work items:

```
C#
```

```
private static readonly Action<ILogger, Exception>
s_failedToProcessWorkItem;
```

For the [Action](#), specify:

- The log level.
- A unique event identifier ([EventId](#)) with the name of the static extension method.
- The message template (named format string).

As work items are dequeued for processing, the worker service app sets the:

- Log level to [LogLevel.Critical](#).
- Event ID to `13` with the name of the `FailedToProcessWorkItem` method.
- Message template (named format string) to a string.

```
C#
```

```
s_failedToProcessWorkItem = LoggerMessage.Define(
    LogLevel.Critical,
    new EventId(13, nameof(FailedToProcessWorkItem)),
    "Epic failure processing item!");
```

The [LoggerMessage.Define](#) method is used to configure and define an [Action](#) delegate, which represents a log message.

Structured logging stores may use the event name when it's supplied with the event ID to enrich logging. For example, [Serilog](#) uses the event name.

The [Action](#) is invoked through a strongly typed extension method. The `PriorityItemProcessed` method logs a message every time a work item is processed. `FailedToProcessWorkItem` is called if and when an exception occurs:

C#

```
protected override async Task ExecuteAsync(
    CancellationToken stoppingToken)
{
    using IDisposable? scope = _logger.ProcessingWorkScope(DateTime.Now);
    while (!stoppingToken.IsCancellationRequested)
    {
        WorkItem? nextItem = _priorityQueue.ProcessNextHighestPriority();
        try
        {
            if (nextItem is not null)
            {
                _logger.PriorityItemProcessed(nextItem);
            }
        }
        catch (Exception ex)
        {
            _loggerFailedToProcessWorkItem(ex);
        }

        await Task.Delay(1_000, stoppingToken);
    }
}
```

Inspect the app's console output:

Console

```
crit: WorkerServiceOptions.Example.Worker[13]
  Epic failure processing item!
  System.Exception: Failed to verify communications.
    at
WorkerServiceOptions.Example.Worker.ExecuteAsync(CancellationToken
stoppingToken) in
  ..\Worker.cs:line 27
```

To pass parameters to a log message, define up to six types when creating the static field. The sample app logs the work item details when processing items by defining a `WorkItem` type for the `Action` field:

C#

```
private static readonly Action<ILogger, WorkItem, Exception>
s_processingPriorityItem;
```

The delegate's log message template receives its placeholder values from the types provided. The sample app defines a delegate for adding a work item where the item

parameter is a `WorkItem`:

C#

```
s_processingPriorityItem = LoggerMessage.Define<WorkItem>(
    LogLevel.Information,
    new EventId(1, nameof(PriorityItemProcessed)),
    "Processing priority item: {Item}");
```

The static extension method for logging that a work item is being processed, `PriorityItemProcessed`, receives the work item argument value and passes it to the `Action` delegate:

C#

```
public static void PriorityItemProcessed(
    this ILogger logger, WorkItem workItem) =>
    s_processingPriorityItem(logger, workItem, default!);
```

In the worker service's `ExecuteAsync` method, `PriorityItemProcessed` is called to log the message:

C#

```
protected override async Task ExecuteAsync(
    CancellationToken stoppingToken)
{
    using IDisposable? scope = _logger.ProcessingWorkScope(DateTime.Now);
    while (!stoppingToken.IsCancellationRequested)
    {
        WorkItem? nextItem = _priorityQueue.ProcessNextHighestPriority();
        try
        {
            if (nextItem is not null)
            {
                _logger.PriorityItemProcessed(nextItem);
            }
        }
        catch (Exception ex)
        {
            _logger FailedToProcessWorkItem(ex);
        }

        await Task.Delay(1_000, stoppingToken);
    }
}
```

Inspect the app's console output:

Console

```
info: WorkerServiceOptions.Example.Worker[1]
    Processing priority item: Priority-Extreme (50db062a-9732-4418-936d-
110549ad79e4): 'Verify communications'
```

Define logger message scope

The [DefineScope\(string\)](#) method creates a `Func<TResult>` delegate for defining a [log scope](#). `DefineScope` overloads permit passing up to three type parameters to a named format string (template).

As is the case with the [Define](#) method, the string provided to the [DefineScope](#) method is a template and not an interpolated string. Placeholders are filled in the order that the types are specified. Placeholder names in the template should be descriptive and consistent across templates. They serve as property names within structured log data. We recommend [Pascal casing](#) for placeholder names. For example, `{Item}`, `{DateTime}`.

Define a [log scope](#) to apply to a series of log messages using the [DefineScope](#) method. Enable `IncludeScopes` in the console logger section of `appsettings.json`:

JSON

```
{
  "Logging": {
    "Console": {
      "IncludeScopes": true
    },
    "LogLevel": {
      "Default": "Information",
      "Microsoft": "Warning",
      "Microsoft.Hosting.Lifetime": "Information"
    }
  }
}
```

To create a log scope, add a field to hold a `Func<TResult>` delegate for the scope. The sample app creates a field called `_processingWorkScope` (`Internal/LoggerExtensions.cs`):

C#

```
private static Func<ILogger, DateTime, IDisposable?> s_processingWorkScope;
```

Use `DefineScope` to create the delegate. Up to three types can be specified for use as template arguments when the delegate is invoked. The sample app uses a message template that includes the date time in which processing started:

```
C#
```

```
s_processingWorkScope =
    LoggerMessage.DefineScope<DateTime>(
        "Processing work, started at: {DateTime}");
```

Provide a static extension method for the log message. Include any type parameters for named properties that appear in the message template. The sample app takes in a `DateTime` for a custom time stamp to log and returns `_processingWorkScope`:

```
C#
```

```
public static IDisposable? ProcessingWorkScope(
    this ILogger logger, DateTime time) =>
    s_processingWorkScope(logger, time);
```

The scope wraps the logging extension calls in a `using` block:

```
C#
```

```
protected override async Task ExecuteAsync(
    CancellationToken stoppingToken)
{
    using IDisposable? scope =
        _logger.ProcessingWorkScope(DateTime.Now);
    while (!stoppingToken.IsCancellationRequested)
    {
        WorkItem? nextItem =
            _priorityQueue.ProcessNextHighestPriority();
        try
        {
            if (nextItem is not null)
            {
                _logger.PriorityItemProcessed(nextItem);
            }
        }
        catch (Exception ex)
        {
            _loggerFailedToProcessWorkItem(ex);
        }

        await Task.Delay(1_000, stoppingToken);
    }
}
```

```
    }  
}
```

Inspect the log messages in the app's console output. The following result shows priority ordering of log messages with the log scope message included:

```
Console  
  
info: WorkerServiceOptions.Example.Worker[1]  
      => Processing work, started at: 09/25/2020 14:30:45  
      Processing priority item: Priority-Extreme (f5090ede-a337-4041-b914-f6bc0db5ae64): 'Verify communications'  
info: Microsoft.Hosting.Lifetime[0]  
      Application started. Press Ctrl+C to shut down.  
info: Microsoft.Hosting.Lifetime[0]  
      Hosting environment: Development  
info: Microsoft.Hosting.Lifetime[0]  
      Content root path: ..\worker-service-options  
info: WorkerServiceOptions.Example.Worker[1]  
      => Processing work, started at: 09/25/2020 14:30:45  
      Processing priority item: Priority-High (496d440f-2007-4391-b179-09d75ab52373): 'Validate collection'  
info: WorkerServiceOptions.Example.Worker[1]  
      => Processing work, started at: 09/25/2020 14:30:45  
      Processing priority item: Priority-Medium (dea9e3f4-d7df-46d2-b7cd-5e0232eb98a5): 'Propagate selections'  
info: WorkerServiceOptions.Example.Worker[1]  
      => Processing work, started at: 09/25/2020 14:30:45  
      Processing priority item: Priority-Medium (089d7f0d-da72-4b55-92fe-57b147838056): 'Enter pooling [contention]'  
info: WorkerServiceOptions.Example.Worker[1]  
      => Processing work, started at: 09/25/2020 14:30:45  
      Processing priority item: Priority-Low (6e68c4be-089f-4450-9080-1ea63fcbb686): 'Health check network'  
info: WorkerServiceOptions.Example.Worker[1]  
      => Processing work, started at: 09/25/2020 14:30:45  
      Processing priority item: Priority-Deferred (6f324134-6bb6-455f-81d4-553ab307c421): 'Ping weather service'  
info: WorkerServiceOptions.Example.Worker[1]  
      => Processing work, started at: 09/25/2020 14:30:45  
      Processing priority item: Priority-Deferred (37bf736c-7a26-4a2a-9e56-e89bcf3b8f35): 'Set process state'
```

Log level guarded optimizations

Another performance optimization can be made by checking the [LogLevel](#), with `ILogger.IsEnabled(LogLevel)` before an invocation to the corresponding `Log*` method. When logging isn't configured for the given `LogLevel`, the following statements are true:

- `ILogger.Log` isn't called.
- An allocation of `object[]` representing the parameters is avoided.
- Value type boxing is avoided.

For more information:

- Micro benchmarks in the .NET runtime ↗
- Background and motivation for log level checks ↗

Console log formatting

Article • 06/23/2023

In .NET 5, support for custom formatting was added to console logs in the `Microsoft.Extensions.Logging.Console` namespace. There are three predefined formatting options available: [Simple](#), [Systemd](#), and [Json](#).

ⓘ Important

Previously, the `ConsoleLoggerFormat` enum allowed for selecting the desired log format, either human readable which was the `Default`, or single line which is also known as `Systemd`. However, these were **not** customizable, and are now deprecated.

In this article, you will learn about console log formatters. The sample source code demonstrates how to:

- Register a new formatter
- Select a registered formatter to use
 - Either through code, or [configuration](#)
- Implement a custom formatter
 - Update configuration via `IOptionsMonitor<TOptions>`
 - Enable custom color formatting

ⓘ Tip

All of the logging example source code is available in the [Samples Browser](#) for download. For more information, see [Browse code samples: Logging in .NET](#).

Register formatter

The [Console logging provider](#) has several predefined formatters, and exposes the ability to author your own custom formatter. To register any of the available formatters, use the corresponding `Add{Type}Console` extension method:

| Available types | Method to register type |
|--|---|
| ConsoleFormatterNames.Json | <code>ConsoleLoggerExtensions.AddJsonConsole</code> |

| Available types | Method to register type |
|---|---|
| ConsoleFormatterNames.Simple | ConsoleLoggerExtensions.AddSimpleConsole |
| ConsoleFormatterNames.Systemd | ConsoleLoggerExtensions.AddSystemdConsole |

Simple

To use the `Simple` console formatter, register it with `AddSimpleConsole`:

C#

```
using Microsoft.Extensions.Logging;

using ILoggerFactory loggerFactory =
    LoggerFactory.Create(builder =>
        builder.AddSimpleConsole(options =>
    {
        options.IncludeScopes = true;
        options.SingleLine = true;
        options.TimestampFormat = "HH:mm:ss ";
    }));
    
ILogger<Program> logger = loggerFactory.CreateLogger<Program>();
using (logger.BeginScope("[scope is enabled]"))
{
    logger.LogInformation("Hello World!");
    logger.LogInformation("Logs contain timestamp and log level.");
    logger.LogInformation("Each log message is fit in a single line.");
}
```

In the preceding sample source code, the `ConsoleFormatterNames.Simple` formatter was registered. It provides logs with the ability to not only wrap information such as time and log level in each log message, but also allows for ANSI color embedding and indentation of messages.

Systemd

The `ConsoleFormatterNames.Systemd` console logger:

- Uses the "Syslog" log level format and severities
- Does **not** format messages with colors
- Always logs messages in a single line

This is commonly useful for containers, which often make use of `Systemd` console logging. With .NET 5, the `Simple` console logger also enables a compact version that

logs in a single line, and also allows for disabling colors as shown in an earlier sample.

C#

```
using Microsoft.Extensions.Logging;

using ILoggerFactory loggerFactory =
    LoggerFactory.Create(builder =>
        builder.AddSystemdConsole(options =>
    {
        options.IncludeScopes = true;
        options.TimestampFormat = "HH:mm:ss ";
    }));
}

ILogger<Program> logger = loggerFactory.CreateLogger<Program>();
using (logger.BeginScope("[scope is enabled]"))
{
    logger.LogInformation("Hello World!");
    logger.LogInformation("Logs contain timestamp and log level.");
    logger.LogInformation("Systemd console logs never provide color
options.");
    logger.LogInformation("Systemd console logs always appear in a single
line.");
}
```

Json

To write logs in a JSON format, the `Json` console formatter is used. The sample source code shows how an ASP.NET Core app might register it. Using the `webapp` template, create a new ASP.NET Core app with the `dotnet new` command:

.NET CLI

```
dotnet new webapp -o Console.ExampleFormatters.Json
```

When running the app, using the template code, you get the default log format below:

Console

```
info: Console.ExampleFormatters.Json.Startup[0]
      Hello .NET friends!
info: Microsoft.Hosting.Lifetime[14]
      Now listening on: https://localhost:5001
info: Microsoft.Hosting.Lifetime[14]
      Now listening on: http://localhost:5000
info: Microsoft.Hosting.Lifetime[0]
      Application started. Press Ctrl+C to shut down.
info: Microsoft.Hosting.Lifetime[0]
      Hosting environment: Development
```

```
info: Microsoft.Hosting.Lifetime[0]
      Content root path: .\snippets\logging\console-formatter-json
```

By default, the `Simple` console log formatter is selected with default configuration. You can change this by calling `AddJsonConsole` in the `Program.cs`:

C#

```
using System.Text.Json;

HostApplicationBuilder builder = Host.CreateApplicationBuilder(args);

builder.Logging.AddJsonConsole(options =>
{
    options.IncludeScopes = false;
    options.TimestampFormat = "HH:mm:ss ";
    options.JsonWriterOptions = new JsonWriterOptions
    {
        Indented = true
    };
});

using IHost host = builder.Build();

var logger =
    host.Services
        .GetRequiredService<ILoggerFactory>()
        .CreateLogger<Program>();

logger.LogInformation("Hello .NET friends!");

await host.RunAsync();
```

Alternatively, you can also configure this using logging configuration, such as that found in the `appsettings.json` file:

JSON

```
{
  "Logging": {
    "LogLevel": {
      "Default": "Information",
      "Microsoft": "Warning",
      "Microsoft.Hosting.Lifetime": "Information"
    },
    "Console": {
      "LogLevel": {
        "Default": "Information",
        "Microsoft": "Warning",
        "Microsoft.Hosting.Lifetime": "Information"
      },
    }
}
```

```
        "FormatterName": "json",
        "FormatterOptions": {
            "SingleLine": true,
            "IncludeScopes": true,
            "TimestampFormat": "HH:mm:ss",
            "UseUtcTimestamp": true,
            "JsonWriterOptions": {
                "Indented": true
            }
        }
    },
    "AllowedHosts": "*"
}
```

Run the app again, with the above change, the log message is now formatted as JSON:

JSON

```
{
    "Timestamp": "02:28:19",
    "EventId": 0,
    "LogLevel": "Information",
    "Category": "Console.ExampleFormatters.Json.Startup",
    "Message": "Hello .NET friends!",
    "State": {
        "Message": "Hello .NET friends!",
        "{OriginalFormat}": "Hello .NET friends!"
    }
}
{
    "Timestamp": "02:28:21",
    "EventId": 14,
    "LogLevel": "Information",
    "Category": "Microsoft.Hosting.Lifetime",
    "Message": "Now listening on: https://localhost:5001",
    "State": {
        "Message": "Now listening on: https://localhost:5001",
        "address": "https://localhost:5001",
        "{OriginalFormat}": "Now listening on: {address}"
    }
}
{
    "Timestamp": "02:28:21",
    "EventId": 14,
    "LogLevel": "Information",
    "Category": "Microsoft.Hosting.Lifetime",
    "Message": "Now listening on: http://localhost:5000",
    "State": {
        "Message": "Now listening on: http://localhost:5000",
        "address": "http://localhost:5000",
        "{OriginalFormat}": "Now listening on: {address}"
    }
}
```

```

}
{
  "Timestamp": "02:28:21 ",
  "EventId": 0,
  "LogLevel": "Information",
  "Category": "Microsoft.Hosting.Lifetime",
  "Message": "Application started. Press Ctrl+Shift+B to shut down.",
  "State": {
    "Message": "Application started. Press Ctrl+Shift+B to shut down.",
    "{OriginalFormat)": "Application started. Press Ctrl+Shift+B to shut
down."
  }
}
{
  "Timestamp": "02:28:21 ",
  "EventId": 0,
  "LogLevel": "Information",
  "Category": "Microsoft.Hosting.Lifetime",
  "Message": "Hosting environment: Development",
  "State": {
    "Message": "Hosting environment: Development",
    "envName": "Development",
    "{OriginalFormat)": "Hosting environment: {envName}"
  }
}
{
  "Timestamp": "02:28:21 ",
  "EventId": 0,
  "LogLevel": "Information",
  "Category": "Microsoft.Hosting.Lifetime",
  "Message": "Content root path: .\\snippets\\logging\\console-formatter-
json",
  "State": {
    "Message": "Content root path: .\\snippets\\logging\\console-formatter-
json",
    "contentRoot": ".\\snippets\\logging\\console-formatter-json",
    "{OriginalFormat)": "Content root path: {contentRoot}"
  }
}

```

💡 Tip

The `Json` console formatter, by default, logs each message in a single line. In order to make it more readable while configuring the formatter, set `JsonWriterOptions.Indented` to `true`.

⊗ Caution

When using the Json console formatter, do not pass in log messages that have already been serialized as JSON. The logging infrastructure itself already manages the serialization of log messages, so if you're to pass in a log message that is already serialized—it will be double serialized, thus causing malformed output.

Set formatter with configuration

The previous samples have shown how to register a formatter programmatically. Alternatively, this can be done with [configuration](#). Consider the previous web application sample source code, if you update the `appsettings.json` file rather than calling `ConfigureLogging` in the `Program.cs` file, you could get the same outcome. The updated `appsettings.json` file would configure the formatter as follows:

JSON

```
{  
  "Logging": {  
    "LogLevel": {  
      "Default": "Information",  
      "Microsoft": "Warning",  
      "Microsoft.Hosting.Lifetime": "Information"  
    },  
    "Console": {  
      "LogLevel": {  
        "Default": "Information",  
        "Microsoft": "Warning",  
        "Microsoft.Hosting.Lifetime": "Information"  
      },  
      "FormatterName": "json",  
      "FormatterOptions": {  
        "SingleLine": true,  
        "IncludeScopes": true,  
        "TimestampFormat": "HH:mm:ss ",  
        "UseUtcTimestamp": true,  
        "JsonWriterOptions": {  
          "Indented": true  
        }  
      }  
    },  
    "AllowedHosts": "*"  
  }  
}
```

The two key values that need to be set are `"FormatterName"` and `"FormatterOptions"`. If a formatter with the value set for `"FormatterName"` is already registered, that formatter is selected, and its properties can be configured as long as they are provided as a key

inside the `"FormatterOptions"` node. The predefined formatter names are reserved under [ConsoleFormatterNames](#):

- [ConsoleFormatterNames.Json](#)
- [ConsoleFormatterNames.Simple](#)
- [ConsoleFormatterNames.Systemd](#)

Implement a custom formatter

To implement a custom formatter, you need to:

- Create a subclass of [ConsoleFormatter](#), this represents your custom formatter
- Register your custom formatter with
 - [ConsoleLoggerExtensions.AddConsole](#)
 - [ConsoleLoggerExtensions.AddConsoleFormatter<TFormatter,TOptions>\(ILoggingBuilder, Action<TOptions>\)](#)

Create an extension method to handle this for you:

C#

```
using Microsoft.Extensions.Logging;

namespace Console.ExampleFormatters.Custom;

public static class ConsoleLoggerExtensions
{
    public static ILoggingBuilder AddCustomFormatter(
        this ILoggingBuilder builder,
        Action<CustomOptions> configure) =>
        builder.AddConsole(options => options.FormatterName = "customName")
            .AddConsoleFormatter<CustomFormatter, CustomOptions>(configure);
}
```

The `CustomOptions` are defined as follows:

C#

```
using Microsoft.Extensions.Logging.Console;

namespace Console.ExampleFormatters.Custom;

public sealed class CustomOptions : ConsoleFormatterOptions
{
    public string? CustomPrefix { get; set; }
}
```

In the preceding code, the options are a subclass of `ConsoleFormatterOptions`.

The `AddConsoleFormatter` API:

- Registers a subclass of `ConsoleFormatter`
- Handles configuration:
 - Uses a change token to synchronize updates, based on the [options pattern](#), and the `IOptionsMonitor` interface

C#

```
using Console.ExampleFormatters.Custom;
using Microsoft.Extensions.Logging;

using ILoggerFactory loggerFactory =
    LoggerFactory.Create(builder =>
        builder.AddCustomFormatter(options =>
            options.CustomPrefix = " ~~~~~ "));

ILogger<Program> logger = loggerFactory.CreateLogger<Program>();
using (logger.BeginScope("TODO: Add logic to enable scopes"))
{
    logger.LogInformation("Hello World!");
    logger.LogInformation("TODO: Add logic to enable timestamp and log level
info.");
}
```

Define a `CustomFormatter` subclass of `ConsoleFormatter`:

C#

```
using Microsoft.Extensions.Logging;
using Microsoft.Extensions.Logging.Abstractions;
using Microsoft.Extensions.Logging.Console;
using Microsoft.Extensions.Options;

namespace Console.ExampleFormatters.Custom;

public sealed class CustomFormatter : ConsoleFormatter, IDisposable
{
    private readonly IDisposable? _optionsReloadToken;
    private CustomOptions _formatterOptions;

    public CustomFormatter(IOptionsMonitor<CustomOptions> options)
        // Case insensitive
        : base("customName") =>
            (_optionsReloadToken, _formatterOptions) =
                (options.OnChange(ReloadLoggerOptions), options.CurrentValue);

    private void ReloadLoggerOptions(CustomOptions options) =>
        _formatterOptions = options;
```

```

public override void Write<TState>(
    in LogEntry<TState> logEntry,
    IExternalScopeProvider? scopeProvider,
    TextWriter textWriter)
{
    string? message =
        logEntry.Formatter?.Invoke(
            logEntry.State, logEntry.Exception);

    if (message is null)
    {
        return;
    }

    CustomLogicGoesHere(textWriter);
    textWriter.WriteLine(message);
}

private void CustomLogicGoesHere(TextWriter textWriter)
{
    textWriter.Write(_formatterOptions.CustomPrefix);
}

public void Dispose() => _optionsReloadToken?.Dispose();
}

```

The preceding `CustomFormatter.Write<TState>` API dictates what text gets wrapped around each log message. A standard `ConsoleFormatter` should be able to wrap around scopes, time stamps, and severity level of logs at a minimum. Additionally, you can encode ANSI colors in the log messages, and provide desired indentations as well. The implementation of the `CustomFormatter.Write<TState>` lacks these capabilities.

For inspiration on further customizing formatting, see the existing implementations in the `Microsoft.Extensions.Logging.Console` namespace:

- [SimpleConsoleFormatter](#).
- [SystemdConsoleFormatter](#)
- [JsonConsoleFormatter](#)

Custom configuration options

To further customize the logging extensibility, your derived `ConsoleFormatterOptions` class can be configured from any [configuration provider](#). For example, you could use the [JSON configuration provider](#) to define your custom options. First define your `ConsoleFormatterOptions` subclass.

C#

```
using Microsoft.Extensions.Logging.Console;

namespace Console.ExampleFormatters.CustomWithConfig;

public sealed class CustomWrappingConsoleFormatterOptions : 
ConsoleFormatterOptions
{
    public string? CustomPrefix { get; set; }

    public string? CustomSuffix { get; set; }
}
```

The preceding console formatter options class defines two custom properties, representing a prefix and suffix. Next, define the *appsettings.json* file that will configure your console formatter options.

JSON

```
{
    "Logging": {
        "LogLevel": {
            "Default": "Information",
            "Microsoft": "Warning",
            "Microsoft.Hosting.Lifetime": "Information"
        },
        "Console": {
            "LogLevel": {
                "Default": "Information",
                "Microsoft": "Warning",
                "Microsoft.Hosting.Lifetime": "Information"
            },
            "FormatterName": "CustomTimePrefixingFormatter",
            "FormatterOptions": {
                "CustomPrefix": "|-<[",
                "CustomSuffix": "]>-|",
                "SingleLine": true,
                "IncludeScopes": true,
                "TimestampFormat": "HH:mm:ss.fffff ",
                "UseUtcTimestamp": true,
                "JsonWriterOptions": {
                    "Indented": true
                }
            }
        }
    },
    "AllowedHosts": "*"
}
```

In the preceding JSON config file:

- The "Logging" node defines a "Console".
- The "Console" node specifies a "FormatterName" of "CustomTimePrefixingFormatter", which maps to a custom formatter.
- The "FormatterOptions" node defines a "CustomPrefix", and "CustomSuffix", as well as a few other derived options.

💡 Tip

The `$.Logging.Console.FormatterOptions` JSON path is reserved, and will map to a custom **ConsoleFormatterOptions** when added using the **AddConsoleFormatter** extension method. This provides the ability to define custom properties, in addition to the ones available.

Consider the following `CustomDatePrefixingFormatter`:

C#

```
using Microsoft.Extensions.Logging;
using Microsoft.Extensions.Logging.Abstractions;
using Microsoft.Extensions.Logging.Console;
using Microsoft.Extensions.Options;

namespace Console.ExampleFormatters.CustomWithConfig;

public sealed class CustomTimePrefixingFormatter : ConsoleFormatter,
IDisposable
{
    private readonly IDisposable? _optionsReloadToken;
    private CustomWrappingConsoleFormatterOptions _formatterOptions;

    public CustomTimePrefixingFormatter(IOptionsMonitor<CustomWrappingConsoleFormatterOptions> options)
        // Case insensitive
        : base(nameof(CustomTimePrefixingFormatter)) =>
        (_optionsReloadToken, _formatterOptions) =
            (options.OnChange(ReloadLoggerOptions), options.CurrentValue);

    private void ReloadLoggerOptions(CustomWrappingConsoleFormatterOptions options) =>
        _formatterOptions = options;

    public override void Write<TState>(
        in LogEntry<TState> logEntry,
        IExternalScopeProvider? scopeProvider,
        TextWriter textWriter)
    {
        string message =
            logEntry.Formatter(
```

```

        logEntry.State, logEntry.Exception);

    if (message == null)
    {
        return;
    }

    WritePrefix(textWriter);
    textWriter.Write(message);
    WriteSuffix(textWriter);
}

private void WritePrefix(TextWriter textWriter)
{
    DateTime now = _formatterOptions.UseUtcTimestamp
        ? DateTime.UtcNow
        : DateTime.Now;

    textWriter.WriteLine($""""
        {_formatterOptions.CustomPrefix}
{now.ToString(_formatterOptions.TimestampFormat)}
""");
}

private void WriteSuffix(TextWriter textWriter) =>
    textWriter.WriteLine($" {_formatterOptions.CustomSuffix}");
}

public void Dispose() => _optionsReloadToken?.Dispose();
}

```

In the preceding formatter implementation:

- The `CustomWrappingConsoleFormatterOptions` are monitored for change, and updated accordingly.
- Messages that are written are wrapped with the configured prefix, and suffix.
- A timestamp is added after the prefix, but before the message using the configured `ConsoleFormatterOptions.UseUtcTimestamp` and `ConsoleFormatterOptions.TimestampFormat` values.

To use custom configuration options, with custom formatter implementations, add when calling `ConfigureLogging(IHostBuilder, Action<HostBuilderContext, ILoggingBuilder>)`.

C#

```

using Console.ExampleFormatters.CustomWithConfig;
using Microsoft.Extensions.DependencyInjection;
using Microsoft.Extensions.Hosting;
using Microsoft.Extensions.Logging;

HostApplicationBuilder builder = Host.CreateApplicationBuilder(args);

```

```
builder.Logging.AddConsole()
    .AddConsoleFormatter<
        CustomTimePrefixingFormatter, CustomWrappingConsoleFormatterOptions>
();
using IHost host = builder.Build();

ILoggerFactory loggerFactory =
host.Services.GetRequiredService<ILoggerFactory>();
	ILogger<Program> logger = loggerFactory.CreateLogger<Program>();

using (logger.BeginScope("Logging scope"))
{
    logger.LogInformation("Hello World!");
    logger.LogInformation("The .NET developer community happily welcomes
you.");
}
```

The following console output is similar to what you might expect to see from using this `CustomTimePrefixingFormatter`.

Console

```
|-<[ 15:03:15.6179 Hello World! ]>-|
|-<[ 15:03:15.6347 The .NET developer community happily welcomes you. ]>-|
```

Implement custom color formatting

In order to properly enable color capabilities in your custom logging formatter, you can extend the `SimpleConsoleFormatterOptions` as it has a `SimpleConsoleFormatterOptions.ColorBehavior` property that can be useful for enabling colors in logs.

Create a `CustomColorOptions` that derives from `SimpleConsoleFormatterOptions`:

C#

```
using Microsoft.Extensions.Logging.Console;

namespace Console.ExampleFormatters.Custom;

public class CustomColorOptions : SimpleConsoleFormatterOptions
{
    public string? CustomPrefix { get; set; }
}
```

Next, write some extension methods in a `TextWriterExtensions` class that allow for conveniently embedding ANSI coded colors within formatted log messages:

C#

```
namespace Console.ExampleFormatters.Custom;

public static class TextWriterExtensions
{
    const string DefaultForegroundColor = "\x1B[39m\x1B[22m";
    const string DefaultBackgroundColor = "\x1B[49m";

    public static void WriteWithColor(
        this TextWriter textWriter,
        string message,
        ConsoleColor? background,
        ConsoleColor? foreground)
    {
        // Order:
        // 1. background color
        // 2. foreground color
        // 3. message
        // 4. reset foreground color
        // 5. reset background color

        var backgroundColor = background.HasValue ?
GetBackgroundColorEscapeCode(background.Value) : null;
        var foregroundColor = foreground.HasValue ?
GetForegroundColorEscapeCode(foreground.Value) : null;

        if (backgroundColor != null)
        {
            textWriter.Write(backgroundColor);
        }
        if (foregroundColor != null)
        {
            textWriter.Write(foregroundColor);
        }

        textWriter.WriteLine(message);

        if (foregroundColor != null)
        {
            textWriter.Write(DefaultForegroundColor);
        }
        if (backgroundColor != null)
        {
            textWriter.Write(DefaultBackgroundColor);
        }
    }

    static string GetForegroundColorEscapeCode(ConsoleColor color) =>
        color switch
    {
        ConsoleColor.Black => "\x1B[30m",
        ConsoleColor.DarkRed => "\x1B[31m",
        ConsoleColor.DarkGreen => "\x1B[32m",
    }
}
```

```

        ConsoleColor.DarkYellow => "\x1B[33m",
        ConsoleColor.DarkBlue => "\x1B[34m",
        ConsoleColor.DarkMagenta => "\x1B[35m",
        ConsoleColor.DarkCyan => "\x1B[36m",
        ConsoleColor.Gray => "\x1B[37m",
        ConsoleColor.Red => "\x1B[1m\x1B[31m",
        ConsoleColor.Green => "\x1B[1m\x1B[32m",
        ConsoleColor.Yellow => "\x1B[1m\x1B[33m",
        ConsoleColor.Blue => "\x1B[1m\x1B[34m",
        ConsoleColor.Magenta => "\x1B[1m\x1B[35m",
        ConsoleColor.Cyan => "\x1B[1m\x1B[36m",
        ConsoleColor.White => "\x1B[1m\x1B[37m",

        _ => DefaultForegroundColor
    };

    static string GetBackgroundColorEscapeCode(ConsoleColor color) =>
        color switch
    {
        ConsoleColor.Black => "\x1B[40m",
        ConsoleColor.DarkRed => "\x1B[41m",
        ConsoleColor.DarkGreen => "\x1B[42m",
        ConsoleColor.DarkYellow => "\x1B[43m",
        ConsoleColor.DarkBlue => "\x1B[44m",
        ConsoleColor.DarkMagenta => "\x1B[45m",
        ConsoleColor.DarkCyan => "\x1B[46m",
        ConsoleColor.Gray => "\x1B[47m",

        _ => DefaultBackgroundColor
    };
}

```

A custom color formatter that handles applying custom colors could be defined as follows:

```

C#

using Microsoft.Extensions.Logging;
using Microsoft.Extensions.Logging.Abstractions;
using Microsoft.Extensions.Logging.Console;
using Microsoft.Extensions.Options;

namespace Console.ExampleFormatters.Custom;

public sealed class CustomColorFormatter : ConsoleFormatter, IDisposable
{
    private readonly IDisposable? _optionsReloadToken;
    private CustomColorOptions _formatterOptions;

    private bool ConsoleColorFormattingEnabled =>
        _formatterOptions.ColorBehavior == LoggerColorBehavior.Enabled ||
        _formatterOptions.ColorBehavior == LoggerColorBehavior.Default &&
        System.Console.IsOutputRedirected == false;

```

```

public CustomColorFormatter(IOptionsMonitor<CustomColorOptions> options)
    // Case insensitive
    : base("customName") =>
    (_optionsReloadToken, _formatterOptions) =
        (options.OnChange(ReloadLoggerOptions), options.CurrentValue);

private void ReloadLoggerOptions(CustomColorOptions options) =>
    _formatterOptions = options;

public override void Write<TState>(
    in LogEntry<TState> logEntry,
    IExternalScopeProvider? scopeProvider,
    TextWriter textWriter)
{
    if (logEntry.Exception is null)
    {
        return;
    }

    string? message =
        logEntry.Formatter?.Invoke(
            logEntry.State, logEntry.Exception);

    if (message is null)
    {
        return;
    }

    CustomLogicGoesHere(textWriter);
    textWriter.WriteLine(message);
}

private void CustomLogicGoesHere(TextWriter textWriter)
{
    if (ConsoleColorFormattingEnabled)
    {
        textWriter.WriteLineColor(
            _formatterOptions.CustomPrefix ?? string.Empty,
            ConsoleColor.Black,
            ConsoleColor.Green);
    }
    else
    {
        textWriter.Write(_formatterOptions.CustomPrefix);
    }
}

public void Dispose() => _optionsReloadToken?.Dispose();
}

```

When you run the application, the logs will show the `CustomPrefix` message in the color green when `FormatterOptions.ColorBehavior` is `Enabled`.

Note

When `LoggerColorBehavior` is `Disabled`, log messages do *not* interpret embedded ANSI color codes within log messages. Instead, they output the raw message. For example, consider the following:

C#

```
logger.LogInformation("Random log \x1B[42mwith green background\x1B[49m message");
```

This would output the verbatim string, and it is *not* colorized.

Output

```
Random log \x1B[42mwith green background\x1B[49m message
```

.NET Generic Host

Article • 12/13/2023

In this article, you learn about the various patterns for configuring and building a .NET Generic Host available in the [Microsoft.Extensions.Hosting](#) NuGet package. The .NET Generic Host is responsible for app startup and lifetime management. The Worker Service templates create a .NET Generic Host, [HostApplicationBuilder](#). The Generic Host can be used with other types of .NET applications, such as Console apps.

A *host* is an object that encapsulates an app's resources and lifetime functionality, such as:

- Dependency injection (DI)
- Logging
- Configuration
- App shutdown
- `IHostedService` implementations

When a host starts, it calls `IHostedService.StartAsync` on each implementation of `IHostedService` registered in the service container's collection of hosted services. In a worker service app, all `IHostedService` implementations that contain `BackgroundService` instances have their `BackgroundService.ExecuteAsync` methods called.

The main reason for including all of the app's interdependent resources in one object is lifetime management: control over app startup and graceful shutdown.

Set up a host

The host is typically configured, built, and run by code in the `Program` class. The `Main` method:

`IHostApplicationBuilder`

- Calls a `CreateApplicationBuilder` method to create and configure a builder object.
- Calls `Build()` to create an `IHost` instance.
- Calls `Run` or `RunAsync` method on the host object.

The .NET Worker Service templates generate the following code to create a Generic Host:

C#

```
using Example.WorkerService;

HostApplicationBuilder builder = Host.CreateApplicationBuilder(args);
builder.Services.AddHostedService<Worker>();

IHost host = builder.Build();
host.Run();
```

For more information on Worker Services, see [Worker Services in .NET](#).

Host builder settings

IHostApplicationBuilder

The [CreateApplicationBuilder](#) method:

- Sets the content root to the path returned by [GetCurrentDirectory\(\)](#).
- Loads [host configuration](#) from:
 - Environment variables prefixed with `DOTNET_`.
 - Command-line arguments.
- Loads app configuration from:
 - `appsettings.json`.
 - `appsettings.{Environment}.json`.
 - Secret Manager when the app runs in the `Development` environment.
 - Environment variables.
 - Command-line arguments.
- Adds the following logging providers:
 - Console
 - Debug
 - EventSource
 - EventLog (only when running on Windows)
- Enables scope validation and [dependency validation](#) when the environment is `Development`.

The [HostApplicationBuilder.Services](#) is an [Microsoft.Extensions.DependencyInjection.IServiceCollection](#) instance. These services are used to build an [IServiceProvider](#) that's used with dependency injection to resolve the registered services.

Framework-provided services

When you call either [IHostBuilder.Build\(\)](#) or [HostApplicationBuilder.Build\(\)](#), the following services are registered automatically:

- [IHostApplicationLifetime](#)
- [IHostLifetime](#)
- [IHostEnvironment](#)

IHostApplicationLifetime

Inject the [IHostApplicationLifetime](#) service into any class to handle post-startup and graceful shutdown tasks. Three properties on the interface are cancellation tokens used to register app start and app stop event handler methods. The interface also includes a [StopApplication\(\)](#) method.

The following example is an [IHostedService](#) implementation that registers [IHostApplicationLifetime](#) events:

C#

```
using Microsoft.Extensions.Hosting;
using Microsoft.Extensions.Logging;

namespace AppLifetime.Example;

public sealed class ExampleHostedService : IHostedService
{
    private readonly ILogger _logger;

    public ExampleHostedService(
        ILogger<ExampleHostedService> logger,
        IHostApplicationLifetime appLifetime)
    {
        _logger = logger;

        appLifetime.ApplicationStarted.Register(OnStarted);
        appLifetime.ApplicationStopping.Register(OnStopping);
        appLifetime.ApplicationStopped.Register(OnStopped);
    }

    public Task StartAsync(CancellationToken cancellationToken)
    {
        _logger.LogInformation("1. StartAsync has been called.");

        return Task.CompletedTask;
    }
}
```

```
public Task StopAsync(CancellationToken cancellationToken)
{
    _logger.LogInformation("4. StopAsync has been called.");

    return Task.CompletedTask;
}

private void OnStarted()
{
    _logger.LogInformation("2. OnStarted has been called.");
}

private void OnStopping()
{
    _logger.LogInformation("3. OnStopping has been called.");
}

private void OnStopped()
{
    _logger.LogInformation("5. OnStopped has been called.");
}
}
```

The Worker Service template could be modified to add the `ExampleHostedService` implementation:

C#

```
using Microsoft.Extensions.DependencyInjection;
using Microsoft.Extensions.Hosting;
using AppLifetime.Example;

HostApplicationBuilder builder = Host.CreateApplicationBuilder(args);

builder.Services.AddHostedService<ExampleHostedService>();
using IHost host = builder.Build();

await host.RunAsync();
```

The application would write the following sample output:

C#

```
// Sample output:
//      info: ExampleHostedService[0]
//          1. StartAsync has been called.
//      info: ExampleHostedService[0]
//          2. OnStarted has been called.
//      info: Microsoft.Hosting.Lifetime[0]
//          Application started. Press Ctrl+C to shut down.
//      info: Microsoft.Hosting.Lifetime[0]
```

```
//      Hosting environment: Production
//      info: Microsoft.Hosting.Lifetime[0]
//      Content root path: ..\app-lifetime\bin\Debug\net7.0
//      info: ExampleHostedService[0]
//      3. OnStopping has been called.
//      info: Microsoft.Hosting.Lifetime[0]
//      Application is shutting down...
//      info: ExampleHostedService[0]
//      4. StopAsync has been called.
//      info: ExampleHostedService[0]
//      5. OnStopped has been called.
```

IHostLifetime

The [IHostLifetime](#) implementation controls when the host starts and when it stops. The last implementation registered is used.

`Microsoft.Extensions.Hosting.Internal.ConsoleLifetime` is the default `IHostLifetime` implementation. For more information on the lifetime mechanics of shutdown, see [Host shutdown](#).

IHostEnvironment

Inject the [IHostEnvironment](#) service into a class to get information about the following settings:

- [IHostEnvironment.ApplicationName](#)
- [IHostEnvironment.ContentRootFileProvider](#)
- [IHostEnvironment.ContentRootPath](#)
- [IHostEnvironment.EnvironmentName](#)

Additionally, the `IHostEnvironment` service exposes the ability to evaluate the environment with the help of these extension methods:

- [HostingEnvironmentExtensions.IsDevelopment](#)
- [HostingEnvironmentExtensions.IsEnvironment](#)
- [HostingEnvironmentExtensions.IsProduction](#)
- [HostingEnvironmentExtensions.IsStaging](#)

Host configuration

Host configuration is used to configure properties of the [IHostEnvironment](#) implementation.

IHostApplicationBuilder

The host configuration is available in [IHostApplicationBuilder.Configuration](#) property and the environment implementation is available in [IHostApplicationBuilder.Environment](#) property. To configure the host, access the [Configuration](#) property and call any of the available extension methods.

To add host configuration, consider the following example:

C#

```
using Microsoft.Extensions.Configuration;
using Microsoft.Extensions.Hosting;

HostApplicationBuilder builder = Host.CreateApplicationBuilder(args);

builder.Environment.ContentRootPath = Directory.GetCurrentDirectory();
builder.Configuration.AddJsonFile("hostsettings.json", optional: true);
builder.Configuration.AddEnvironmentVariables(prefix: "PREFIX_");
builder.Configuration.AddCommandLine(args);

using IHost host = builder.Build();

// Application code should start here.

await host.RunAsync();
```

The preceding code:

- Sets the content root to the path returned by [GetCurrentDirectory\(\)](#).
- Loads host configuration from:
 - *hostsettings.json*.
 - Environment variables prefixed with `PREFIX_`.
 - Command-line arguments.

App configuration

IHostApplicationBuilder

App configuration is created by calling [ConfigureAppConfiguration](#) on an [IHostApplicationBuilder](#). The public [IHostApplicationBuilder.Configuration](#) property

allows consumers to read from or make changes to the existing configuration using available extension methods.

For more information, see [Configuration in .NET](#).

Host shutdown

There are several ways in which a hosted process is stopped. Most commonly, a hosted process can be stopped in the following ways:

- If someone doesn't call [Run](#) or [HostingAbstractionsHostExtensions.WaitForShutdown](#) and the app exits normally with `Main` completing.
- If the app crashes.
- If the app is forcefully shut down using [SIGKILL](#) (or `CTRL + Z`).

The hosting code isn't responsible for handling these scenarios. The owner of the process needs to deal with them the same as any other app. There are several other ways in which a hosted service process can be stopped:

- If `ConsoleLifetime` is used ([UseConsoleLifetime](#)), it listens for the following signals and attempts to stop the host gracefully.
 - [SIGINT](#) (or `CTRL + C`).
 - [SIGQUIT](#) (or `CTRL + BREAK` on Windows, `CTRL + \` on Unix).
 - [SIGTERM](#) (sent by other apps, such as `docker stop`).
- If the app calls [Environment.Exit](#).

The built-in hosting logic handles these scenarios, specifically the `ConsoleLifetime` class. `ConsoleLifetime` tries to handle the "shutdown" signals SIGINT, SIGQUIT, and SIGTERM to allow for a graceful exit to the application.

Before .NET 6, there wasn't a way for .NET code to gracefully handle SIGTERM. To work around this limitation, `ConsoleLifetime` would subscribe to [System.AppDomain.ProcessExit](#). When `ProcessExit` was raised, `ConsoleLifetime` would signal the host to stop and block the `ProcessExit` thread, waiting for the host to stop.

The process exit handler would allow for the clean-up code in the application to run—for example, [IHost.StopAsync](#) and code after [HostingAbstractionsHostExtensions.Run](#) in the `Main` method.

However, there were other issues with this approach because SIGTERM wasn't the only way `ProcessExit` was raised. SIGTERM is also raised when app code calls

`Environment.Exit`. `Environment.Exit` isn't a graceful way of shutting down a process in the `Microsoft.Extensions.Hosting` app model. It raises the `ProcessExit` event and then exits the process. The end of the `Main` method doesn't get executed. Background and foreground threads are terminated, and `finally` blocks *aren't* executed.

Since `ConsoleLifetime` blocked `ProcessExit` while waiting for the host to shut down, this behavior led to [deadlocks](#) from `Environment.Exit` also blocks waiting for the call to `ProcessExit`. Additionally, since the SIGTERM handling was attempting to gracefully shut down the process, `ConsoleLifetime` would set the `ExitCode` to `0`, which [clobbered](#) the user's exit code passed to `Environment.Exit`.

In .NET 6, [POSIX signals](#) are supported and handled. The `ConsoleLifetime` handles SIGTERM gracefully, and no longer gets involved when `Environment.Exit` is invoked.

💡 Tip

For .NET 6+, `ConsoleLifetime` no longer has logic to handle scenario `Environment.Exit`. Apps that call `Environment.Exit` and need to perform clean-up logic can subscribe to `ProcessExit` themselves. Hosting will no longer attempt to gracefully stop the host in these scenarios.

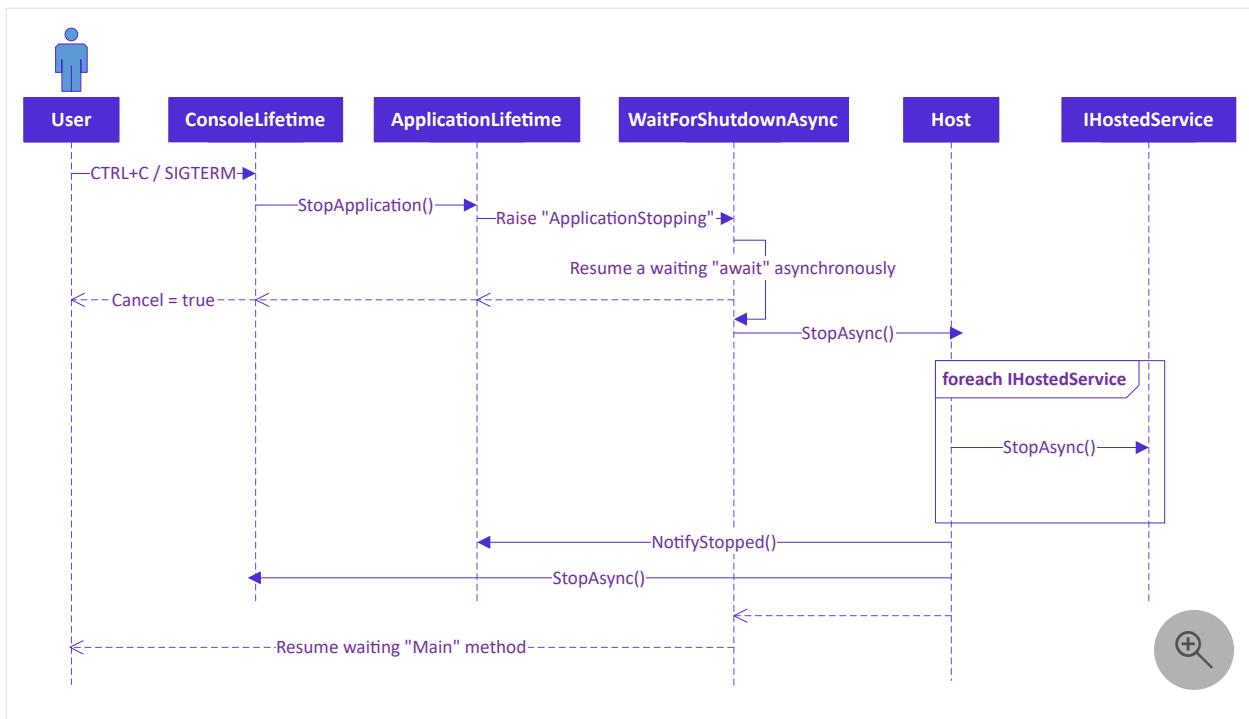

If your application uses hosting, and you want to gracefully stop the host, you can call `IHostApplicationLifetime.StopApplication` instead of `Environment.Exit`.

Hosting shutdown process

The following sequence diagram shows how the signals are handled internally in the hosting code. Most users don't need to understand this process. But for developers that need a deep understanding, a good visual may help you get started.

After the host has been started, when a user calls `Run` or `WaitForShutdown`, a handler gets registered for `IApplicationLifetime.ApplicationStopping`. Execution is paused in `WaitForShutdown`, waiting for the `ApplicationStopping` event to be raised. The `Main` method doesn't return right away, and the app stays running until `Run` or `WaitForShutdown` returns.

When a signal is sent to the process, it initiates the following sequence:

1. The control flows from `ConsoleLifetime` to `ApplicationLifetime` to raise the `ApplicationStopping` event. This signals `WaitForShutdownAsync` to unblock the `Main` execution code. In the meantime, the POSIX signal handler returns with `Cancel = true` since the POSIX signal has been handled.
2. The `Main` execution code starts executing again and tells the host to `StopAsync()`, which in turn stops all the hosted services, and raises any other stopped events.
3. Finally, `WaitForShutdown` exits, allowing for any application clean-up code to execute, and for the `Main` method to exit gracefully.

Host shutdown in web server scenarios

There are various other common scenarios in which graceful shutdown works in Kestrel for both HTTP/1.1 and HTTP/2 protocols, and how you can configure it in different environments with a load balancer to drain traffic smoothly. While web server configuration is beyond the scope of this article, you can find more information on [Configure options for the ASP.NET Core Kestrel web server documentation](#).

When the Host receives a shutdown signal (for example, `CTL + C` or `StopAsync`), it notifies the application by signaling `ApplicationStopping`. You should subscribe to this event if you have any long-running operations that need to finish gracefully.

Next, the Host calls `IHostBuilder`'s `StopAsync` with a shutdown timeout that you can configure (default 30s). Kestrel (and Http.Sys) close their port bindings and stop accepting new connections. They also tell the current connections to stop processing new requests. For HTTP/2 and HTTP/3, a preliminary `GOAWAY` message is sent to the client. For HTTP/1.1,

they stop the connection loop because requests are processed in order. IIS behaves differently, by rejecting new requests with a 503 status code.

The active requests have until the shutdown timeout to complete. If they're all complete before the timeout, the server returns control to the host sooner. If the timeout expires, the pending connections and requests are aborted forcefully, which can cause errors in the logs and to the clients.

Load balancer considerations

To ensure a smooth transition of clients to a new destination when working with a load balancer, you can follow these steps:

- Bring up the new instance and start balancing traffic to it (you may already have several instances for scaling purposes).
- Disable or remove the old instance in the load balancer configuration so it stops receiving new traffic.
- Signal the old instance to shut down.
- Wait for it to drain or time out.

Introduction to resilient app development

Article • 11/29/2023

Resiliency is the ability of an app to recover from transient failures and continue to function. In the context of .NET programming, resilience is achieved by designing apps that can handle failures gracefully and recover quickly. To help build resilient apps in .NET, the following two packages are available on NuGet:

[+] Expand table

| NuGet package | Description |
|--|--|
|  Microsoft.Extensions.Resilience | This NuGet package provides mechanisms to harden apps against transient failures. |
|  Microsoft.Extensions.Http.Resilience | This NuGet package provides resilience mechanisms specifically for the HttpClient class. |

These two NuGet packages are built on top of [Polly](#), which is a popular open-source project. Polly is a .NET resilience and transient fault-handling library that allows developers to express strategies such as [retry](#), [circuit breaker](#), timeout, [bulkhead isolation](#), [rate-limiting](#), fallback, and hedging in a fluent and thread-safe manner.

ⓘ Important

The [Microsoft.Extensions.Http.Polly](#) NuGet package is deprecated. Use either of the aforementioned packages instead.

Get started

To get started with resilience in .NET, install the [Microsoft.Extensions.Resilience](#) NuGet package.

.NET CLI

.NET CLI

```
dotnet add package Microsoft.Extensions.Resilience --version 8.0.0
```

For more information, see [dotnet add package](#) or [Manage package dependencies in .NET applications](#).

Build a resilience pipeline

To use resilience, you must first build a pipeline of resilience-based strategies. Each configured strategy executes in order of configuration. In other words, order is important. The entry point is an extension method on the [IServiceCollection](#) type, named `AddResiliencePipeline`. This method takes an identifier of the pipeline and a delegate that configures the pipeline. The delegate is passed an instance of `ResiliencePipelineBuilder`, which is used to add resilience strategies to the pipeline.

Consider the following string-based `key` example:

C#

```
using Microsoft.Extensions.DependencyInjection;
using Polly;
using Polly.CircuitBreaker;
using Polly.Registry;
using Polly.Retry;
using Polly.Timeout;

var services = new ServiceCollection();

const string key = "Retry-Timeout";

services.AddResiliencePipeline(key, static builder =>
{
    // See: https://www.pollydocs.org:strategies/retry.html
    builder.AddRetry(new RetryStrategyOptions
    {
        ShouldHandle = new
        PredicateBuilder().Handle<TimeoutRejectedException>()
    });

    // See: https://www.pollydocs.org:strategies/timeout.html
    builder.AddTimeout(TimeSpan.FromSeconds(1.5));
});
```

The preceding code:

- Creates a new `ServiceCollection` instance.
- Defines a `key` to identify the pipeline.
- Adds a resilience pipeline to the `ServiceCollection` instance.
- Configures the pipeline with a retry and timeout strategies.

Each pipeline is configured for a given `key`, and each `key` is used to identify its corresponding `ResiliencePipeline` when getting the pipeline from the provider. The `key` is a generic type parameter of the `AddResiliencePipeline` method.

Resilience pipeline builder extensions

To add a strategy to the pipeline, call any of the available `Add*` extension methods on the `ResiliencePipelineBuilder` instance.

- `AddRetry`: Try again if something fails, which is useful when the problem is temporary and might go away.
- `AddCircuitBreaker`: Stop trying if something is broken or busy, which benefits you by avoiding wasted time and making things worse.
- `AddTimeout`: Give up if something takes too long, which can improve performance by freeing up resources.
- `AddRateLimiter`: Limit how many requests you accept, which enables you to control inbound load.
- `AddConcurrencyLimiter`: Limit how many requests you make, which enables you to control outbound load.
- `AddFallback`: Do something else when experiencing failures, which improves user experience.
- `AddHedging`: Issue multiple requests in case of high latency or failure, which can improve responsiveness.

For more information, see [Resilience strategies](#). For examples, see [Build resilient HTTP apps: Key development patterns](#).

Metrics enrichment

Enrichment is the automatic augmentation of telemetry with well-known state, in the form of name/value pairs. For example, an app might emit a log that includes the *operation* and *result code* as columns to represent the outcome of some operation. In this situation and depending on peripheral context, enrichment adds *Cluster name*, *Process name*, *Region*, *Tenant ID*, and more to the log as it's sent to the telemetry backend. When enrichment is added, the app code doesn't need to do anything extra to benefit from enriched metrics.

How enrichment works

Imagine 1,000 globally distributed service instances generating logs and metrics. When you encounter an issue on your [service dashboard](#), it's crucial to quickly identify the problematic region or data center. Enrichment ensures that metric records contain the necessary information to pinpoint failures in distributed systems. Without enrichment, the burden falls on the app code to internally manage this state, integrate it into the logging process, and manually transmit it. Enrichment simplifies this process, seamlessly handling it without affecting the app's logic.

In the case of resiliency, when you add enrichment the following dimensions are added to the outgoing telemetry:

- `error.type`: Low-cardinality version of an exception's information.
- `request.name`: The name of the request.
- `request.dependency.name`: The name of the dependency.

Under the covers, resilience enrichment is built on top of Polly's Telemetry MeteringEnricher. For more information, see [Polly: Metering enrichment ↗](#).

Add resilience enrichment

In addition to registering a resilience pipeline, you can also register resilience enrichment. To add enrichment, call the [AddResilienceEnricher\(IServiceCollection\)](#) extensions method on the `IServiceCollection` instance.

```
C#
```

```
services.AddResilienceEnricher();
```

By calling the `AddResilienceEnricher` extension method, you're adding dimensions on top of the default ones that are built into the underlying Polly library. The following enrichment dimensions are added:

- Exception enrichment based on the [IExceptionSummarizer](#), which provides a mechanism to summarize exceptions for use in telemetry. For more information, see [Exception summarization](#).
- Request metadata enrichment based on [RequestMetadata](#), which holds the request metadata for telemetry. For more information, see [Polly: Telemetry metrics ↗](#).

Use resilience pipeline

To use a configured resilience pipeline, you must get the pipeline from a `ResiliencePipelineProvider< TKey >`. When you added the pipeline earlier, the `key` was of type `string`, so you must get the pipeline from the `ResiliencePipelineProvider< string >`.

C#

```
using ServiceProvider provider = services.BuildServiceProvider();

ResiliencePipelineProvider<string> pipelineProvider =
    provider.GetRequiredService<ResiliencePipelineProvider<string>>();

ResiliencePipeline pipeline = pipelineProvider.GetPipeline(key);
```

The preceding code:

- Builds a `ServiceProvider` from the `ServiceCollection` instance.
- Gets the `ResiliencePipelineProvider< string >` from the service provider.
- Retrieves the `ResiliencePipeline` from the `ResiliencePipelineProvider< string >`.

Execute resilience pipeline

To use the resilience pipeline, call any of the available `Execute*` methods on the `ResiliencePipeline` instance. For example, consider an example call to `ExecuteAsync` method:

C#

```
await pipeline.ExecuteAsync(static cancellationToken =>
{
    // Code that could potentially fail.

    return ValueTask.CompletedTask;
});
```

The preceding code executes the delegate within the `ExecuteAsync` method. When there are failures, the configured strategies are executed. For example, if the `RetryStrategy` is configured to retry three times, the delegate is executed four times (one initial attempt plus three retry attempts) before the failure is propagated.

Network programming in .NET

Article • 10/27/2022

.NET provides a layered, extensible, and managed implementation of Internet services that can be quickly and easily integrated into your apps. Your network apps can build on pluggable protocols to automatically take advantage of various Internet protocols, or they can use a managed implementation of cross-platform socket interfaces to work with the network on the socket level.

Internet apps

Internet apps can be classified broadly into two kinds: client apps that request information and server apps that respond to information requests from clients. The classic Internet client-server app is the World Wide Web, where people use browsers to access documents and other data stored on web servers worldwide.

Apps are not limited to just one of these roles; for instance, the familiar middle-tier app server responds to requests from clients by requesting data from another server, in which case it is acting as both a server and a client.

The client app requests by identifying the requested Internet resource and the communication protocol to use for the request and response. If necessary, the client also provides any additional data required to complete the request, such as proxy location or authentication information (user name, password, and so on). Once the request is formed, the request can be sent to the server.

Identifying resources

.NET uses a uniform resource identifier (URI) to identify the requested Internet resource and communication protocol. The URI consists of at least three, and possibly four, fragments: the scheme identifier, which identifies the communications protocol for the request and response; the server identifier, which consists of either a domain name system (DNS) hostname or a TCP address that uniquely identifies the server on the Internet; the path identifier, which locates the requested information on the server; and an optional query string, which passes information from the client to the server.

The [System.Uri](#) type is used as a representation of a uniform resource identifier (URI) and easy access to the parts of the URI. To create a `Uri` instance you can pass it a string:

C#

```
const string uriString =
    "https://learn.microsoft.com/en-us/dotnet/path?key=value#bookmark";

Uri canonicalUri = new(uriString);
Console.WriteLine(canonicalUri.Host);
Console.WriteLine(canonicalUri.PathAndQuery);
Console.WriteLine(canonicalUri.Fragment);
// Sample output:
//      learn.microsoft.com
//      /en-us/dotnet/path?key=value
//      #bookmark
```

The `Uri` class automatically performs validation and canonicalization per [RFC 3986](#). These validation and canonicalization rules are used to ensure that a URI is well-formed and that the URI is in a canonical form.

Network availability

Article • 08/27/2022

The [System.Net.NetworkInformation](#) namespace enables you to gather information about network events, changes, statistics, and properties. In this article, you'll learn how to use the [System.Net.NetworkInformation.NetworkChange](#) class to determine whether the network address or availability has changed. Additionally, you'll see about the network statistics and properties on an interface or protocol basis. Finally, you'll use the [System.Net.NetworkInformation.Ping](#) class to determine whether a remote host is reachable.

Network change events

The [System.Net.NetworkInformation.NetworkChange](#) class enables you to determine whether the network address or availability has changed. To use this class, create an event handler to process the change, and associate it with a [NetworkAddressChangedEventHandler](#) or a [NetworkAvailabilityChangedEventHandler](#).

C#

```
NetworkChange.NetworkAvailabilityChanged += OnNetworkAvailabilityChanged;

static void OnNetworkAvailabilityChanged(
    object? sender, NetworkAvailabilityEventArgs networkAvailability) =>
    Console.WriteLine($"Network is available:
{networkAvailability.IsAvailable}");

Console.WriteLine(
    "Listening changes in network availability. Press any key to
continue.");
Console.ReadLine();

NetworkChange.NetworkAvailabilityChanged -= OnNetworkAvailabilityChanged;
```

The preceding C# code:

- Registers an event handler for the [NetworkChange.NetworkAvailabilityChanged](#) event.
- The event handler simply writes the availability status to the console.
- A message is written to the console letting the user know that the code is listening for changes in network availability and waits for a key press to exit.
- Unregisters the event handler.

C#

```
NetworkChange.NetworkAddressChanged += OnNetworkAddressChanged;

static void OnNetworkAddressChanged(
    object? sender, EventArgs args)
{
    foreach ((string name, OperationalStatus status) in
        NetworkInterface.GetAllNetworkInterfaces()
            .Select(networkInterface =>
                (networkInterface.Name,
                networkInterface.OperationalStatus)))
    {
        Console.WriteLine(
            $"{name} is {status}");
    }
}

Console.WriteLine(
    "Listening for address changes. Press any key to continue.");
Console.ReadLine();

NetworkChange.NetworkAddressChanged -= OnNetworkAddressChanged;
```

The preceding C# code:

- Registers an event handler for the `NetworkChange.NetworkAddressChanged` event.
- The event handler iterates over `NetworkInterface.GetAllNetworkInterfaces()`, writing their name and operational status to the console.
- A message is written to the console letting the user know that the code is listening for changes in network availability and waits for a key press to exit.
- Unregisters the event handler.

Network statistics and properties

You can gather network statistics and properties on an interface or protocol basis. The `NetworkInterface`, `NetworkInterfaceType`, and `PhysicalAddress` classes give information about a particular network interface, while the `IPInterfaceProperties`, `IPGlobalProperties`, `IPGlobalStatistics`, `TcpStatistics`, and `UdpStatistics` classes give information about layer 3 and layer 4 packets.

C#

```
ShowStatistics(NetworkInterfaceComponent.IPv4);
ShowStatistics(NetworkInterfaceComponent.IPv6);
```

```

static void ShowStatistics(NetworkInterfaceComponent version)
{
    var properties = IPGlobalProperties.GetIPGlobalProperties();
    var stats = version switch
    {
        NetworkInterfaceComponent.IPv4 => properties.GetTcpIPv4Statistics(),
        _ => properties.GetTcpIPv6Statistics()
    };

    Console.WriteLine($"TCP/{version} Statistics");
    Console.WriteLine($"  Minimum Transmission Timeout : {stats.MinimumTransmissionTimeout:#,#}");
    Console.WriteLine($"  Maximum Transmission Timeout : {stats.MaximumTransmissionTimeout:#,#}");
    Console.WriteLine("  Connection Data");
    Console.WriteLine($"    Current : {stats.CurrentConnections:#,#}");
    Console.WriteLine($"    Cumulative : {stats.CumulativeConnections:#,#}");
    Console.WriteLine($"    Initiated : {stats.ConnectionsInitiated:#,#}");
    Console.WriteLine($"    Accepted : {stats.ConnectionsAccepted:#,#}");
    Console.WriteLine($"    Failed Attempts : {stats.FailedConnectionAttempts:#,#}");
    Console.WriteLine($"    Reset : {stats.ResetConnections:#,#}");
    Console.WriteLine("  Segment Data");
    Console.WriteLine($"    Received : {stats.SegmentsReceived:#,#}");
    Console.WriteLine($"    Sent : {stats.SegmentsSent:#,#}");
    Console.WriteLine($"    Retransmitted : {stats.SegmentsResent:#,#}");
    Console.WriteLine();
}

```

The preceding C# code:

- Calls a custom `ShowStatistics` method to display the statistics for each protocol.
- The `ShowStatistics` method calls `IPGlobalProperties.GetIPGlobalProperties()`, and depending on the given `NetworkInterfaceComponent` will either call `IPGlobalProperties.GetIPv4GlobalStatistics()` or `IPGlobalProperties.GetIPv6GlobalStatistics()`.
- The `TcpStatistics` are written to the console.

Determine if a remote host is reachable

You can use the [Ping](#) class to determine whether a remote host is up, on the network, and reachable.

C#

```
using Ping ping = new();

string hostName = "stackoverflow.com";
PingReply reply = await ping.SendPingAsync(hostName);
Console.WriteLine($"Ping status for ({hostName}): {reply.Status}");
if (reply is { Status: IPStatus.Success })
{
    Console.WriteLine($"Address: {reply.Address}");
    Console.WriteLine($"Roundtrip time: {reply.RoundtripTime}");
    Console.WriteLine($"Time to live: {reply.Options?.Ttl}");
    Console.WriteLine();
}
```

The preceding C# code:

- Instantiate a [Ping](#) object.
- Calls [Ping.SendPingAsync\(String\)](#) with the `"stackoverflow.com"` hostname parameter.
- The status of the ping is written to the console.

Internet Protocol version 6 (IPv6) overview

Article • 10/07/2022

The Internet Protocol version 6 (IPv6) is a suite of standard protocols for the network layer of the Internet. IPv6 is designed to solve many of the problems of the current version of the Internet Protocol suite (known as IPv4) about address depletion, security, auto-configuration, extensibility, and so on. IPv6 expands the capabilities of the Internet to enable new kinds of applications, including peer-to-peer and mobile applications.

The following are the main issues of the current IPv4 protocol:

- Rapid depletion of the address space.

This has led to the use of Network Address Translators (NATs) that map multiple private addresses to a single public IP address. The main problems created by this mechanism are processing overhead and lack of end-to-end connectivity.

- Lack of hierarchy support.

Because of its inherent predefined class organization, IPv4 lacks true hierarchical support. It is impossible to structure the IP addresses in a way that truly maps the network topology. This crucial design flaw creates the need for large routing tables to deliver IPv4 packets to any location on the Internet.

- Complex network configuration.

With IPv4, addresses must be assigned statically or using a configuration protocol such as DHCP. In an ideal situation, hosts would not have to rely on the administration of a DHCP infrastructure. Instead, they would be able to configure themselves based on the network segment in which they are located.

- Lack of built-in authentication and confidentiality.

IPv4 does not require support for any mechanism that provides authentication or encryption of the exchanged data. This changes with IPv6. Internet Protocol security (IPSec) is an IPv6 support requirement.

A new protocol suite must satisfy the following basic requirements:

- Large-scale routing and addressing with low overhead.
- Auto-configuration for various connecting situations.
- Built-in authentication and confidentiality.

IPv6 addressing

With IPv6, addresses are 128 bits long. One reason for such a large address space is to subdivide the available addresses into a hierarchy of routing domains that reflect the Internet's topology. Another reason is to map the addresses of network adapters (or interfaces) that connect devices to the network. IPv6 features an inherent capability to resolve addresses at their lowest level, which is at the network interface level, and also has auto-configuration capabilities.

Text representation

The following are the three conventional forms used to represent the IPv6 addresses as text strings:

- **Colon-hexadecimal form:**

This is the preferred form `n:n:n:n:n:n:n:n`. Each `n` represents the hexadecimal value of one of the eight 16-bit elements of the address. For example:

`3FFE:FFFF:7654:FEDA:1245:BA98:3210:4562`.

- **Compressed form:**

Due to the address length, it is common to have addresses containing a long string of zeros. To simplify writing these addresses, use the compressed form, in which a single contiguous sequence of 0 blocks is represented by a double-colon symbol (`::`). This symbol can appear only once in an address. For example, the multicast address `FFED:0:0:0:0:BA98:3210:4562` in compressed form is

`FFED::BA98:3210:4562`. The unicast address `3FFE:FFFF:0:0:8:800:20C4:0` in compressed form is `3FFE:FFFF::8:800:20C4:0`. The loopback address `0:0:0:0:0:0:1` in compressed form is `::1`. The unspecified address `0:0:0:0:0:0:0:0` in compressed form is `::`.

- **Mixed form:**

This form combines IPv4 and IPv6 addresses. In this case, the address format is `n:n:n:n:n:n:d.d.d.d`, where each `n` represents the hexadecimal values of the six IPv6 high-order 16-bit address elements, and each `d` represents the decimal value of an IPv4 address.

Address types

The leading bits in the address define the specific IPv6 address type. The variable-length field containing these leading bits is called a Format Prefix (FP).

An IPv6 unicast address is divided into two parts. The first part contains the address prefix, and the second part contains the interface identifier. A concise way to express an IPv6 address/prefix combination is as follows: ipv6-address/prefix-length.

The following is an example of an address with a 64-bit prefix.

`3FFE:FFFF:0:CD30:0:0:0:0/64`.

The prefix in this example is `3FFE:FFFF:0:CD30`. The address can also be written in a compressed form, as `3FFE:FFFF:0:CD30::/64`.

IPv6 defines the following address types:

- **Unicast address:**

An identifier for a single interface. A packet sent to this address is delivered to the identified interface. The unicast addresses are distinguished from the multicast addresses by the value of the high-order octet. The multicast addresses' high-order octet has the hexadecimal value of FF. Any other value for this octet identifies a unicast address. The following are different types of unicast addresses:

- **Link-local addresses:**

These addresses are used on a single link and have the following format:

`FE80::*InterfaceID*`. Link-local addresses are used between nodes on a link for auto-address configuration, neighbor discovery, or when no routers are present. A link-local address is used primarily at startup and when the system has not yet acquired addresses of larger scope.

- **Site-local addresses:**

These addresses are used on a single site and have the following format:

`FEC0::*SubnetID*::*InterfaceID*`. The site-local addresses are used for addressing inside a site without the need for a global prefix.

- **Global IPv6 unicast addresses:**

These addresses can be used across the Internet and have the following format:

`*GlobalRoutingPrefix*::*SubnetID*::*InterfaceID*`.

- **Multicast address:**

An identifier for a set of interfaces (typically belonging to different nodes). A packet sent to this address is delivered to all the interfaces identified by the address. The multicast address types supersede the IPv4 broadcast addresses.

- **Anycast address:**

An identifier for a set of interfaces (typically belonging to different nodes). A packet sent to this address is delivered to only one interface identified by the address. This is the nearest interface as identified by routing metrics. Anycast addresses are taken from the unicast address space and are not syntactically distinguishable. The addressed interface performs the distinction between unicast and anycast addresses as a function of its configuration.

In general, a node always has a link-local address. It might have a site-local address and one or more global addresses.

IPv6 routing

A flexible routing mechanism is a benefit of IPv6. Due to how IPv4 network IDs were and are allocated, large routing tables need to be maintained by the routers that are on the Internet backbones. These routers must know all the routes to forward packets that are potentially directed to any node on the Internet. With its ability to aggregate addresses, IPv6 allows flexible addressing and drastically reduces the size of routing tables. In this new addressing architecture, intermediate routers must keep track only of the local portion of their network to forward the messages appropriately.

Neighbor discovery

Some of the features provided by *neighbor discovery* are:

- **Router discovery:** This allows hosts to identify local routers.
- **Address resolution:** This allows nodes to resolve a link-layer address for a corresponding next-hop address (a replacement for Address Resolution Protocol [ARP]).
- **Address auto-configuration:** This allows hosts to automatically configure site-local and global addresses.

Neighbor discovery uses Internet Control Message Protocol for IPv6 (ICMPv6) messages that include:

- **Router advertisement:** Sent by a router on a pseudo-periodic basis or in response to a router solicitation. IPv6 routers use router advertisements to advertise their

availability, address prefixes, and other parameters.

- **Router solicitation:** Sent by a host to request that routers on the link send a router advertisement immediately.
- **Neighbor solicitation:** Sent by nodes for address resolution, duplicate address detection, or to verify that a neighbor is still reachable.
- **Neighbor advertisement:** Sent by nodes to respond to a neighbor solicitation or to notify neighbors of a change in link-layer address.
- **Redirect:** Sent by routers to indicate a better next-hop address to a particular destination for a sending node.

IPv6 auto-configuration

One important goal for IPv6 is to support node Plug and Play. That is, it should be possible to plug a node into an IPv6 network and have it automatically configured without any human intervention.

Auto-configuration types

IPv6 supports the following types of auto-configuration:

- **Stateful auto-configuration:**

This type of configuration requires a certain level of human intervention because it needs a Dynamic Host Configuration Protocol for IPv6 (DHCPv6) server for the installation and administration of the nodes. The DHCPv6 server keeps a list of nodes to which it supplies configuration information. It also maintains state information so the server knows how long each address is in use, and when it might be available for reassignment.

- **Stateless auto-configuration:**

This type of configuration is suitable for small organizations and individuals. In this case, each host determines its addresses from the contents of received router advertisements. Using the IEEE EUI-64 standard to define the network ID portion of the address, it is reasonable to assume the uniqueness of the host address on the link.

Regardless of how the address is determined, the node must verify that its potential address is unique to the local link. This is done by sending a neighbor solicitation message to the potential address. If the node receives any response, it knows that the address is already in use and must determine another address.

IPv6 mobility

The proliferation of mobile devices has introduced a new requirement: A device must be able to arbitrarily change locations on the IPv6 Internet and still maintain existing connections. To provide this functionality, a mobile node is assigned a home address at which it can always be reached. When the mobile node is at home, it connects to the home link and uses its home address. When the mobile node is away from home, a home agent, which is usually a router, relays messages between the mobile node and the nodes with which it is communicating.

Disable or enable IPv6

To use the IPv6 protocol, ensure that you are running a version of the operating system that supports IPv6 and ensure that the operating system and the networking classes are configured properly.

Configuration Steps

The following table lists various configurations

| OS IPv6 enabled? | Code IPv6 enabled? | Description |
|------------------|--------------------|--|
| ✗ No | ✗ No | Can parse IPv6 addresses. |
| ✗ No | ✓ Yes | Can parse IPv6 addresses. |
| ✓ Yes | ✗ No | Can parse IPv6 addresses and resolve IPv6 addresses using name resolution methods not marked obsolete. |
| ✓ Yes | ✓ Yes | Can parse and resolve IPv6 addresses using all methods including those marked obsolete. |

IPv6 is enabled by default. To configure this switch in an environment variable, use the `DOTNET_SYSTEM_NET_DISABLEIPV6` environment variable. For more information, see [.NET environment variables: DOTNET_SYSTEM_NET_DISABLEIPV6](#).

Service discovery in .NET

Article • 12/11/2023

In this article, you learn how to use the `Microsoft.Extensions.ServiceDiscovery` library. Service discovery is a way for developers to use logical names instead of physical addresses (IP address and port) to refer to external services.

Get Started

To get started with service discovery in .NET, install the [Microsoft.Extensions.ServiceDiscovery](#) NuGet package.

.NET CLI

.NET CLI

```
dotnet add package Microsoft.Extensions.ServiceDiscovery --prerelease
```

For more information, see [dotnet add package](#) or [Manage package dependencies in .NET applications](#).

Example usage

In the `Program.cs` file of your project, call the [AddServiceDiscovery](#) extension method to add service discovery to the host, configuring default service endpoint resolvers:

C#

```
builder.Services.AddServiceDiscovery();
```

Add service discovery to an individual [IHttpClientBuilder](#) by calling the [UseServiceDiscovery](#) extension method:

C#

```
builder.Services.AddHttpClient<CatalogServiceClient>(static client =>
{
    client.BaseAddress = new("http://catalog");
})
.UseServiceDiscovery();
```

Alternatively, you can add service discovery to all [HttpClient](#) instances by default:

C#

```
builder.Services.ConfigureHttpClientDefaults(static http =>
{
    // Turn on service discovery by default
    http.UseServiceDiscovery();
});
```

Resolve service endpoints from configuration

The [AddServiceDiscovery](#) extension method adds a configuration-based endpoint resolver by default. This resolver reads endpoints from the [.NET configuration system](#). The library supports configuration through *appsettings.json*, environment variables, or any other [IConfiguration](#) source.

Here's an example demonstrating how to configure endpoints for the service named *catalog* via [appsettings.json](#):

JSON

```
{
  "Services": {
    "catalog": [
      "localhost:8080",
      "10.46.24.90:80",
    ]
  }
}
```

The preceding example adds two endpoints for the service named *catalog*: `localhost:8080`, and `"10.46.24.90:80"`. Each time the *catalog* is resolved, one of these endpoints is selected.

If service discovery was added to the host using the [AddServiceDiscoveryCore](#) extension method on [IServiceCollection](#), the configuration-based endpoint resolver can be added by calling the [AddConfigurationServiceEndPointResolver](#) extension method on [IServiceCollection](#).

Configuration

The configuration resolver is configured using the [ConfigurationServiceEndPointOptionsResolver](#) class, which offers these configuration

options:

- **SectionName**: The name of the configuration section that contains service endpoints. It defaults to "Services".
- **ApplyHostNameMetadata**: A delegate used to determine if host name metadata should be applied to resolved endpoints. It defaults to a function that returns `false`.

To configure these options, you can use the `Configure` extension method on the `IServiceCollection` within your application's `Startup` class or `Program` file:

C#

```
var builder = WebApplication.CreateBuilder(args);

builder.Services.Configure<ConfigurationServiceEndPointResolverOptions>(
    static options =>
{
    options.SectionName = "MyServiceEndpoints";

    // Configure the logic for applying host name metadata
    options.ApplyHostNameMetadata = static endpoint =>
    {
        // Your custom logic here. For example:
        return endpoint.EndPoint is DnsEndPoint dnsEp
            && dnsEp.Host.StartsWith("internal");
    };
});
```

The preceding example demonstrates setting a custom section name for your service endpoints and providing custom conditional logic for applying host name metadata.

Resolve service endpoints using platform-provided service discovery

Certain platforms, like Azure Container Apps and Kubernetes (when configured accordingly), offer service discovery capabilities without necessitating a service discovery client library. In cases where an application is deployed in such environments, using the platform's built-in functionality can be advantageous. The pass-through resolver is designed to facilitate this scenario. It enables the utilization of alternative resolvers, such as configuration, in different environments, such as a developer's machine. Importantly, this flexibility is achieved without the need for any code modifications or the implementation of conditional guards.

The pass-through resolver performs no external resolution and instead resolves endpoints by returning the input service name represented as a [DnsEndPoint](#).

The pass-through provider is configured by-default when adding service discovery via the `AddServiceDiscovery` extension method.

If service discovery was added to the host using the `AddServiceDiscoveryCore` extension method on `IServiceCollection`, the pass-through provider can be added by calling the `AddPassThroughServiceEndPointResolver` extension method on `IServiceCollection`.

Load-balancing with endpoint selectors

Each time an endpoint is resolved via the `HttpClient` pipeline, a single endpoint is selected from the set of all known endpoints for the requested service. If multiple endpoints are available, it may be desirable to balance traffic across all such endpoints. To accomplish this, a customizable *endpoint selector* can be used. By default, endpoints are selected in round-robin order. To use a different endpoint selector, provide an `IServiceEndPointSelector` instance to the [UseServiceDiscovery](#) method call. For example, to select a random endpoint from the set of resolved endpoints, specify `RandomServiceEndPointSelectorProvider.Instance` as the endpoint selector:

```
C#
```

```
builder.Services.AddHttpClient<CatalogServiceClient>(
    static client => client.BaseAddress = new("http://catalog")
)
.UseServiceDiscovery(RandomServiceEndPointSelectorProvider.Instance);
```

The `Microsoft.Extensions.ServiceDiscovery` package includes the following endpoint selector providers:

- `PickFirstServiceEndPointSelectorProvider.Instance`: Pick-first, which always selects the first endpoint.
- `RoundRobinServiceEndPointSelectorProvider.Instance`: Round-robin, which cycles through endpoints.
- `RandomServiceEndPointSelectorProvider.Instance`: Random, which selects endpoints randomly.
- `PowerOfTwoChoicesServiceEndPointSelectorProvider.Instance`: Power-of-two-choices, which attempt to pick the least used endpoint based on the *Power of Two Choices* algorithm for distributed load balancing, degrading to randomly selecting an endpoint when either of the provided endpoints don't have the `IEndPointLoadFeature` feature.

Endpoint selectors are created via an `IServiceEndPointSelectorProvider` instance, such as the providers previously listed. The provider's `CreateSelector()` method is called to create a selector, which is an instance of `IServiceEndPointSelector`. The `IServiceEndPointSelector` instance is given the set of known endpoints when they're resolved, using the `IServiceEndPointSelector.SetEndPoints` method. To choose an endpoint from the collection, the `IServiceEndPointSelector.GetEndPoint` method is called, returning a single `ServiceEndPoint`. The `context` value passed to `GetEndPoint` is used to provide extra context that may be useful to the selector. For example, in the `HttpClient` case, the `HttpRequestMessage` is passed. None of the provided implementations of `IServiceEndPointSelector` inspect the context, and it can be ignored unless you're using a selector, which does make use of it.

Resolution order

When service endpoints are being resolved, each registered resolver is called in the order of registration and given the opportunity to modify the collection of `ServiceEndPoints` which are returned back to the caller. The providers included in the `Microsoft.Extensions.ServiceDiscovery` series of packages skip resolution if there are existing endpoints in the collection when they're called. For example, consider a case where the following providers are registered: *Configuration, DNS SRV, Pass-through*. When resolution occurs, the providers are called in-order. If the *Configuration* providers discover no endpoints, the *DNS SRV* provider performs resolution and may add one or more endpoints. If the *DNS SRV* provider adds an endpoint to the collection, the *Pass-through* provider skips its resolution and returns immediately instead.

HTTP support in .NET

Article • 05/22/2023

Hypertext Transfer Protocol (or HTTP) is a protocol for requesting resources from a web server. The [System.Net.Http.HttpClient](#) class exposes the ability to send HTTP requests and receive HTTP responses from a resource identified by a URI. Many types of resources are available on the web, and HTTP defines a set of request methods for accessing these resources.

HTTP request methods

The request methods are differentiated via several factors, first by their *verb* but also by the following characteristics:

- A request method is *idempotent* if it can be successfully processed multiple times without changing the result. For more information, see [RFC 9110: 9.2.2. Idempotent Methods](#).
- A request method is *cacheable* when its corresponding response can be stored for reuse. For more information, see [RFC 9110: Section 9.2.3. Methods and Caching](#).
- A request method is considered a *safe method* if it doesn't modify the state of a resource. All *safe methods* are also *idempotent*, but not all *idempotent* methods are considered *safe*. For more information, see [RFC 9110: Section 9.2.1. Safe Methods](#).

| HTTP method | Is idempotent | Is cacheable | Is safe |
|-------------|---------------|-----------------------|---------|
| GET | ✓ Yes | ✓ Yes | ✓ Yes |
| POST | ✗ No | ⚠ [†] Rarely | ✗ No |
| PUT | ✓ Yes | ✗ No | ✗ No |
| PATCH | ✗ No | ✗ No | ✗ No |
| DELETE | ✓ Yes | ✗ No | ✗ No |
| HEAD | ✓ Yes | ✓ Yes | ✓ Yes |
| OPTIONS | ✓ Yes | ✗ No | ✓ Yes |
| TRACE | ✓ Yes | ✗ No | ✓ Yes |
| CONNECT | ✗ No | ✗ No | ✗ No |

[†]The `POST` method is only cacheable when the appropriate `Cache-Control` or `Expires` response headers are present. This is very uncommon in practice.

HTTP status codes

.NET provides comprehensive support for the HTTP protocol, which accounts for most internet traffic, with the `HttpClient`. For more information, see [Make HTTP requests with the HttpClient class](#). Applications receive HTTP protocol errors by catching an `HttpRequestException`. HTTP status codes are either reported in `HttpResponseMessage` with the `HttpResponseMessage.StatusCode` or in `HttpRequestException` with the `HttpRequestException.StatusCode` in case the called method doesn't return a response message. For more information about error handling, see [HTTP error handling](#), and for more information about status codes, see [RFC 9110, HTTP Semantics: Status Codes](#).

Informational status codes

The informational status codes reflect an interim response. Most of the interim responses, for example `StatusCode.Continue`, are handled internally with `HttpClient` and are never surfaced to the user.

| HTTP status code | <code>HttpStatusCode</code> |
|------------------|--|
| 100 | <code>(HttpStatusCode.Continue)</code> |
| 101 | <code>(HttpStatusCode.SwitchingProtocols)</code> |
| 102 | <code>(HttpStatusCode.Processing)</code> |
| 103 | <code>(HttpStatusCode.EarlyHints)</code> |

Successful status codes

The successful status codes indicate that the client's request was successfully received, understood, and accepted.

| HTTP status code | <code>HttpStatusCode</code> |
|------------------|---|
| 200 | <code>(HttpStatusCode.OK)</code> |
| 201 | <code>(HttpStatusCode.Created)</code> |
| 202 | <code>(HttpStatusCode.Accepted)</code> |
| 203 | <code>(HttpStatusCode.NonAuthoritativeInformation)</code> |

| | |
|-------------------------|--------------------------------|
| HTTP status code | HttpStatusCode |
| 204 | HttpStatusCode.NoContent |
| 205 | HttpStatusCode.ResetContent |
| 206 | HttpStatusCode.PartialContent |
| 207 | HttpStatusCode.MultiStatus |
| 208 | HttpStatusCode.AlreadyReported |
| 226 | HttpStatusCode.IMUsed |

Redirection status codes

Redirection status codes require the user agent to take action to fulfill the request. Automatic redirection is turned on by default, it can be changed with [HttpClientHandler.AllowAutoRedirect](#) or [SocketsHttpHandler.AllowAutoRedirect](#).

| | |
|-------------------------|---|
| HTTP status code | HttpStatusCode |
| 300 | HttpStatusCode.MultipleChoices or HttpStatusCode.Ambiguous |
| 301 | HttpStatusCode.MovedPermanently or HttpStatusCode.Moved |
| 302 | HttpStatusCode.Found or HttpStatusCode.Redirect |
| 303 | HttpStatusCode.SeeOther or HttpStatusCode.RedirectMethod |
| 304 | HttpStatusCode.NotModified |
| 305 | HttpStatusCode.UseProxy |
| 306 | HttpStatusCode.Unused |
| 307 | HttpStatusCode.TemporaryRedirect or HttpStatusCode.RedirectKeepVerb |
| 308 | HttpStatusCode.PermanentRedirect |

Client error status codes

The client error status codes indicate that the client's request was invalid.

| | |
|-------------------------|-----------------------------|
| HTTP status code | HttpStatusCode |
| 400 | HttpStatusCode.BadRequest |
| 401 | HttpStatusCode.Unauthorized |

| HTTP status code | HttpStatusCode |
|------------------|---|
| 402 | HttpStatusCode.PaymentRequired |
| 403 | HttpStatusCode.Forbidden |
| 404 | HttpStatusCode.NotFound |
| 405 | HttpStatusCode.MethodNotAllowed |
| 406 | HttpStatusCode.NotAcceptable |
| 407 | HttpStatusCode.ProxyAuthenticationRequired |
| 408 | HttpStatusCode.RequestTimeout |
| 409 | HttpStatusCode.Conflict |
| 410 | HttpStatusCode.Gone |
| 411 | HttpStatusCode.LengthRequired |
| 412 | HttpStatusCode.PreconditionFailed |
| 413 | HttpStatusCode.RequestEntityTooLarge |
| 414 | HttpStatusCode.RequestUriTooLong |
| 415 | HttpStatusCode.UnsupportedMediaType |
| 416 | HttpStatusCode.RequestedRangeNotSatisfiable |
| 417 | HttpStatusCode.ExpectationFailed |
| 418 | I'm a teapot ↴ □ |
| 421 | HttpStatusCode.MisdirectedRequest |
| 422 | HttpStatusCode.UnprocessableEntity |
| 423 | HttpStatusCode.Locked |
| 424 | HttpStatusCode.FailedDependency |
| 426 | HttpStatusCode.UpgradeRequired |
| 428 | HttpStatusCode.PreconditionRequired |
| 429 | HttpStatusCode.TooManyRequests |
| 431 | HttpStatusCode.RequestHeaderFieldsTooLarge |
| 451 | HttpStatusCode.UnavailableForLegalReasons |

HTTP status code

HttpStatusCode

Server error status codes

The server error status codes indicate that the server encountered an unexpected condition that prevented it from fulfilling the request.

| HTTP status code | HttpStatusCode |
|------------------|--|
| 500 | HttpStatusCode.InternalServerError |
| 501 | HttpStatusCode.NotImplemented |
| 502 | HttpStatusCode.BadGateway |
| 503 | HttpStatusCode.ServiceUnavailable |
| 504 | HttpStatusCode.GatewayTimeout |
| 505 | HttpStatusCode.HttpVersionNotSupported |
| 506 | HttpStatusCode.VariantAlsoNegotiates |
| 507 | HttpStatusCode.InsufficientStorage |
| 508 | HttpStatusCode.LoopDetected |
| 510 | HttpStatusCode.NotExtended |
| 511 | HttpStatusCode.NetworkAuthenticationRequired |

Guidelines for using HttpClient

Article • 09/01/2023

The [System.Net.Http.HttpClient](#) class sends HTTP requests and receives HTTP responses from a resource identified by a URI. An [HttpClient](#) instance is a collection of settings that's applied to all requests executed by that instance, and each instance uses its own connection pool, which isolates its requests from others. Starting in .NET Core 2.1, the [SocketsHttpHandler](#) class provides the implementation, making behavior consistent across all platforms.

DNS behavior

[HttpClient](#) only resolves DNS entries when a connection is created. It does not track any time to live (TTL) durations specified by the DNS server. If DNS entries change regularly, which can happen in some scenarios, the client won't respect those updates. To solve this issue, you can limit the lifetime of the connection by setting the [PooledConnectionLifetime](#) property, so that DNS lookup is repeated when the connection is replaced. Consider the following example:

C#

```
var handler = new SocketsHttpHandler
{
    PooledConnectionLifetime = TimeSpan.FromMinutes(15) // Recreate every 15
    minutes
};
var sharedClient = new HttpClient(handler);
```

The preceding `HttpClient` is configured to reuse connections for 15 minutes. After the timespan specified by [PooledConnectionLifetime](#) has elapsed, the connection is closed and a new one is created.

Pooled connections

The connection pool for an [HttpClient](#) is linked to the underlying [SocketsHttpHandler](#). When the [HttpClient](#) instance is disposed, it disposes all existing connections inside the pool. If you later send a request to the same server, a new connection must be recreated. As a result, there's a performance penalty for unnecessary connection creation. Moreover, TCP ports are not released immediately after connection closure. (For more information on that, see TCP `TIME-WAIT` in [RFC 9293](#).) If the rate of requests

is high, the operating system limit of available ports might be exhausted. To avoid port exhaustion problems, we [recommend](#) reusing `HttpClient` instances for as many HTTP requests as possible.

Recommended use

To summarize recommended `HttpClient` use in terms of lifetime management, you should use either *long-lived* clients and set `PooledConnectionLifetime` (.NET Core and .NET 5+) or *short-lived* clients created by `IHttpClientFactory`.

- In .NET Core and .NET 5+:
 - Use a `static` or *singleton* `HttpClient` instance with `PooledConnectionLifetime` set to the desired interval, such as 2 minutes, depending on expected DNS changes. This solves both the port exhaustion and DNS changes problems without adding the overhead of `IHttpClientFactory`. If you need to be able to mock your handler, you can register it separately.

💡 Tip

If you only use a limited number of `HttpClient` instances, that's also an acceptable strategy. What matters is that they're not created and disposed with each request, as they each contain a connection pool. Using more than one instance is necessary for scenarios with multiple proxies or to separate cookie containers without completely disabling cookie handling.

- Using `IHttpClientFactory`, you can have multiple, differently configured clients for different use cases. However, be aware that the factory-created clients are intended to be short-lived, and once the client is created, the factory no longer has control over it.

The factory pools `HttpMessageHandler` instances, and, if its lifetime hasn't expired, a handler can be reused from the pool when the factory creates a new `HttpClient` instance. This reuse avoids any socket exhaustion issues.

If you desire the configurability that `IHttpClientFactory` provides, we recommend using the [typed-client approach](#).

- In .NET Framework, use `IHttpClientFactory` to manage your `HttpClient` instances. If you don't use the factory and instead create a new client instance for each request yourself, you can exhaust available ports.

💡 Tip

If your app requires cookies, consider disabling automatic cookie handling or avoiding `IHttpClientFactory`. Pooling the `HttpMessageHandler` instances results in sharing of `CookieContainer` objects. Unanticipated `CookieContainer` object sharing often results in incorrect code.

For more information about managing `HttpClient` lifetime with `IHttpClientFactory`, see [IHttpClientFactory guidelines](#).

Resilience policies with static clients

It's possible to configure a `static` or `singleton` client to use any number of resilience policies using the following pattern:

C#

```
using System;
using System.Net.Http;
using Microsoft.Extensions.Http;
using Polly;
using Polly.Extensions.Http;

var retryPolicy = HttpPolicyExtensions
    .HandleTransientHttpError()
    .WaitAndRetryAsync(3, retryAttempt => TimeSpan.FromSeconds(Math.Pow(2,
retryAttempt)));

var socketHandler = new SocketsHttpHandler { PooledConnectionLifetime =
TimeSpan.FromMinutes(15) };
var policyHandler = new PolicyHttpMessageHandler(retryPolicy)
{
    InnerHandler = socketHandler,
};

var httpClient = new HttpClient(policyHandler);
```

The preceding code:

- Relies on [Microsoft.Extensions.Http.Polly](#) NuGet package, transitively the [Polly.Extensions.Http](#) NuGet package for the `HttpPolicyExtensions` type.
- Specifies a transient HTTP error handler, configured with retry policy that with each attempt will exponentially backoff delay intervals.
- Defines a pooled connection lifetime of fifteen minutes for the `socketHandler`.
- Passes the `socketHandler` to the `policyHandler` with the retry logic.

- Instantiates an `HttpClient` given the `policyHandler`.

Make HTTP requests with the HttpClient class

Article • 11/02/2023

In this article, you'll learn how to make HTTP requests and handle responses with the `HttpClient` class.

ⓘ Important

All of the example HTTP requests target one of the following URLs:

- <https://jsonplaceholder.typicode.com>: Free fake API for testing and prototyping.
- <https://www.example.com>: This domain is for use in illustrative examples in documents.

HTTP endpoints commonly return JavaScript Object Notation (JSON) data, but not always. For convenience, the optional [System.Net.Http.Json](#) NuGet package provides several extension methods for `HttpClient` and `HttpContent` that perform automatic serialization and deserialization using `System.Text.Json`. The examples that follow call attention to places where these extensions are available.

💡 Tip

All of the source code from this article is available in the [GitHub: .NET Docs](#) repository.

Create an `HttpClient`

Most of the following examples reuse the same `HttpClient` instance, and therefore only need to be configured once. To create an `HttpClient`, use the `HttpClient` class constructor. For more information, see [Guidelines for using HttpClient](#).

C#

```
// HttpClient lifecycle management best practices:  
//  
https://learn.microsoft.com/dotnet/fundamentals/networking/http/httpclient-guidelines#recommended-use
```

```
private static HttpClient sharedClient = new()
{
    BaseAddress = new Uri("https://jsonplaceholder.typicode.com"),
};
```

The preceding code:

- Instantiates a new `HttpClient` instance as a `static` variable. As per the [guidelines](#), it's recommended to reuse `HttpClient` instances during the application's lifecycle.
- Sets the `HttpClient.BaseAddress` to `"https://jsonplaceholder.typicode.com"`.

This `HttpClient` instance uses the base address when making subsequent requests. To apply other configuration, consider:

- Setting `HttpClient.DefaultRequestHeaders`.
- Applying a nondefault `HttpClient.Timeout`.
- Specifying the `HttpClient.DefaultRequestVersion`.

Tip

Alternatively, you can create `HttpClient` instances using a factory-pattern approach that allows you to configure any number of clients and consume them as dependency injection services. For more information, see [HTTP client factory with .NET](#).

Make an HTTP request

To make an HTTP request, you call any of the following APIs:

| HTTP method | API |
|-------------|--|
| GET | HttpClient.GetAsync |
| GET | HttpClient.GetByteArrayAsync |
| GET | HttpClient.GetStreamAsync |
| GET | HttpClient.GetStringAsync |
| POST | HttpClient.PostAsync |
| PUT | HttpClient.PutAsync |
| PATCH | HttpClient.PatchAsync |

| HTTP method | API |
|-----------------------------|-------------------------------------|
| DELETE | <code>HttpClient.DeleteAsync</code> |
| [†] USER SPECIFIED | <code>HttpClient.SendAsync</code> |

[†]A `USER SPECIFIED` request indicates that the `SendAsync` method accepts any valid `HttpMethod`.

⚠ Warning

Making HTTP requests is considered network I/O-bound work. While there is a synchronous `HttpClient.Send` method, it is recommended to use the asynchronous APIs instead, unless you have good reason not to.

HTTP content

The `HttpContent` type is used to represent an HTTP entity body and corresponding content headers. For HTTP methods (or request methods) that require a body, `POST`, `PUT`, and `PATCH`, you use the `HttpContent` class to specify the body of the request. Most examples show how to prepare the `StringContent` subclass with a JSON payload, but other subclasses exist for different [content \(MIME\) types](#).

- `ByteArrayContent`: Provides HTTP content based on a byte array.
- `FormUrlEncodedContent`: Provides HTTP content for name/value tuples encoded using `"application/x-www-form-urlencoded"` MIME type.
- `JsonContent`: Provides HTTP content based on JSON.
- `MultipartContent`: Provides a collection of `HttpContent` objects that get serialized using the `"multipart/*"` MIME type specification.
- `MultipartFormDataContent`: Provides a container for content encoded using `"multipart/form-data"` MIME type.
- `ReadOnlyMemoryContent`: Provides HTTP content based on a `ReadOnlyMemory<T>`.
- `StreamContent`: Provides HTTP content based on a stream.
- `StringContent`: Provides HTTP content based on a string.

The `HttpContent` class is also used to represent the response body of the `HttpResponseMessage`, accessible on the `HttpResponseMessage.Content` property.

HTTP Get

A `GET` request shouldn't send a body and is used (as the method name indicates) to retrieve (or get) data from a resource. To make an HTTP `GET` request, given an `HttpClient` and a URI, use the `HttpClient.GetAsync` method:

C#

```
static async Task GetAsync(HttpClient httpClient)
{
    using HttpResponseMessage response = await
httpClient.GetAsync("todos/3");

    response.EnsureSuccessStatusCode()
    .WriteRequestToConsole();

    var jsonResponse = await response.Content.ReadAsStringAsync();
    Console.WriteLine($"{jsonResponse}\n");

    // Expected output:
    //   GET https://jsonplaceholder.typicode.com/todos/3 HTTP/1.1
    //   {
    //     "userId": 1,
    //     "id": 3,
    //     "title": "fugiat veniam minus",
    //     "completed": false
    //   }
}
```

The preceding code:

- Makes a `GET` request to "`https://jsonplaceholder.typicode.com/todos/3`".
- Ensures that the response is successful.
- Writes the request details to the console.
- Reads the response body as a string.
- Writes the JSON response body to the console.

The `WriteRequestToConsole` is a custom extension method that isn't part of the framework, but if you're curious about how it's implemented, consider the following C# code:

C#

```
static class HttpResponseMessageExtensions
{
    internal static void WriteRequestToConsole(this HttpResponseMessage
response)
    {
        if (response is null)
        {
            return;
        }

        // Implementation of WriteRequestToConsole goes here
    }
}
```

```
        }

        var request = response.RequestMessage;
        Console.Write($"{request?.Method} ");
        Console.Write($"{request?.RequestUri} ");
        Console.WriteLine($"HTTP/{request?.Version}");

    }
}
```

This functionality is used to write the request details to the console in the following form:

```
<HTTP Request Method> <Request URI> <HTTP/Version>
```

As an example, the `GET` request to `https://jsonplaceholder.typicode.com/todos/3` outputs the following message:

Output

```
GET https://jsonplaceholder.typicode.com/todos/3 HTTP/1.1
```

HTTP Get from JSON

The <https://jsonplaceholder.typicode.com/todos> endpoint returns a JSON array of "todo" objects. Their JSON structure resembles the following:

JSON

```
[
  {
    "userId": 1,
    "id": 1,
    "title": "example title",
    "completed": false
  },
  {
    "userId": 1,
    "id": 2,
    "title": "another example title",
    "completed": true
  }
]
```

The C# `Todo` object is defined as follows:

C#

```
public record class Todo(
    int? UserId = null,
    int? Id = null,
    string? Title = null,
    bool? Completed = null);
```

It's a `record class` type, with optional `Id`, `Title`, `Completed`, and `UserId` properties. For more information on the `record` type, see [Introduction to record types in C#](#). To automatically deserialize `GET` requests into strongly-typed C# object, use the `GetFromJsonAsync` extension method that's part of the [System.Net.Http.Json](#) NuGet package.

C#

```
static async Task GetFromJsonAsync(HttpClient httpClient)
{
    var todos = await httpClient.GetFromJsonAsync<List<Todo>>(
        "todos?userId=1&completed=false");

    Console.WriteLine("GET https://jsonplaceholder.typicode.com/todos?
userId=1&completed=false HTTP/1.1");
    todos.ForEach(Console.WriteLine);
    Console.WriteLine();

    // Expected output:
    //   GET https://jsonplaceholder.typicode.com/todos?
    userId=1&completed=false HTTP/1.1
    //   Todo { UserId = 1, Id = 1, Title = delectus aut autem, Completed =
    False }
    //   Todo { UserId = 1, Id = 2, Title = quis ut nam facilis et officia
    qui, Completed = False }
    //   Todo { UserId = 1, Id = 3, Title = fugiat veniam minus, Completed =
    False }
    //   Todo { UserId = 1, Id = 5, Title = laboriosam mollitia et enim
    quasi adipisci quia provident illum, Completed = False }
    //   Todo { UserId = 1, Id = 6, Title = qui ullam ratione quibusdam
    voluptatem quia omnis, Completed = False }
    //   Todo { UserId = 1, Id = 7, Title = illo expedita consequatur quia
    in, Completed = False }
    //   Todo { UserId = 1, Id = 9, Title = molestiae perspiciatis ipsa,
    Completed = False }
    //   Todo { UserId = 1, Id = 13, Title = et doloremque nulla, Completed
    = False }
    //   Todo { UserId = 1, Id = 18, Title = dolorum est consequatur ea
    mollitia in culpa, Completed = False }
}
```

In the preceding code:

- A `GET` request is made to `"https://jsonplaceholder.typicode.com/todos?userId=1&completed=false"`.
 - The query string represents the filtering criteria for the request.
- The response is automatically deserialized into a `List<Todo>` when successful.
- The request details are written to the console, along with each `Todo` object.

HTTP Post

A `POST` request sends data to the server for processing. The `Content-Type` header of the request signifies what **MIME type** the body is sending. To make an HTTP `POST` request, given an `HttpClient` and a `Uri`, use the `HttpClient.PostAsync` method:

C#

```
static async Task PostAsync(HttpClient httpClient)
{
    using StringContent jsonContent = new(
        JsonSerializer.Serialize(new
        {
            userId = 77,
            id = 1,
            title = "write code sample",
            completed = false
        }),
        Encoding.UTF8,
        "application/json");

    using HttpResponseMessage response = await httpClient.PostAsync(
        "todos",
        jsonContent);

    response.EnsureSuccessStatusCode()
        .WriteRequestToConsole();

    var jsonResponse = await response.Content.ReadAsStringAsync();
    Console.WriteLine($"{jsonResponse}\n");

    // Expected output:
    // POST https://jsonplaceholder.typicode.com/todos HTTP/1.1
    // {
    //     "userId": 77,
    //     "id": 201,
    //     "title": "write code sample",
    //     "completed": false
    // }
}
```

The preceding code:

- Prepares a `StringContent` instance with the JSON body of the request (MIME type of `"application/json"`).
- Makes a `POST` request to `"https://jsonplaceholder.typicode.com/todos"`.
- Ensures that the response is successful, and writes the request details to the console.
- Writes the response body as a string to the console.

HTTP Post as JSON

To automatically serialize `POST` request arguments and deserialize responses into strongly-typed C# objects, use the `PostAsJsonAsync` extension method that's part of the [System.Net.Http.Json](#) NuGet package.

C#

```
static async Task PostAsJsonAsync(HttpClient httpClient)
{
    using HttpResponseMessage response = await httpClient.PostAsJsonAsync(
        "todos",
        new Todo(UserId: 9, Id: 99, Title: "Show extensions", Completed:
false));

    response.EnsureSuccessStatusCode()
        .WriteRequestToConsole();

    var todo = await response.Content.ReadFromJsonAsync<Todo>();
    Console.WriteLine($"{todo}\n");

    // Expected output:
    // POST https://jsonplaceholder.typicode.com/todos HTTP/1.1
    // Todo { UserId = 9, Id = 201, Title = Show extensions, Completed =
False }
}
```

The preceding code:

- Serializes the `Todo` instance as JSON, and makes a `POST` request to `"https://jsonplaceholder.typicode.com/todos"`.
- Ensures that the response is successful, and writes the request details to the console.
- Deserializes the response body into a `Todo` instance, and writes the `Todo` to the console.

HTTP Put

The `PUT` request method either replaces an existing resource or creates a new one using request body payload. To make an HTTP `PUT` request, given an `HttpClient` and a URI, use the `HttpClient.PutAsync` method:

C#

```
static async Task PutAsync(HttpClient httpClient)
{
    using StringContent jsonContent = new(
        JsonSerializer.Serialize(new
        {
            userId = 1,
            id = 1,
            title = "foo bar",
            completed = false
        }),
        Encoding.UTF8,
        "application/json");

    using HttpResponseMessage response = await httpClient.PutAsync(
        "todos/1",
        jsonContent);

    response.EnsureSuccessStatusCode()
        .WriteRequestToConsole();

    var jsonResponse = await response.Content.ReadAsStringAsync();
    Console.WriteLine($"{jsonResponse}\n");

    // Expected output:
    //   PUT https://jsonplaceholder.typicode.com/todos/1 HTTP/1.1
    //   {
    //     "userId": 1,
    //     "id": 1,
    //     "title": "foo bar",
    //     "completed": false
    //   }
}
```

The preceding code:

- Prepares a `StringContent` instance with the JSON body of the request (MIME type of `"application/json"`).
- Makes a `PUT` request to `"https://jsonplaceholder.typicode.com/todos/1"`.
- Ensures that the response is successful, and writes the request details and JSON response body to the console.

HTTP Put as JSON

To automatically serialize `PUT` request arguments and deserialize responses into strongly typed C# objects, use the [PutAsJsonAsync](#) extension method that's part of the [System.Net.Http.Json](#) NuGet package.

C#

```
static async Task PutAsJsonAsync(HttpClient httpClient)
{
    using HttpResponseMessage response = await httpClient.PutAsJsonAsync(
        "todos/5",
        new Todo(Title: "partially update todo", Completed: true));

    response.EnsureSuccessStatusCode()
        .WriteRequestToConsole();

    var todo = await response.Content.ReadFromJsonAsync<Todo>();
    Console.WriteLine($"{todo}\n");

    // Expected output:
    //   PUT https://jsonplaceholder.typicode.com/todos/5 HTTP/1.1
    //   Todo { UserId = , Id = 5, Title = partially update todo, Completed
    = True }
}
```

The preceding code:

- Serializes the `Todo` instance as JSON, and makes a `PUT` request to `"https://jsonplaceholder.typicode.com/todos/5"`.
- Ensures that the response is successful, and writes the request details to the console.
- Deserializes the response body into a `Todo` instance, and writes the `Todo` to the console.

HTTP Patch

The `PATCH` request is a partial update to an existing resource. It doesn't create a new resource, and it's not intended to replace an existing resource. Instead, it updates a resource only partially. To make an HTTP `PATCH` request, given an `HttpClient` and a URI, use the [HttpClient.PatchAsync](#) method:

C#

```
static async Task PatchAsync(HttpClient httpClient)
{
    using StringContent jsonContent = new(
        JsonSerializer.Serialize(new
    {
```

```

        completed = true
    }),
    Encoding.UTF8,
    "application/json");

    using HttpResponseMessage response = await httpClient.PatchAsync(
        "todos/1",
        jsonContent);

    response.EnsureSuccessStatusCode()
    .WriteRequestToConsole();

    var jsonResponse = await response.Content.ReadAsStringAsync();
    Console.WriteLine($"{{jsonResponse}}\n");

    // Expected output
    // PATCH https://jsonplaceholder.typicode.com/todos/1 HTTP/1.1
    // {
    //   "userId": 1,
    //   "id": 1,
    //   "title": "delectus aut autem",
    //   "completed": true
    // }
}

```

The preceding code:

- Prepares a `StringContent` instance with the JSON body of the request (MIME type of `"application/json"`).
- Makes a `PATCH` request to `"https://jsonplaceholder.typicode.com/todos/1"`.
- Ensures that the response is successful, and writes the request details and JSON response body to the console.

No extension methods exist for `PATCH` requests in the `System.Net.Http.Json` NuGet package.

HTTP Delete

A `DELETE` request deletes an existing resource. A `DELETE` request is *idempotent* but not *safe*, meaning multiple `DELETE` requests to the same resources yield the same result, but the request affects the state of the resource. To make an HTTP `DELETE` request, given an `HttpClient` and a URI, use the `HttpClient.DeleteAsync` method:

C#

```

static async Task DeleteAsync(HttpClient httpClient)
{
    using HttpResponseMessage response = await

```

```
httpClient.DeleteAsync("todos/1");

response.EnsureSuccessStatusCode()
    .WriteRequestToConsole();

var jsonResponse = await response.Content.ReadAsStringAsync();
Console.WriteLine($"{jsonResponse}\n");

// Expected output
// DELETE https://jsonplaceholder.typicode.com/todos/1 HTTP/1.1
// {}
}
```

The preceding code:

- Makes a `DELETE` request to `"https://jsonplaceholder.typicode.com/todos/1"`.
- Ensures that the response is successful, and writes the request details to the console.

Tip

The response to a `DELETE` request (just like a `PUT` request) may or may not include a body.

HTTP Head

The `HEAD` request is similar to a `GET` request. Instead of returning the resource, it only returns the headers associated with the resource. A response to the `HEAD` request doesn't return a body. To make an HTTP `HEAD` request, given an `HttpClient` and a URI, use the `HttpClient.SendAsync` method with the `HttpMethod` set to `HttpMethod.Head`:

C#

```
static async Task HeadAsync(HttpClient httpClient)
{
    using HttpRequestMessage request = new(
        HttpMethod.Head,
        "https://www.example.com");

    using HttpResponseMessage response = await
    httpClient.SendAsync(request);

    response.EnsureSuccessStatusCode()
        .WriteRequestToConsole();

    foreach (var header in response.Headers)
    {
```

```

        Console.WriteLine($"{header.Key}: {string.Join(", ", header.Value)}");
    }
    Console.WriteLine();

    // Expected output:
    // HEAD https://www.example.com/ HTTP/1.1
    // Accept-Ranges: bytes
    // Age: 550374
    // Cache-Control: max-age=604800
    // Date: Wed, 10 Aug 2022 17:24:55 GMT
    // ETag: "3147526947"
    // Server: ECS, (cha / 80E2)
    // X-Cache: HIT
}

```

The preceding code:

- Makes a `HEAD` request to `"https://www.example.com/"`.
- Ensures that the response is successful, and writes the request details to the console.
- Iterates over all of the response headers, writing each one to the console.

HTTP Options

The `OPTIONS` request is used to identify which HTTP methods a server or endpoint supports. To make an HTTP `OPTIONS` request, given an `HttpClient` and a URI, use the `HttpClient.SendAsync` method with the `HttpMethod` set to `HttpMethod.Options`:

C#

```

static async Task OptionsAsync(HttpClient httpClient)
{
    using HttpRequestMessage request = new(
        HttpMethod.Options,
        "https://www.example.com");

    using HttpResponseMessage response = await
    httpClient.SendAsync(request);

    response.EnsureSuccessStatusCode()
        .WriteRequestToConsole();

    foreach (var header in response.Content.Headers)
    {
        Console.WriteLine($"{header.Key}: {string.Join(", ", header.Value)}");
    }
    Console.WriteLine();
}

```

```
// Expected output
//   OPTIONS https://www.example.com/ HTTP/1.1
//   Allow: OPTIONS, GET, HEAD, POST
//   Content-Type: text/html; charset=utf-8
//   Expires: Wed, 17 Aug 2022 17:28:42 GMT
//   Content-Length: 0
}
```

The preceding code:

- Sends an `OPTIONS` HTTP request to `"https://www.example.com/"`.
- Ensures that the response is successful, and writes the request details to the console.
- Iterates over all of the response content headers, writing each one to the console.

HTTP Trace

The `TRACE` request can be useful for debugging as it provides application-level loop-back of the request message. To make an HTTP `TRACE` request, create an `HttpRequestMessage` using the `HttpMethod.Trace`:

C#

```
using HttpRequestMessage request = new(
    HttpMethod.Trace,
    "{ValidRequestUri}");
```

⊗ Caution

The `TRACE` HTTP method is not supported by all HTTP servers. It can expose a security vulnerability if used unwisely. For more information, see [Open Web Application Security Project \(OWASP\): Cross Site Tracing](#).

Handle an HTTP response

Whenever you're handling an HTTP response, you interact with the `HttpResponseMessage` type. Several members are used when evaluating the validity of a response. The HTTP status code is available via the `HttpResponseMessage.StatusCode` property. Imagine that you've sent a request given a client instance:

C#

```
using HttpResponseMessage response = await httpClient.SendAsync(request);
```

To ensure that the `response` is `OK` (HTTP status code 200), you can evaluate it as shown in the following example:

C#

```
if (response is { StatusCode: HttpStatusCode.OK })
{
    // Omitted for brevity...
}
```

There are other HTTP status codes that represent a successful response, such as `CREATED` (HTTP status code 201), `ACCEPTED` (HTTP status code 202), `NO CONTENT` (HTTP status code 204), and `RESET CONTENT` (HTTP status code 205). You can use the [HttpResponseMessage.IsSuccessStatusCode](#) property to evaluate these codes as well, which ensures that the response status code is within the range 200-299:

C#

```
if (response.IsSuccessStatusCode)
{
    // Omitted for brevity...
}
```

If you need to have the framework throw the [HttpRequestException](#), you can call the [HttpResponseMessage.EnsureSuccessStatusCode\(\)](#) method:

C#

```
response.EnsureSuccessStatusCode();
```

This code throws an `HttpRequestException` if the response status code isn't within the 200-299 range.

HTTP valid content responses

With a valid response, you can access the response body using the [Content](#) property. The body is available as an [HttpContent](#) instance, which you can use to access the body as a stream, byte array, or string:

C#

```
await using Stream responseStream =
    await response.Content.ReadAsStreamAsync();
```

In the preceding code, the `responseStream` can be used to read the response body.

C#

```
byte[] responseByteArray = await response.Content.ReadAsByteArrayAsync();
```

In the preceding code, the `responseByteArray` can be used to read the response body.

C#

```
string responseString = await response.Content.ReadAsStringAsync();
```

In the preceding code, the `responseString` can be used to read the response body.

Finally, when you know an HTTP endpoint returns JSON, you can deserialize the response body into any valid C# object by using the [System.Net.Http.Json](#) NuGet package:

C#

```
T? result = await response.Content.ReadFromJsonAsync<T>();
```

In the preceding code, `result` is the response body deserialized as the type `T`.

HTTP error handling

When an HTTP request fails, the [HttpRequestException](#) is thrown. Catching that exception alone may not be sufficient, as there are other potential exceptions thrown that you might want to consider handling. For example, the calling code may have used a cancellation token that was canceled before the request was completed. In this scenario, you'd catch the [TaskCanceledException](#):

C#

```
using var cts = new CancellationTokenSource();
try
{
    // Assuming:
    // httpClient.Timeout = TimeSpan.FromSeconds(10)
```

```
        using var response = await httpClient.GetAsync(
            "http://localhost:5001/sleepFor?seconds=100", cts.Token);
    }
    catch (OperationCanceledException ex) when (cts.IsCancellationRequested)
    {
        // When the token has been canceled, it is not a timeout.
        Console.WriteLine($"Canceled: {ex.Message}");
    }
}
```

Likewise, when making an HTTP request, if the server doesn't respond before the `HttpClient.Timeout` is exceeded the same exception is thrown. However, in this scenario, you can distinguish that the timeout occurred by evaluating the `Exception.InnerException` when catching the `TaskCanceledException`:

C#

```
try
{
    // Assuming:
    //   httpClient.Timeout = TimeSpan.FromSeconds(10)

    using var response = await httpClient.GetAsync(
        "http://localhost:5001/sleepFor?seconds=100");
}
catch (OperationCanceledException ex) when (ex.InnerException is
TimeoutException tex)
{
    Console.WriteLine($"Timed out: {ex.Message}, {tex.Message}");
}
```

In the preceding code, when the inner exception is a `TimeoutException` the timeout occurred, and the request wasn't canceled by the cancellation token.

To evaluate the HTTP status code when catching an `HttpRequestException`, you can evaluate the `HttpRequestException.StatusCode` property:

C#

```
try
{
    // Assuming:
    //   httpClient.Timeout = TimeSpan.FromSeconds(10)

    using var response = await httpClient.GetAsync(
        "http://localhost:5001/doesNotExist");

    response.EnsureSuccessStatusCode();
}
catch (HttpRequestException ex) when (ex is { StatusCode:
    HttpStatusCode.NotFound })
```

```
{  
    // Handle 404  
    Console.WriteLine($"Not found: {ex.Message}");  
}
```

In the preceding code, the `EnsureSuccessStatusCode()` method is called to throw an exception if the response isn't successful. The `HttpRequestException.StatusCode` property is then evaluated to determine if the response was a `404` (HTTP status code 404). There are several helper methods on `HttpClient` that implicitly call `EnsureSuccessStatusCode` on your behalf, consider the following APIs:

- `HttpClient.GetByteArrayAsync`
- `HttpClient.GetStreamAsync`
- `HttpClient.GetStringAsync`

💡 Tip

All `HttpClient` methods used to make HTTP requests that don't return an `HttpResponseMessage` implicitly call `EnsureSuccessStatusCode` on your behalf.

When calling these methods, you can handle the `HttpRequestException` and evaluate the `HttpRequestException.StatusCode` property to determine the HTTP status code of the response:

C#

```
try  
{  
    // These extension methods will throw HttpRequestException  
    // with StatusCode set when the HTTP request status code isn't 2xx:  
    //  
    //    GetByteArrayAsync  
    //    GetStreamAsync  
    //    GetStringAsync  
  
    using var stream = await httpClient.GetStreamAsync(  
        "https://localhost:5001/doesNotExist");  
}  
catch (HttpRequestException ex) when (ex is { StatusCode:  
    HttpStatusCode.NotFound })  
{  
    // Handle 404  
    Console.WriteLine($"Not found: {ex.Message}");  
}
```

There might be scenarios in which you need to throw the [HttpRequestException](#) in your code. The [HttpRequestException\(\)](#) constructor is public, and you can use it to throw an exception with a custom message:

```
C#  
  
try  
{  
    using var response = await httpClient.GetAsync(  
        "https://localhost:5001/doesNotExists");  
  
    // Throw for anything higher than 400.  
    if (response is { StatusCode: >= HttpStatusCode.BadRequest })  
    {  
        throw new HttpRequestException(  
            "Something went wrong", inner: null, response.StatusCode);  
    }  
}  
catch (HttpRequestException ex) when (ex is { StatusCode:  
HttpStatusCode.NotFound })  
{  
    Console.WriteLine($"Not found: {ex.Message}");  
}
```

HTTP proxy

An HTTP proxy can be configured in one of two ways. A default is specified on the [HttpClient.DefaultProxy](#) property. Alternatively, you can specify a proxy on the [HttpClientHandler.Proxy](#) property.

Global default proxy

The [HttpClient.DefaultProxy](#) is a static property that determines the default proxy that all [HttpClient](#) instances use if no proxy is set explicitly in the [HttpClientHandler](#) passed through its constructor.

The default instance returned by this property initializes following a different set of rules depending on your platform:

- **For Windows:** Reads proxy configuration from environment variables or, if those aren't defined, from the user's proxy settings.
- **For macOS:** Reads proxy configuration from environment variables or, if those aren't defined, from the system's proxy settings.
- **For Linux:** Reads proxy configuration from environment variables or, in case those aren't defined, this property initializes a non-configured instance that bypasses all

addresses.

The environment variables used for `DefaultProxy` initialization on Windows and Unix-based platforms are:

- `HTTP_PROXY`: the proxy server used on HTTP requests.
- `HTTPS_PROXY`: the proxy server used on HTTPS requests.
- `ALL_PROXY`: the proxy server used on HTTP and/or HTTPS requests in case `HTTP_PROXY` and/or `HTTPS_PROXY` aren't defined.
- `NO_PROXY`: a comma-separated list of hostnames that should be excluded from proxying. Asterisks aren't supported for wildcards; use a leading dot in case you want to match a subdomain. Examples: `NO_PROXY=.example.com` (with leading dot) will match `www.example.com`, but won't match `example.com`. `NO_PROXY=example.com` (without leading dot) won't match `www.example.com`. This behavior might be revisited in the future to match other ecosystems better.

On systems where environment variables are case-sensitive, the variable names may be all lowercase or all uppercase. The lowercase names are checked first.

The proxy server may be a hostname or IP address, optionally followed by a colon and port number, or it may be an `http` URL, optionally including a username and password for proxy authentication. The URL must be start with `http`, not `https`, and can't include any text after the hostname, IP, or port.

Proxy per client

The `HttpClientHandler.Proxy` property identifies the `WebProxy` object to use to process requests to Internet resources. To specify that no proxy should be used, set the `Proxy` property to the proxy instance returned by the `GlobalProxySelection.GetEmptyWebProxy()` method.

The local computer or application config file may specify that a default proxy is used. If the `Proxy` property is specified, then the proxy settings from the `Proxy` property override the local computer or application config file and the handler uses the proxy settings specified. If no proxy is specified in a config file and the `Proxy` property is unspecified, the handler uses the proxy settings inherited from the local computer. If there are no proxy settings, the request is sent directly to the server.

The `HttpClientHandler` class parses a proxy bypass list with wildcard characters inherited from local computer settings. For example, the `HttpClientHandler` class parses a bypass

list of "nt*" from browsers as a regular expression of "nt.*". So a URL of `http://nt.com` would bypass the proxy using the `HttpClientHandler` class.

The `HttpClientHandler` class supports local proxy bypass. The class considers a destination to be local if any of the following conditions are met:

1. The destination contains a flat name (no dots in the URL).
2. The destination contains a loopback address ([Loopback](#) or [IPv6Loopback](#)) or the destination contains an [IPAddress](#) assigned to the local computer.
3. The domain suffix of the destination matches the local computer's domain suffix ([DomainName](#)).

For more information about configuring a proxy, see:

- [WebProxy.Address](#)
- [WebProxy.BypassProxyOnLocal](#)
- [WebProxy.BypassArrayList](#)

IHttpClientFactory with .NET

Article • 05/19/2023

In this article, you'll learn how to use the `IHttpClientFactory` to create `HttpClient` types with various .NET fundamentals, such as dependency injection (DI), logging, and configuration. The `HttpClient` type was introduced in .NET Framework 4.5, which was released in 2012. In other words, it's been around for a while. `HttpClient` is used for making HTTP requests and handling HTTP responses from web resources identified by a `Uri`. The HTTP protocol makes up the vast majority of all internet traffic.

With modern application development principles driving best practices, the `IHttpClientFactory` serves as a factory abstraction that can create `HttpClient` instances with custom configurations. `IHttpClientFactory` was introduced in .NET Core 2.1. Common HTTP-based .NET workloads can take advantage of resilient and transient-fault-handling third-party middleware with ease.

ⓘ Note

If your app requires cookies, it might be better to avoid using `IHttpClientFactory` in your app. For alternative ways of managing clients, see [Guidelines for using HTTP clients](#).

ⓘ Important

Lifetime management of `HttpClient` instances created by `IHttpClientFactory` is completely different from instances created manually. The strategies are to use either **short-lived** clients created by `IHttpClientFactory` or **long-lived** clients with `PooledConnectionLifetime` set up. For more information, see the [HttpClient lifetime management](#) section and [Guidelines for using HTTP clients](#).

The `IHttpClientFactory` type

All of the sample source code in this article relies on the [Microsoft.Extensions.Http](#) NuGet package. Additionally, HTTP `GET` requests are made to the free [{JSON} Placeholder](#) API to get user `Todo` objects.

When you call any of the `AddHttpClient` extension methods, you're adding the `IHttpClientFactory` and related services to the `IServiceCollection`. The

`IHttpClientFactory` type offers the following benefits:

- Exposes the `HttpClient` class as a DI-ready type.
- Provides a central location for naming and configuring logical `HttpClient` instances.
- Codifies the concept of outgoing middleware via delegating handlers in `HttpClient`.
- Provides extension methods for Polly-based middleware to take advantage of delegating handlers in `HttpClient`.
- Manages the caching and lifetime of underlying `HttpClientHandler` instances. Automatic management avoids common Domain Name System (DNS) problems that occur when manually managing `HttpClient` lifetimes.
- Adds a configurable logging experience (via `ILogger`) for all requests sent through clients created by the factory.

Consumption patterns

There are several ways `IHttpClientFactory` can be used in an app:

- [Basic usage](#)
- [Named clients](#)
- [Typed clients](#)
- [Generated clients](#)

The best approach depends upon the app's requirements.

Basic usage

To register the `IHttpClientFactory`, call `AddHttpClient`:

C#

```
using Shared;
using BasicHttp.Example;
using Microsoft.Extensions.DependencyInjection;
using Microsoft.Extensions.Hosting;
using Microsoft.Extensions.Logging;

HostApplicationBuilder builder = Host.CreateApplicationBuilder(args);

builder.Services.AddHttpClient();
builder.Services.AddTransient<TodoService>();
```

```
using IHost host = builder.Build();
```

Consuming services can require the `IHttpClientFactory` as a constructor parameter with DI. The following code uses `IHttpClientFactory` to create an `HttpClient` instance:

C#

```
using System.Net.Http.Json;
using System.Text.Json;
using Microsoft.Extensions.Logging;
using Shared;

namespace BasicHttp.Example;

public sealed class TodoService(
    IHttpClientFactory httpClientFactory,
    ILogger<TodoService> logger)
{
    public async Task<Todo[]> GetUserTodosAsync(int userId)
    {
        // Create the client
        using HttpClient client = httpClientFactory.CreateClient();

        try
        {
            // Make HTTP GET request
            // Parse JSON response deserialize into Todo types
            Todo[]? todos = await client.GetFromJsonAsync<Todo[]>(
                $"https://jsonplaceholder.typicode.com/todos?userId={userId}",
                new JsonSerializerOptions(JsonSerializerDefaults.Web));

            return todos ?? [];
        }
        catch (Exception ex)
        {
            logger.LogError("Error getting something fun to say: {Error}", ex);
        }

        return [];
    }
}
```

Using `IHttpClientFactory` like in the preceding example is a good way to refactor an existing app. It has no impact on how `HttpClient` is used. In places where `HttpClient` instances are created in an existing app, replace those occurrences with calls to [CreateClient](#).

Named clients

Named clients are a good choice when:

- The app requires many distinct uses of `HttpClient`.
- Many `HttpClient` instances have different configurations.

Configuration for a named `HttpClient` can be specified during registration on the `IServiceCollection`:

C#

```
using Shared;
using NamedHttp.Example;
using Microsoft.Extensions.DependencyInjection;
using Microsoft.Extensions.Hosting;
using Microsoft.Extensions.Logging;

HostApplicationBuilder builder = Host.CreateApplicationBuilder(args);

string? httpClientName = builder.Configuration[ "TodoHttpClientName" ];
ArgumentException.ThrowIfNullOrEmpty(httpClientName);

builder.Services.AddHttpClient(
    httpClientName,
    client =>
{
    // Set the base address of the named client.
    client.BaseAddress = new
Uri("https://jsonplaceholder.typicode.com/");

    // Add a user-agent default request header.
    client.DefaultRequestHeaders.UserAgent.ParseAdd( "dotnet-docs" );
});
```

In the preceding code, the client is configured with:

- A name that's pulled from the configuration under the `"TodoHttpClientName"`.
- The base address `https://jsonplaceholder.typicode.com/`.
- A `"User-Agent"` header.

You can use configuration to specify HTTP client names, which is helpful to avoid misnaming clients when adding and creating. In this example, the `appsettings.json` file is used to configure the HTTP client name:

JSON

```
{  
    "TodoHttpClientName": "JsonPlaceholderApi"  
}
```

It's easy to extend this configuration and store more details about how you'd like your HTTP client to function. For more information, see [Configuration in .NET](#).

Create client

Each time `CreateClient` is called:

- A new instance of `HttpClient` is created.
- The configuration action is called.

To create a named client, pass its name into `CreateClient`:

C#

```
using System.Net.Http.Json;  
using System.Text.Json;  
using Microsoft.Extensions.Configuration;  
using Microsoft.Extensions.Logging;  
using Shared;  
  
namespace NamedHttp.Example;  
  
public sealed class TodoService  
{  
    private readonly IHttpClientFactory _httpClientFactory = null!;  
    private readonly IConfiguration _configuration = null!;  
    private readonly ILogger<TodoService> _logger = null!;  
  
    public TodoService(  
        IHttpClientFactory httpClientFactory,  
        IConfiguration configuration,  
        ILogger<TodoService> logger) =>  
        (_httpClientFactory, _configuration, _logger) =  
            (httpClientFactory, configuration, logger);  
  
    public async Task<Todo[]> GetUserTodosAsync(int userId)  
    {  
        // Create the client  
        string? httpClientName = _configuration["TodoHttpClientName"];  
        using HttpClient client =  
            _httpClientFactory.CreateClient(httpClientName ?? "");  
  
        try  
        {  
            // Make HTTP GET request  
        }
```

```

        // Parse JSON response deserialize into Todo type
        Todo[]? todos = await client.GetFromJsonAsync<Todo[]>(
            $"todos?userId={userId}",
            new JsonSerializerOptions(JsonSerializerDefaults.Web));

        return todos ?? [];
    }
    catch (Exception ex)
    {
        _logger.LogError("Error getting something fun to say: {Error}",
ex);
    }

    return [];
}
}

```

In the preceding code, the HTTP request doesn't need to specify a hostname. The code can pass just the path, since the base address configured for the client is used.

Typed clients

Typed clients:

- Provide the same capabilities as named clients without the need to use strings as keys.
- Provide [IntelliSense](#) and compiler help when consuming clients.
- Provide a single location to configure and interact with a particular `HttpClient`. For example, a single typed client might be used:
 - For a single backend endpoint.
 - To encapsulate all logic dealing with the endpoint.
- Work with DI and can be injected where required in the app.

A typed client accepts an `HttpClient` parameter in its constructor:

C#

```

using System.Net.Http.Json;
using System.Text.Json;
using Microsoft.Extensions.Logging;
using Shared;

namespace TypedHttp.Example;

public sealed class TodoService(
    HttpClient httpClient,
    ILogger<TodoService> logger) : IDisposable
{

```

```

public async Task<Todo[]> GetUserTodosAsync(int userId)
{
    try
    {
        // Make HTTP GET request
        // Parse JSON response deserialize into Todo type
        Todo[]? todos = await httpClient.GetFromJsonAsync<Todo[]>(
            $"todos?userId={userId}",
            new JsonSerializerOptions(JsonSerializerDefaults.Web));

        return todos ?? [];
    }
    catch (Exception ex)
    {
        logger.LogError("Error getting something fun to say: {Error}",
ex);
    }

    return [];
}

public void Dispose() => httpClient?.Dispose();
}

```

In the preceding code:

- The configuration is set when the typed client is added to the service collection.
- The `HttpClient` is assigned as a class-scoped variable (field), and used with exposed APIs.

API-specific methods can be created that expose `HttpClient` functionality. For example, the `GetUserTodosAsync` method encapsulates code to retrieve user-specific `Todo` objects.

The following code calls `AddHttpClient` to register a typed client class:

C#

```

using Shared;
using TypedHttp.Example;
using Microsoft.Extensions.DependencyInjection;
using Microsoft.Extensions.Hosting;
using Microsoft.Extensions.Logging;

HostApplicationBuilder builder = Host.CreateApplicationBuilder(args);

```

```
builder.Services.AddHttpClient<TodoService>(
    client =>
{
    // Set the base address of the typed client.
    client.BaseAddress = new
Uri("https://jsonplaceholder.typicode.com/");

    // Add a user-agent default request header.
    client.DefaultRequestHeaders.UserAgent.ParseAdd("dotnet-docs");
});
```

The typed client is registered as transient with DI. In the preceding code, `AddHttpClient` registers `TodoService` as a transient service. This registration uses a factory method to:

1. Create an instance of `HttpClient`.
2. Create an instance of `TodoService`, passing in the instance of `HttpClient` to its constructor.

ⓘ Important

Using typed clients in singleton services can be dangerous. For more information, see the [Avoid Typed clients in singleton services](#) section.

ⓘ Note

When registering a typed client with the `AddHttpClient<TClient>` method, the `TClient` type must have a constructor that accepts an `HttpClient` parameter. Additionally, the `TClient` type shouldn't be registered with the DI container separately.

Generated clients

`IHttpClientFactory` can be used in combination with third-party libraries such as [Refit](#). Refit is a REST library for .NET. It allows for declarative REST API definitions, mapping interface methods to endpoints. An implementation of the interface is generated dynamically by the `RestService`, using `HttpClient` to make the external HTTP calls.

Consider the following `record` type:

C#

```
namespace Shared;

public record class Todo(
    int UserId,
    int Id,
    string Title,
    bool Completed);
```

The following example relies on the [Refit.HttpClientFactory](#) NuGet package, and is a simple interface:

C#

```
using Refit;
using Shared;

namespace GeneratedHttp.Example;

public interface ITodoService
{
    [Get("/todos?userId={userId}")]
    Task<Todo[]> GetUserTodosAsync(int userId);
}
```

The preceding C# interface:

- Defines a method named `GetUserTodosAsync` that returns a `Task<Todo[]>` instance.
- Declares a `Refit.GetAttribute` attribute with the path and query string to the external API.

A typed client can be added, using Refit to generate the implementation:

C#

```
using GeneratedHttp.Example;
using Microsoft.Extensions.DependencyInjection;
using Microsoft.Extensions.Hosting;
using Microsoft.Extensions.Logging;
using Refit;
using Shared;

HostApplicationBuilder builder = Host.CreateApplicationBuilder(args);
```

```
builder.Services.AddRefitClient<ITodoService>()
    .ConfigureHttpClient(client =>
{
    // Set the base address of the named client.
    client.BaseAddress = new
Uri("https://jsonplaceholder.typicode.com/");

    // Add a user-agent default request header.
    client.DefaultRequestHeaders.UserAgent.ParseAdd("dotnet-docs");
});
```

The defined interface can be consumed where necessary, with the implementation provided by DI and Refit.

Make POST, PUT, and DELETE requests

In the preceding examples, all HTTP requests use the `GET` HTTP verb. `HttpClient` also supports other HTTP verbs, including:

- `POST`
- `PUT`
- `DELETE`
- `PATCH`

For a complete list of supported HTTP verbs, see [HttpMethod](#). For more information on making HTTP requests, see [Send a request using HttpClient](#).

The following example shows how to make an HTTP `POST` request:

C#

```
public async Task CreateItemAsync(Item item)
{
    using StringContent json = new(
        JsonSerializer.Serialize(item, new
JsonSerializerOptions(JsonSerializerDefaults.Web)),
        Encoding.UTF8,
        MediaTypeNames.Application.Json);

    using HttpResponseMessage httpResponse =
        await httpClient.PostAsync("/api/items", json);

    httpResponse.EnsureSuccessStatusCode();
}
```

In the preceding code, the `CreateItemAsync` method:

- Serializes the `Item` parameter to JSON using `System.Text.Json`. This uses an instance of `JsonSerializerOptions` to configure the serialization process.
- Creates an instance of `StringContent` to package the serialized JSON for sending in the HTTP request's body.
- Calls `PostAsync` to send the JSON content to the specified URL. This is a relative URL that gets added to the `HttpClient.BaseAddress`.
- Calls `EnsureSuccessStatusCode` to throw an exception if the response status code does not indicate success.

`HttpClient` also supports other types of content. For example, `MultipartContent` and `StreamContent`. For a complete list of supported content, see [HttpContent](#).

The following example shows an HTTP `PUT` request:

C#

```
public async Task UpdateItemAsync(Item item)
{
    using StringContent json = new(
        JsonSerializer.Serialize(item, new
JsonSerializerOptions(JsonSerializerDefaults.Web)),
        Encoding.UTF8,
        MediaTypeNames.Application.Json);

    using HttpResponseMessage httpResponse =
        await httpClient.PutAsync($""/api/items/{item.Id}", json);

    httpResponse.EnsureSuccessStatusCode();
}
```

The preceding code is very similar to the `POST` example. The `UpdateItemAsync` method calls `PutAsync` instead of `PostAsync`.

The following example shows an HTTP `DELETE` request:

C#

```
public async Task DeleteItemAsync(Guid id)
{
    using HttpResponseMessage httpResponse =
        await httpClient.DeleteAsync($""/api/items/{id}");

    httpResponse.EnsureSuccessStatusCode();
}
```

In the preceding code, the `DeleteItemAsync` method calls `DeleteAsync`. Because HTTP DELETE requests typically contain no body, the `DeleteAsync` method doesn't provide an overload that accepts an instance of `HttpContent`.

To learn more about using different HTTP verbs with `HttpClient`, see [HttpClient](#).

HttpClient lifetime management

A new `HttpClient` instance is returned each time `createClient` is called on the `IHttpClientFactory`. One `HttpClientHandler` instance is created per client name. The factory manages the lifetimes of the `HttpClientHandler` instances.

`IHttpClientFactory` caches the `HttpClientHandler` instances created by the factory to reduce resource consumption. An `HttpClientHandler` instance may be reused from the cache when creating a new `HttpClient` instance if its lifetime hasn't expired.

Caching of handlers is desirable as each handler typically manages its own underlying HTTP connection pool. Creating more handlers than necessary can result in socket exhaustion and connection delays. Some handlers also keep connections open indefinitely, which can prevent the handler from reacting to DNS changes.

The default handler lifetime is two minutes. To override the default value, call `SetHandlerLifetime` for each client, on the `IServiceCollection`:

```
C#  
  
services.AddHttpClient("Named.Client")  
    .SetHandlerLifetime(TimeSpan.FromMinutes(5));
```

ⓘ Important

`HttpClient` instances created by `IHttpClientFactory` are intended to be **short-lived**.

- Recycling and recreating `HttpMessageHandler`'s when their lifetime expires is essential for `IHttpClientFactory` to ensure the handlers react to DNS changes. `HttpClient` is tied to a specific handler instance upon its creation, so new `HttpClient` instances should be requested in a timely manner to ensure the client will get the updated handler.

- Disposing of such `HttpClient` instances **created by the factory** will not lead to socket exhaustion, as its disposal **will not** trigger disposal of the `HttpMessageHandler`. `IHttpClientFactory` tracks and disposes of resources used to create `HttpClient` instances, specifically the `HttpMessageHandler` instances, as soon their lifetime expires and there's no `HttpClient` using them anymore.

Keeping a single `HttpClient` instance alive for a long duration is a common pattern that can be used as an **alternative** to `IHttpClientFactory`, however, this pattern requires additional setup, such as `PooledConnectionLifetime`. You can use either **long-lived** clients with `PooledConnectionLifetime`, or **short-lived** clients created by `IHttpClientFactory`. For information about which strategy to use in your app, see [Guidelines for using HTTP clients](#).

Configure the `HttpMessageHandler`

It may be necessary to control the configuration of the inner `HttpMessageHandler` used by a client.

An `IHttpClientBuilder` is returned when adding named or typed clients. The `ConfigurePrimaryHttpMessageHandler` extension method can be used to define a delegate on the `IServiceCollection`. The delegate is used to create and configure the primary `HttpMessageHandler` used by that client:

```
C#  
  
.ConfigurePrimaryHttpMessageHandler(() =>  
{  
    return new HttpClientHandler  
    {  
        AllowAutoRedirect = false,  
        UseDefaultCredentials = true  
    };  
});
```

Configuring the `HttpClientHandler` lets you specify a proxy for the `HttpClient` instance among various other properties of the handler. For more information, see [Proxy per client](#).

Additional configuration

There are several additional configuration options for controlling the

`IHttpClientHandler`:

[+] Expand table

| Method | Description |
|--|--|
| AddHttpMessageHandler | Adds an additional message handler for a named <code>HttpClient</code> . |
| AddTypedClient | Configures the binding between the <code>TClient</code> and the named <code>HttpClient</code> associated with the <code>IHttpClientBuilder</code> . |
| ConfigureHttpClient | Adds a delegate that will be used to configure a named <code>HttpClient</code> . |
| ConfigureHttpMessageHandlerBuilder | Adds a delegate that will be used to configure message handlers using <code>HttpMessageHandlerBuilder</code> for a named <code>HttpClient</code> . |
| ConfigurePrimaryHttpMessageHandler | Configures the primary <code>HttpMessageHandler</code> from the dependency injection container for a named <code>HttpClient</code> . |
| RedactLoggedHeaders | Sets the collection of HTTP header names for which values should be redacted before logging. |
| SetHandlerLifetime | Sets the length of time that a <code>HttpMessageHandler</code> instance can be reused. Each named client can have its own configured handler lifetime value. |

Using `IHttpClientFactory` together with `SocketsHttpHandler`

The `SocketsHttpHandler` implementation of `HttpMessageHandler` was added in .NET Core 2.1, which allows `PooledConnectionLifetime` to be configured. This setting is used to ensure that the handler reacts to DNS changes, so using `SocketsHttpHandler` is considered to be an alternative to using `IHttpClientFactory`. For more information, see [Guidelines for using HTTP clients](#).

However, `SocketsHttpHandler` and `IHttpClientFactory` can be used together to improve configurability. By using both of these APIs, you benefit from configurability on both a low level (for example, using `LocalCertificateSelectionCallback` for dynamic certificate selection) and a high level (for example, leveraging DI integration and several client configurations).

To use both APIs:

1. Specify `SocketsHttpHandler` as `PrimaryHandler` and set up its `PooledConnectionLifetime` (for example, to a value that was previously in `HandlerLifetime`).
2. As `SocketsHttpHandler` will handle connection pooling and recycling, then handler recycling at the `IHttpClientFactory` level is not needed anymore. You can disable it by setting `HandlerLifetime` to `Timeout.InfiniteTimeSpan`.

C#

```
services.AddHttpClient(name)
    .ConfigurePrimaryHttpMessageHandler(() =>
{
    return new SocketsHttpHandler()
    {
        PooledConnectionLifetime = TimeSpan.FromMinutes(2)
    };
})
    .SetHandlerLifetime(Timeout.InfiniteTimeSpan); // Disable rotation, as
it is handled by PooledConnectionLifetime
```

Avoid typed clients in singleton services

When using the *named client* approach, `IHttpClientFactory` is injected into services, and `HttpClient` instances are created by calling `CreateClient` every time an `HttpClient` is needed.

However, with the *typed client* approach, typed clients are transient objects usually injected into services. That may cause a problem because a typed client can be injected into a singleton service.

ⓘ Important

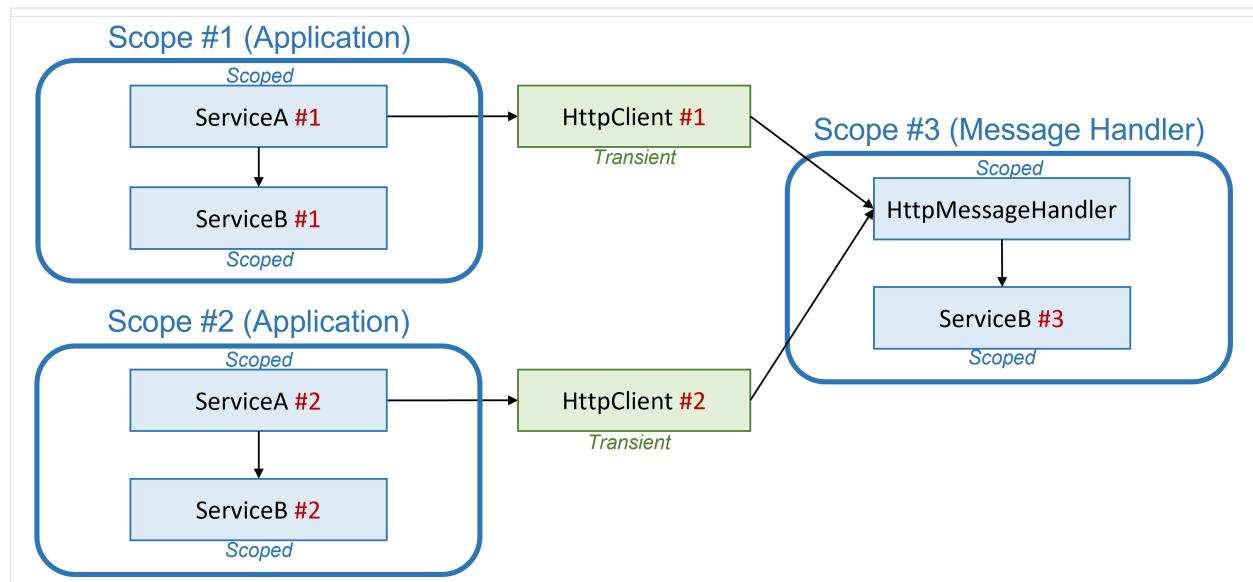

Typed clients are expected to be **short-lived** in the same sense as `HttpClient` instances created by `IHttpClientFactory` (for more information, see [HttpClient lifetime management](#)). As soon as a typed client instance is created, `IHttpClientFactory` has no control over it. If a typed client instance is captured in a singleton, it may prevent it from reacting to DNS changes, defeating one of the purposes of `IHttpClientFactory`.

If you need to use `HttpClient` instances in a singleton service, consider the following options:

- Use the *named client* approach instead, injecting `IHttpClientFactory` in the singleton service and recreating `HttpClient` instances when necessary.
- If you require the *typed client* approach, use `SocketsHttpHandler` with configured `PooledConnectionLifetime` as a primary handler. For more information on using `SocketsHttpHandler` with `IHttpClientFactory`, see the section [Using `IHttpClientFactory` together with `SocketsHttpHandler`](#).

Message Handler Scopes in `IHttpClientFactory`

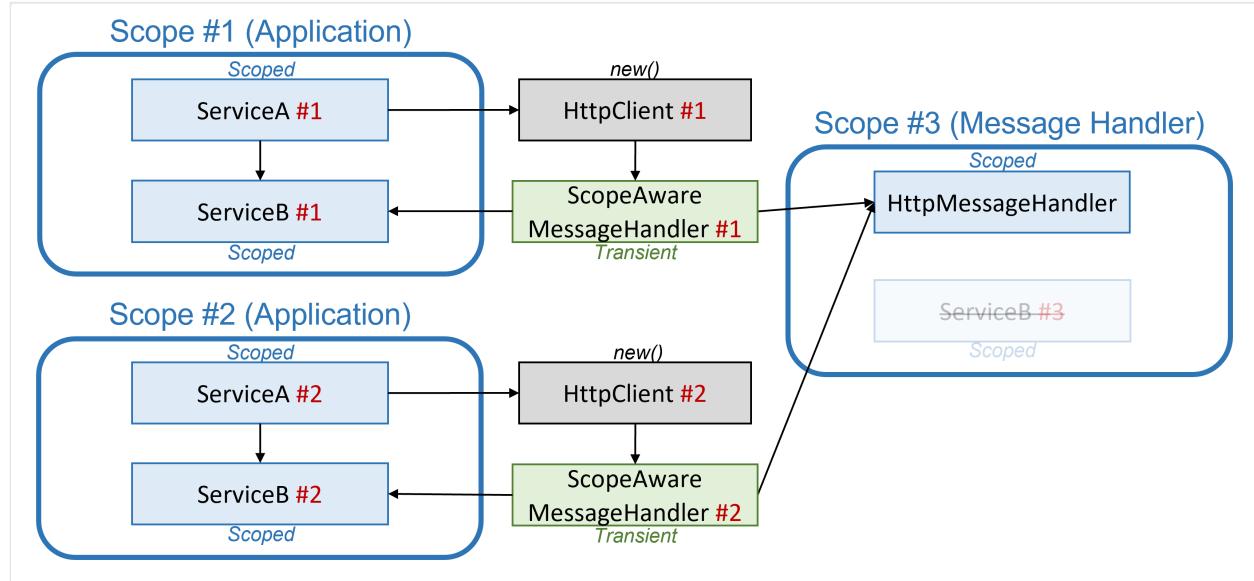

`IHttpClientFactory` creates a separate DI scope per each `HttpMessageHandler` instance. These DI scopes are separate from application DI scopes (for example, ASP.NET incoming request scope, or a user-created manual DI scope), so they will **not** share scoped service instances. Message Handler scopes are tied to handler lifetime and can outlive application scopes, which can lead to, for example, reusing the same `HttpMessageHandler` instance with same injected scoped dependencies between several incoming requests.

Users are strongly advised **not to cache scope-related information** (such as data from `HttpContext`) inside `HttpMessageHandler` instances and use scoped dependencies with caution to avoid leaking sensitive information.

If you require access to an app DI scope from your message handler, for authentication as an example, you'd encapsulate scope-aware logic in a separate transient `DelegatingHandler`, and wrap it around an `HttpMessageHandler` instance from the `IHttpClientFactory` cache. To access the handler call

`IHttpMessageHandlerFactory.CreateHandler` for any registered *named client*. In that case, you'd create an `HttpClient` instance yourself using the constructed handler.

The following example shows creating an `HttpClient` with a scope-aware `DelegatingHandler`:

C#

```

if (scopeAwareHandlerType != null)
{
    if (!typeof(DelegatingHandler).IsAssignableFrom(scopeAwareHandlerType))
    {
        throw new ArgumentException($"""
            Scope aware HttpHandler {scopeAwareHandlerType.Name} should
            be assignable to DelegatingHandler
            """);
    }

    // Create top-most delegating handler with scoped dependencies
    scopeAwareHandler =
    (DelegatingHandler)_scopeServiceProvider.GetRequiredService(scopeAwareHandle
    rType); // should be transient
    if (scopeAwareHandler.InnerHandler != null)
    {
        throw new ArgumentException($"""
            Inner handler of a delegating handler
            {scopeAwareHandlerType.Name} should be null.
            Scope aware HttpHandler should be registered as Transient.
            """);
    }
}

// Get or create HttpResponseMessage from HttpClientFactory
HttpMessageHandler handler = _httpMessageHandlerFactory.CreateHandler(name);

if (scopeAwareHandler != null)

```

```
{  
    scopeAwareHandler.InnerHandler = handler;  
    handler = scopeAwareHandler;  
}  
  
HttpClient client = new(handler);
```

A further workaround can follow with an extension method for registering a scope-aware `DelegatingHandler` and overriding default `IHttpClientFactory` registration by a transient service with access to the current app scope:

C#

```
public static IHttpClientBuilder AddScopeAwareHttpHandler<THandler>(  
    this IHttpClientBuilder builder) where THandler : DelegatingHandler  
{  
    builder.Services.TryAddTransient<THandler>();  
    if (!builder.Services.Any(sd => sd.ImplementationType ==  
typeof(ScopeAwareHttpClientFactory)))  
    {  
        // Override default IHttpClientFactory registration  
        builder.Services.AddTransient<IHttpClientFactory,  
ScopeAwareHttpClientFactory>();  
    }  
  
    builder.Services.Configure<ScopeAwareHttpClientFactoryOptions>(  
        builder.Name, options => options.HttpHandlerType =  
typeof(THandler));  
  
    return builder;  
}
```

For more information, see the [full example ↗](#).

Build resilient HTTP apps: Key development patterns

Article • 10/21/2023

Building robust HTTP apps that can recover from transient fault errors is a common requirement. This article assumes that you've already read [Introduction to resilient app development](#), as this article extends the core concepts conveyed. To help build resilient HTTP apps, the [Microsoft.Extensions.Http.Resilience](#) NuGet package provides resilience mechanisms specifically for the [HttpClient](#). This NuGet package relies on the [Microsoft.Extensions.Resilience](#) library and *Polly*, which is a popular open-source project. For more information, see [Polly](#).

Get started

To use resilience-patterns in HTTP apps, install the [Microsoft.Extensions.Http.Resilience](#) NuGet package.

For more information, see [dotnet add package](#) or [Manage package dependencies in .NET applications](#).

Add resilience to an HTTP client

To add resilience to an [HttpClient](#), you chain a call on the [IHttpClientBuilder](#) type that is returned from calling any of the available [AddHttpClient](#) methods. For more information, see [IHttpClientFactory with .NET](#).

There are several resilience-centric extensions available. Some are standard, thus employing various industry best practices, and others are more customizable. When adding resilience, you should only add one resilience handler and avoid stacking handlers. If you need to add multiple resilience handlers, you should consider using the [AddResilienceHandler](#) extension method, which allows you to customize the resilience strategies.

ⓘ Important

All of the examples within this article rely on the [AddHttpClient](#) API, from the [Microsoft.Extensions.Http](#) library, which returns an [IHttpClientBuilder](#) instance. The [IHttpClientBuilder](#) instance is used to configure the [HttpClient](#) and add the resilience handler.

Add standard resilience handler

The standard resilience handler uses multiple resilience strategies stacked atop one another, with default options to send the requests and handle any transient errors. The standard resilience handler is added by calling the [AddStandardResilienceHandler](#) extension method on an [IHttpClientBuilder](#) instance.

C#

```
var services = new ServiceCollection();

var httpClientBuilder = services.AddHttpClient<ExampleClient>(
    configureClient: static client =>
{
    client.BaseAddress = new("https://jsonplaceholder.typicode.com");
});
```

The preceding code:

- Creates a [ServiceCollection](#) instance.
- Adds an [HttpClient](#) for the [ExampleClient](#) type to the service container.
- Configures the [HttpClient](#) to use `"https://jsonplaceholder.typicode.com"` as the base address.
- Creates the [httpClientBuilder](#) that's used throughout the other examples within this article.

A more real-world example would rely on hosting, such as that described in the [.NET Generic Host](#) article. Using the [Microsoft.Extensions.Hosting](#) NuGet package, consider the following updated example:

C#

```
using Http.Resilience.Example;
using Microsoft.Extensions.DependencyInjection;
using Microsoft.Extensions.Hosting;
```

```
HostApplicationBuilder builder = Host.CreateApplicationBuilder(args);

IHttpClientBuilder httpClientBuilder =
builder.Services.AddHttpClient<ExampleClient>(
    configureClient: static client =>
{
    client.BaseAddress = new("https://jsonplaceholder.typicode.com");
});
```

The preceding code is similar to the manual `ServiceCollection` creation approach, but instead relies on the `Host.CreateApplicationBuilder()` to build out a host that exposes the services.

The `ExampleClient` is defined as follows:

C#

```
using System.Net.Http.Json;

namespace Http.Resilience.Example;

/// <summary>
/// An example client service, that relies on the <see cref="HttpClient"/>
/// instance.
/// </summary>
/// <param name="client">The given <see cref="HttpClient"/> instance.
/// </param>
internal sealed class ExampleClient(HttpClient client)
{
    /// <summary>
    /// Returns an <see cref="IAsyncEnumerable{T}"/> of <see
    cref="Comment"/>s.
    /// </summary>
    public IAsyncEnumerable<Comment?> GetCommentsAsync()
    {
        return client.GetFromJsonAsAsyncEnumerable<Comment>("/comments");
    }
}
```

The preceding code:

- Defines an `ExampleClient` type that has a constructor that accepts an `HttpClient`.
- Exposes a `GetCommentsAsync` method that sends a GET request to the `/comments` endpoint and returns the response.

The `Comment` type is defined as follows:

C#

```
namespace Http.Resilience.Example;

public record class Comment(
    int PostId, int Id, string Name, string Email, string Body);
```

Given that you've created an [IHttpClientBuilder](#) (`httpClientBuilder`), and you now understand the `ExampleClient` implementation and corresponding `Comment` model, consider the following example:

C#

```
httpClientBuilder.AddStandardResilienceHandler();
```

The preceding code adds the standard resilience handler to the `HttpClient`. Like most resilience APIs, there are overloads that allow you to customize the default options and applied resilience strategies.

Standard resilience handler defaults

The default configuration chains five resilience strategies in the following order (from the outermost to the innermost):

| Order | Strategy | Description |
|-------|-----------------------|---|
| 1 | Rate limiter | The rate limiter pipeline limits the maximum number of concurrent requests being sent to the dependency. |
| 2 | Total request timeout | The total request timeout pipeline applies an overall timeout to the execution, ensuring that the request, including retry attempts, doesn't exceed the configured limit. |
| 3 | Retry | The retry pipeline retries the request in case the dependency is slow or returns a transient error. |
| 4 | Circuit breaker | The circuit breaker blocks the execution if too many direct failures or timeouts are detected. |
| 5 | Attempt timeout | The attempt timeout pipeline limits each request attempt duration and throws if it's exceeded. |

Add standard hedging handler

The standard hedging handler wraps the execution of the request with a standard hedging mechanism. Hedging retries slow requests in parallel.

To use the standard hedging handler, call `AddStandardHedgingHandler` extension method.

The following example configures the `ExampleClient` to use the standard hedging handler.

C#

```
httpClientBuilder.AddStandardHedgingHandler();
```

The preceding code adds the standard hedging handler to the [HttpClient](#).

Standard hedging handler defaults

The standard hedging uses a pool of circuit breakers to ensure that unhealthy endpoints aren't hedged against. By default, the selection from the pool is based on the URL authority (scheme + host + port).

Tip

It's recommended that you configure the way the strategies are selected by calling `StandardHedgingHandlerBuilderExtensions.SelectPipelineByAuthority` or `StandardHedgingHandlerBuilderExtensions.SelectPipelineBy` for more advanced scenarios.

The preceding code adds the standard hedging handler to the [IHttpClientBuilder](#). The default configuration chains five resilience strategies in the following order (from the outermost to the innermost):

| Order | Strategy | Description |
|-------|--------------------------------|--|
| 1 | Total request timeout | The total request timeout pipeline applies an overall timeout to the execution, ensuring that the request, including hedging attempts, doesn't exceed the configured limit. |
| 2 | Hedging | The hedging strategy executes the requests against multiple endpoints in case the dependency is slow or returns a transient error. Routing is options, by default it just hedges the URL provided by the original HttpRequestMessage . |
| 3 | Rate limiter (per endpoint) | The rate limiter pipeline limits the maximum number of concurrent requests being sent to the dependency. |
| 4 | Circuit breaker (per endpoint) | The circuit breaker blocks the execution if too many direct failures or timeouts are detected. |

| Order | Strategy | Description |
|-------|--------------------------------|--|
| 5 | Attempt timeout (per endpoint) | The attempt timeout pipeline limits each request attempt duration and throws if it's exceeded. |

Customize hedging handler route selection

When using the standard hedging handler, you can customize the way the request endpoints are selected by calling various extensions on the `IRoutingStrategyBuilder` type. This can be useful for scenarios such as A/B testing, where you want to route a percentage of the requests to a different endpoint:

C#

```
httpClientBuilder.AddStandardHedgingHandler(static IRoutingStrategyBuilder
builder) =>
{
    // Hedging allows sending multiple concurrent requests
    builder.ConfigureOrderedGroups(static options =>
    {
        options.Groups.Add(new UriEndpointGroup()
        {
            Endpoints =
            {
                // Imagine a scenario where 3% of the requests are
                // sent to the experimental endpoint.
                new() { Uri = new("https://example.net/api/experimental"),
Weight = 3 },
                new() { Uri = new("https://example.net/api/stable"), Weight
= 97 }
            }
        });
    });
}
```

The preceding code:

- Adds the hedging handler to the `IHttpClientBuilder`.
- Configures the `IRoutingStrategyBuilder` to use the `ConfigureOrderedGroups` method to configure the ordered groups.
- Adds an `EndpointGroup` to the `orderedGroup` that routes 3% of the requests to the `https://example.net/api/experimental` endpoint and 97% of the requests to the `https://example.net/api/stable` endpoint.
- Configures the `IRoutingStrategyBuilder` to use the `ConfigureWeightedGroups` method to configure the

To configure a weighted group, call the `ConfigureWeightedGroups` method on the `IRoutingStrategyBuilder` type. The following example configures the `IRoutingStrategyBuilder` to use the `ConfigureWeightedGroups` method to configure the weighted groups.

C#

```
httpClientBuilder.AddStandardHedgingHandler(static IRoutingStrategyBuilder builder) =>
{
    // Hedging allows sending multiple concurrent requests
    builder.ConfigureWeightedGroups(static options =>
    {
        options.SelectionMode = WeightedGroupSelectionMode.EveryAttempt;

        options.Groups.Add(new WeightedUriEndpointGroup()
        {
            Endpoints =
            {
                // Imagine A/B testing
                new() { Uri = new("https://example.net/api/a"), Weight = 33 },
                new() { Uri = new("https://example.net/api/b"), Weight = 33 },
                new() { Uri = new("https://example.net/api/c"), Weight = 33 }
            }
        });
    });
}
```

The preceding code:

- Adds the hedging handler to the `IHttpClientBuilder`.
- Configures the `IRoutingStrategyBuilder` to use the `ConfigureWeightedGroups` method to configure the weighted groups.
- Sets the `SelectionMode` to `WeightedGroupSelectionMode.EveryAttempt`.
- Adds a `WeightedEndpointGroup` to the `weightedGroup` that routes 33% of the requests to the `https://example.net/api/a` endpoint, 33% of the requests to the `https://example.net/api/b` endpoint, and 33% of the requests to the `https://example.net/api/c` endpoint.

💡 Tip

The maximum number of hedging attempts directly correlates to the number of configured groups. For example, if you have two groups, the maximum number of

attempts is two.

For more information, see [Polly docs: Hedging resilience strategy](#).

It's common to configure either an ordered group or weighted group, but it's valid to configure both. Using ordered and weighted groups is helpful in scenarios where you want to send a percentage of the requests to a different endpoint, such is the case with A/B testing.

Add custom resilience handlers

To have more control, you can customize the resilience handlers by using the `AddResilienceHandler` API. This method accepts a delegate that configures the `ResiliencePipelineBuilder<HttpResponseMessage>` instance that is used to create the resilience strategies.

To configure a named resilience handler, call the `AddResilienceHandler` extension method with the name of the handler. The following example configures a named resilience handler called `"CustomPipeline"`.

C#

```
httpClientBuilder.AddResilienceHandler(
    "CustomPipeline",
    static builder =>
{
    // See: https://www.pollydocs.org:strategies/retry.html
    builder.AddRetry(new HttpRetryStrategyOptions
    {
        // Customize and configure the retry logic.
        BackoffType = DelayBackoffType.Exponential,
        MaxRetryAttempts = 5,
        UseJitter = true
    });

    // See: https://www.pollydocs.org:strategies/circuit-breaker.html
    builder.AddCircuitBreaker(new HttpCircuitBreakerStrategyOptions
    {
        // Customize and configure the circuit breaker logic.
        SamplingDuration = TimeSpan.FromSeconds(10),
        FailureRatio = 0.2,
        MinimumThroughput = 3,
        ShouldHandle = static args =>
        {
            return ValueTask.FromResult(args is
            {
                Outcome.Result.StatusCode:
            }
        }
    });
});
```

```

        HttpStatusCode.RequestTimeout or
        HttpStatusCode.TooManyRequests
    );
}
});

// See: https://www.pollydocs.org/strategies/timeout.html
builder.AddTimeout(TimeSpan.FromSeconds(5));
});

```

The preceding code:

- Adds a resilience handler with the name `"CustomPipeline"` as the `pipelineName` to the service container.
- Adds a retry strategy with exponential backoff, five retries, and jitter preference to the resilience builder.
- Adds a circuit breaker strategy with a sampling duration of 10 seconds, a failure ratio of 0.2 (20%), a minimum throughput of three, and a predicate that handles `RequestTimeout` and `TooManyRequests` HTTP status codes to the resilience builder.
- Adds a timeout strategy with a timeout of five seconds to the resilience builder.

There are many options available for each of the resilience strategies. For more information, see the [Polly docs: Strategies](#). For more information about configuring `ShouldHandle` delegates, see [Polly docs: Fault handling in reactive strategies](#).

Dynamic reload

Polly supports dynamic reloading of the configured resilience strategies. This means that you can change the configuration of the resilience strategies at run time. To enable dynamic reload, use the appropriate `AddResilienceHandler` overload that exposes the `ResilienceHandlerContext`. Given the context, call `EnableReloads` of the corresponding resilience strategy options:

C#

```

httpClientBuilder.AddResilienceHandler(
    "AdvancedPipeline",
    static (ResiliencePipelineBuilder<HttpResponseMessage> builder,
        ResilienceHandlerContext context) =>
{
    // Enable reloads whenever the named options change
    context.EnableReloads<HttpRetryStrategyOptions>("RetryOptions");

    // Retrieve the named options
    var retryOptions =
        context.GetOptions<HttpRetryStrategyOptions>("RetryOptions");
}
);

```

```
// Add retries using the resolved options
builder.AddRetry(retryOptions);
});
```

The preceding code:

- Adds a resilience handler with the name `"AdvancedPipeline"` as the `pipelineName` to the service container.
- Enables the reloads of the `"AdvancedPipeline"` pipeline whenever the named `RetryStrategyOptions` options change.
- Retrieves the named options from the `IOptionsMonitor<TOptions>` service.
- Adds a retry strategy with the retrieved options to the resilience builder.

For more information, see [Polly docs: Advanced dependency injection ↗](#).

This example relies on an options section that is capable of change, such as an `appsettings.json` file. Consider the following `appsettings.json` file:

JSON

```
{
  "RetryOptions": {
    "Retry": {
      "Backoff": "Linear",
      "UseJitter": false,
      "MaxRetryAttempts": 7
    }
  }
}
```

Now imagine that these options were bound to the app's configuration, binding the `HttpRetryStrategyOptions` to the `"RetryOptions"` section:

C#

```
var section = builder.Configuration.GetSection("RetryOptions");

builder.Services.Configure<HttpRetryStrategyOptions>(section);
```

For more information, see [Options pattern in .NET](#).

Example usage

Your app relies on [dependency injection](#) to resolve the `ExampleClient` and its corresponding `HttpClient`. The code builds the `IServiceProvider` and resolves the `ExampleClient` from it.

C#

```
IHost host = builder.Build();

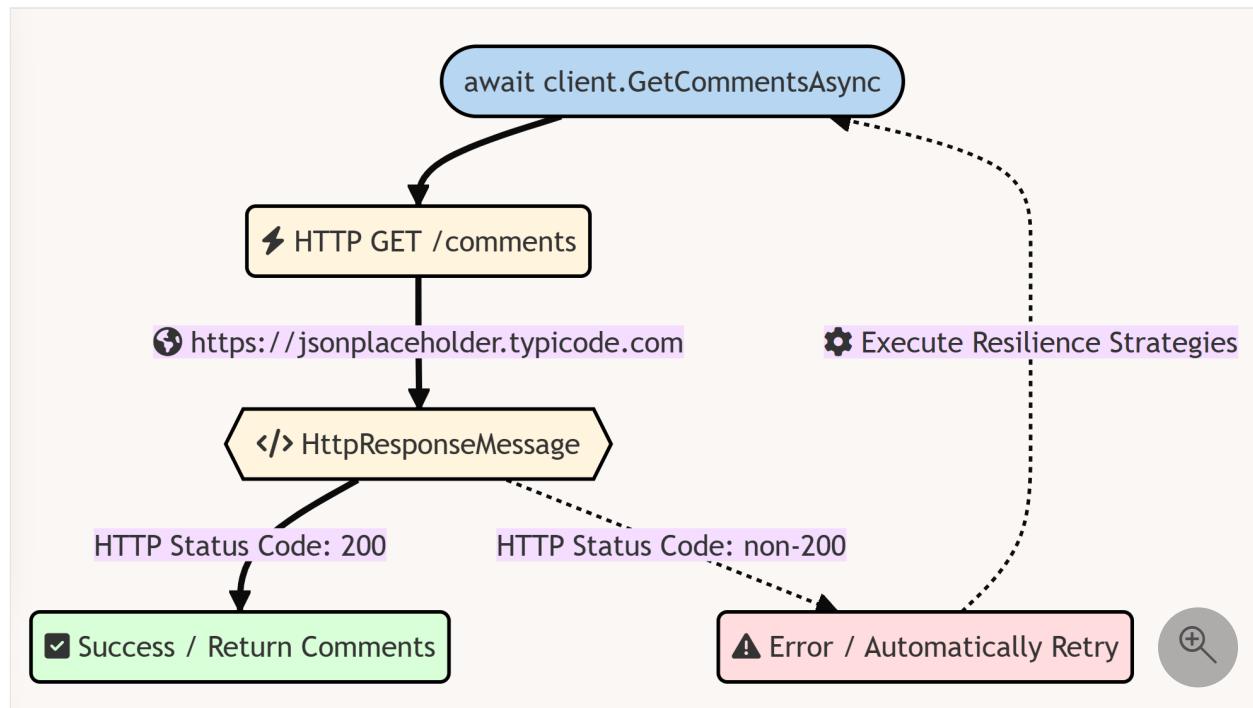

ExampleClient client = host.Services.GetRequiredService<ExampleClient>();

await foreach (Comment? comment in client.GetCommentsAsync())
{
    Console.WriteLine(comment);
}
```

The preceding code:

- Builds the `IServiceProvider` from the `ServiceCollection`.
- Resolves the `ExampleClient` from the `IServiceProvider`.
- Calls the `GetCommentsAsync` method on the `ExampleClient` to get the comments.
- Writes each comment to the console.

Imagine a situation where the network goes down or the server becomes unresponsive. The following diagram shows how the resilience strategies would handle the situation, given the `ExampleClient` and the `GetCommentsAsync` method:

The preceding diagram depicts:

- The `ExampleClient` sends an HTTP GET request to the `/comments` endpoint.

- The [HttpResponseMessage](#) is evaluated:
 - If the response is successful (HTTP 200), the response is returned.
 - If the response is unsuccessful (HTTP non-200), the resilience pipeline employs the configured resilience strategies.

While this is a simple example, it demonstrates how the resilience strategies can be used to handle transient errors. For more information, see [Polly docs: Strategies](#).

Use HTTP/3 with HttpClient

Article • 11/17/2023

[HTTP/3](#) is the third and recently standardized major version of HTTP. HTTP/3 uses the same semantics as HTTP/1.1 and HTTP/2: the same request methods, status codes, and message fields apply to all versions. The differences are in the underlying transport. Both HTTP/1.1 and HTTP/2 use TCP as their transport. HTTP/3 uses a transport technology developed alongside HTTP/3 called [QUIC](#).

HTTP/3 and QUIC both have several benefits compared to HTTP/1.1 and HTTP/2:

- Faster response time for the first request. QUIC and HTTP/3 negotiate the connection in fewer round trips between the client and the server. The first request reaches the server faster.
- Improved experience when there's connection packet loss. HTTP/2 multiplexes multiple requests via one TCP connection. Packet loss on the connection affects all requests. This problem is called "head-of-line blocking". Because QUIC provides native multiplexing, lost packets only affect the requests where data has been lost.
- Supports transitioning between networks. This feature is useful for mobile devices where it's common to switch between WIFI and cellular networks as a mobile device changes location. Currently, HTTP/1.1 and HTTP/2 connections fail with an error when switching networks. An app or web browser must retry any failed HTTP requests. HTTP/3 allows the app or web browser to seamlessly continue when a network changes. [HttpClient](#) and Kestrel don't support network transitions in .NET 7. It may be available in a future release.

ⓘ Important

Apps configured to take advantage of HTTP/3 should be designed to also support HTTP/1.1 and HTTP/2. If issues are identified in HTTP/3, it's recommend disabling HTTP/3 until the issues are resolved in a future release of .NET.

HttpClient settings

The HTTP version can be configured by setting `HttpRequestMessage.Version` to 3.0. However, because not all routers, firewalls, and proxies properly support HTTP/3, it's recommend configuring HTTP/3 together with HTTP/1.1 and HTTP/2. In `HttpClient`, this can be done by specifying:

- `HttpRequestMessage.Version` to 1.1.

- `HttpRequestMessage.VersionPolicy` to `HttpVersionPolicy.RequestVersionOrHigher`.

Platform dependencies

HTTP/3 uses QUIC as its transport protocol. The .NET implementation of HTTP/3 uses [MsQuic](#) to provide QUIC functionality. As a result, .NET support of HTTP/3 depends on MsQuic platform requirements. For more information on how to install [MsQuic](#), see [QUIC Platform dependencies](#). If the platform that `HttpClient` is running on doesn't have all the requirements for HTTP/3, then it's disabled.

Using `HttpClient`

The following code example uses [top-level statements](#) and demonstrates how to specify HTTP3 in the request:

C#

```
// See https://aka.ms/new-console-template for more information
using System.Net;

using var client = new HttpClient
{
    DefaultRequestVersion = HttpVersion.Version30,
    DefaultVersionPolicy = HttpVersionPolicy.RequestVersionExact
};

Console.WriteLine("--- localhost:5001 ---");

HttpResponseMessage resp = await client.GetAsync("https://localhost:5001/");
string body = await resp.Content.ReadAsStringAsync();

Console.WriteLine(
    $"status: {resp.StatusCode}, version: {resp.Version}, " +
    $"body: {body.Substring(0, Math.Min(100, body.Length))}");
```

HTTP/3 Support in .NET 6

In .NET 6, HTTP/3 is available as a *preview feature* because the HTTP/3 specification wasn't yet finalized. Behavioral or performance problems may exist in HTTP/3 with .NET 6. For more information on preview features, see [the preview features specification](#).

To enable HTTP/3 support in .NET 6, include the `RuntimeHostConfigurationOption` node in the project file to enable HTTP/3 with `HttpClient`:

XML

```
<ItemGroup>
  <RuntimeHostConfigurationOption Value="true"
    Include="System.Net.SocketsHttpHandler.Http3Support" />
</ItemGroup>
```

Alternatively, you can call [System.AppContext.SetSwitch](#) from your app code, or set the `DOTNET_SYSTEM_NET_HTTP_SOCKETSHTPHANDLER_HTTP3SUPPORT` environment variable to `true`. For more information, see [.NET environment variables](#): `DOTNET_SYSTEM_NET_HTTP_*`.

The reason for requiring a configuration flag for HTTP/3 is to protect apps from future breakage when using version policy `RequestVersionOrHigher`. When calling a server that currently uses HTTP/1.1 and HTTP/2, if the server later upgrades to HTTP/3, the client would try to use HTTP/3 and potentially be incompatible as the standard isn't final and therefore may change after .NET 6 is released.

.NET 6 is only compatible with the 1.9.x versions of libmsquic. Libmsquic 2.x isn't compatible with .NET 6 due to breaking changes in the library. Libmsquic receives updates to 1.9.x when needed to incorporate security fixes.

HTTP/3 Server

HTTP/3 is supported by ASP.NET with the Kestrel server in .NET 6 (as a preview) and .NET 7 (is fully supported). For more information, see [use HTTP/3 with the ASP.NET Core Kestrel web server](#).

Public test servers

Cloudflare hosts a site for HTTP/3 that can be used to test the client at <https://cloudflare-quic.com>.

Rate limit an HTTP handler in .NET

Article • 03/18/2023

In this article, you'll learn how to create a client-side HTTP handler that rate limits the number of requests it sends. You'll see an [HttpClient](#) that accesses the `"www.example.com"` resource. Resources are consumed by apps that rely on them, and when an app makes too many requests for a single resource, it can lead to *resource contention*. Resource contention occurs when a resource is consumed by too many apps, and the resource is unable to serve all of the apps that are requesting it. This can result in a poor user experience, and in some cases, it can even lead to a denial of service (DoS) attack. For more information on DoS, see [OWASP: Denial of Service ↗](#).

What is rate limiting?

Rate limiting is the concept of limiting how much a resource can be accessed. For example, you may know that a database your app accesses can safely handle 1,000 requests per minute, but it may not handle much more than that. You can put a rate limiter in your app that only allows 1,000 requests every minute and rejects any more requests before they can access the database. Thus, rate limiting your database and allowing your app to handle a safe number of requests. This is a common pattern in distributed systems, where you may have multiple instances of an app running, and you want to ensure that they don't all try to access the database at the same time. There are multiple different rate-limiting algorithms to control the flow of requests.

To use rate limiting in .NET, you'll reference the [System.Threading.RateLimiting ↗](#) NuGet package.

Implement a `DelegatingHandler` subclass

To control the flow of requests, you implement a custom [DelegatingHandler](#) subclass. This is a type of [HttpMessageHandler](#) that allows you to intercept and handle requests before they're sent to the server. You can also intercept and handle responses before they're returned to the caller. In this example, you'll implement a custom `DelegatingHandler` subclass that limits the number of requests that can be sent to a single resource. Consider the following custom `ClientSideRateLimitedHandler` class:

C#

```
internal sealed class ClientSideRateLimitedHandler  
    : DelegatingHandler, IAsyncDisposable
```

```

{
    private readonly RateLimiter _rateLimiter;

    public ClientSideRateLimitedHandler(RateLimiter limiter)
        : base(new HttpClientHandler()) => _rateLimiter = limiter;

    protected override async Task<HttpResponseMessage> SendAsync(
        HttpRequestMessage request, CancellationToken cancellationToken)
    {
        using RateLimitLease lease = await _rateLimiter.AcquireAsync(
            permitCount: 1, cancellationToken);

        if (lease.IsAcquired)
        {
            return await base.SendAsync(request, cancellationToken);
        }

        var response = new
        HttpResponseMessage(HttpStatusCode.TooManyRequests);
        if (lease.TryGetMetadata(
            MetadataName.RetryAfter, out TimeSpan retryAfter))
        {
            response.Headers.Add(
                "Retry-After",
                ((int)retryAfter.TotalSeconds).ToString(
                    NumberFormatInfo.InvariantInfo));
        }

        return response;
    }

    async ValueTask IAsyncDisposable.DisposeAsync()
    {
        await _rateLimiter.DisposeAsync().ConfigureAwait(false);

        Dispose(disposing: false);
        GC.SuppressFinalize(this);
    }
}

protected override void Dispose(bool disposing)
{
    base.Dispose(disposing);

    if (disposing)
    {
        _rateLimiter.Dispose();
    }
}
}

```

The preceding C# code:

- Inherits the `DelegatingHandler` type.

- Implements the [IAsyncDisposable](#) interface.
- Defines a `RateLimiter` field that is assigned from the constructor.
- Overrides the `SendAsync` method to intercept and handle requests before they're sent to the server.
- Overrides the `DisposeAsync()` method to dispose of the `RateLimiter` instance.

Looking a bit closer at the `SendAsync` method, you'll see that it:

- Relies on the `RateLimiter` instance to acquire a `RateLimitLease` from the `AcquireAsync`.
- When the `lease.IsAcquired` property is `true`, the request is sent to the server.
- Otherwise, an [HttpResponseMessage](#) is returned with a `429` status code, and if the `lease` contains a `RetryAfter` value, the `Retry-After` header is set to that value.

Emulate many concurrent requests

To put this custom `DelegatingHandler` subclass to the test, you'll create a console app that emulates many concurrent requests. This `Program` class creates an [HttpClient](#) with the custom `ClientSideRateLimitedHandler`:

C#

```
var options = new TokenBucketRateLimiterOptions
{
    TokenLimit = 8,
    QueueProcessingOrder = QueueProcessingOrder.OldestFirst,
    QueueLimit = 3,
    ReplenishmentPeriod = TimeSpan.FromMilliseconds(1),
    TokensPerPeriod = 2,
    AutoReplenishment = true
};

// Create an HTTP client with the client-side rate limited handler.
using HttpClient client = new(
    handler: new ClientSideRateLimitedHandler(
        limiter: new TokenBucketRateLimiter(options)));

// Create 100 urls with a unique query string.
var oneHundredUrls = Enumerable.Range(0, 100).Select(
    i => $"https://example.com?iteration={i:0#}");

// Flood the HTTP client with requests.
var floodOneThroughFortyNineTask = Parallel.ForEachAsync(
    source: oneHundredUrls.Take(0..49),
    body: (url, cancellationToken) => GetAsync(client, url,
    cancellationToken));
```

```

var floodFiftyThroughOneHundredTask = Parallel.ForEachAsync(
    source: oneHundredUrls.Take(^50..),
    body: (url, cancellationToken) => GetAsync(client, url,
    cancellationToken));

await Task.WhenAll(
    floodOneThroughFortyNineTask,
    floodFiftyThroughOneHundredTask);

static async ValueTask GetAsync(
    HttpClient client, string url, CancellationToken cancellationToken)
{
    using var response =
        await client.GetAsync(url, cancellationToken);

    Console.WriteLine(
        $"URL: {url}, HTTP status code: {response.StatusCode}
({(int)response.StatusCode})");
}

```

In the preceding console app:

- The `TokenBucketRateLimiterOptions` are configured with a token limit of `8`, and queue processing order of `oldestFirst`, a queue limit of `3`, and replenishment period of `1` millisecond, a tokens per period value of `2`, and an auto-replenish value of `true`.
- An `HttpClient` is created with the `ClientSideRateLimitedHandler` that is configured with the `TokenBucketRateLimiter`.
- To emulate 100 requests, `Enumerable.Range` creates 100 URLs, each with a unique query string parameter.
- Two `Task` objects are assigned from the `Parallel.ForEachAsync` method, splitting the URLs into two groups.
- The `HttpClient` is used to send a `GET` request to each URL, and the response is written to the console.
- `Task.WhenAll` waits for both tasks to complete.

Since the `HttpClient` is configured with the `ClientSideRateLimitedHandler`, not all requests will make it to the server resource. You can test this assertion by running the console app. You'll see that only a fraction of the total number of requests are sent to the server, and the rest are rejected with an HTTP status code of `429`. Try altering the `options` object used to create the `TokenBucketRateLimiter` to see how the number of requests that are sent to the server changes.

Consider the following example output:

Output

URL: https://example.com?iteration=06, HTTP status code: TooManyRequests (429)
URL: https://example.com?iteration=60, HTTP status code: TooManyRequests (429)
URL: https://example.com?iteration=55, HTTP status code: TooManyRequests (429)

```

You'll notice that the first logged entries are always the immediately returned 429 responses, and the last entries are always the 200 responses. This is because the rate limit is encountered client-side and avoids making an HTTP call to a server. This is a good thing because it means that the server isn't flooded with requests. It also means that the rate limit is enforced consistently across all clients.

Note also that each URL's query string is unique: examine the `iteration` parameter to see that it's incremented by one for each request. This parameter helps to illustrate that the 429 responses aren't from the first requests, but rather from the requests that are made after the rate limit is reached. The 200 responses arrive later but these requests were made earlier—before the limit was reached.

To have a better understanding of the various rate-limiting algorithms, try rewriting this code to accept a different `RateLimiter` implementation. In addition to the `TokenBucketRateLimiter` you could try:

- `ConcurrencyLimiter`
- `FixedWindowRateLimiter`
- `PartitionedRateLimiter`
- `SlidingWindowRateLimiter`

Summary

In this article, you learned how to implement a custom `ClientSideRateLimitedHandler`. This pattern could be used to implement a rate-limited HTTP client for resources that you know have API limits. In this way, you're preventing your client app from making unnecessary requests to the server, and you're also preventing your app from being blocked by the server. Additionally, with the use of metadata to store retry timing values, you could also implement automatic retry logic.

Customize SNI in HTTP requests

Article • 10/17/2023

When a client and server negotiate an HTTPS connection, a TLS connection needs to be established first. As part of the TLS handshake, the client sends the domain name of the server it's connecting to in one of the TLS extensions. When multiple (virtual) servers are hosted on the same machine, this feature of the TLS protocol allows clients to distinguish which of these servers they're connecting to and to configure TLS settings, such as the server certificate, accordingly.

When an HTTP request using `HttpClient` is made, the implementation automatically selects a value for the server name indication (SNI) extension based on the URL the client is connecting to. For scenarios that require more manual control of the extension, you can use one of the following approaches.

Host header

Host HTTP header performs a similar function as the SNI extension in TLS. It lets the target server distinguish among requests for multiple host names on a single IP address. `HttpClient` automatically fills in the Host header using the request URI. However, you can also set its value manually, and `HttpClient` will also use the new value in the SNI extension. You can use either `HttpRequestMessage.Headers.Host` or `HttpClient.DefaultRequestHeaders.Host` to achieve this effect.

C#

```
using HttpClient client = new();

client.DefaultRequestHeaders.Host = "www.microsoft.com";

using var response = await client.GetAsync("https://127.0.0.1:5001/");

System.Console.WriteLine(response);
```

ⓘ Note

This method doesn't allow you to avoid sending SNI altogether when connecting to a URL with a hostname. If the header is set to empty string, `HttpClient` uses the hostname from the URL instead.

⚠ Note

Customizing the Host header affects server certificate validation. By default, client will expect the server certificate to match the hostname in the Host header.

Manual SslStream authentication via ConnectCallback

A more complicated, but also more powerful, option is to use the `SocketsHttpHandler.ConnectCallback`. Since .NET 7, it's possible to return an authenticated `SslStream` and thus customize how the TLS connection is established. Inside the callback, arbitrary `SslClientAuthenticationOptions` options can be used to perform client-side authentication.

C#

```
var handler = new SocketsHttpHandler
{
    ConnectCallback = async (context, cancellationToken) =>
    {
        var socket = new Socket(SocketType.Stream, ProtocolType.Tcp) { NoDelay = true };
        try
        {
            await socket.ConnectAsync(context.DnsEndPoint,
                cancellationToken);

            var sslStream = new SslStream(new NetworkStream(socket,
                ownsSocket: true));

            // When using HTTP/2, you must also keep in mind to set options like ApplicationProtocols
            await sslStream.AuthenticateAsClientAsync(new SslClientAuthenticationOptions
            {
                TargetHost = context.DnsEndPoint.Host,
            }, cancellationToken);

            return sslStream;
        }
        catch
        {
            socket.Dispose();
            throw;
        }
    }
}
```

```
};

using HttpClient client = new(handler);

using var response = await client.GetAsync("https://www.microsoft.com");

System.Console.WriteLine(response);
```

System.Net.Http.HttpClient class

Article • 01/08/2024

This article provides supplementary remarks to the reference documentation for this API.

The [HttpClient](#) class instance acts as a session to send HTTP requests. An [HttpClient](#) instance is a collection of settings applied to all requests executed by that instance. In addition, every [HttpClient](#) instance uses its own connection pool, isolating its requests from requests executed by other [HttpClient](#) instances.

Instancing

[HttpClient](#) is intended to be instantiated once and reused throughout the life of an application. In .NET Core and .NET 5+, [HttpClient](#) pools connections inside the handler instance and reuses a connection across multiple requests. If you instantiate an [HttpClient](#) class for every request, the number of sockets available under heavy loads will be exhausted. This exhaustion will result in [SocketException](#) errors.

You can configure additional options by passing in a "handler", such as [HttpClientHandler](#) (or [SocketsHttpHandler](#) in .NET Core 2.1 or later), as part of the constructor. The connection properties on the handler cannot be changed once a request has been submitted, so one reason to create a new [HttpClient](#) instance would be if you need to change the connection properties. If different requests require different settings, this may also lead to an application having multiple [HttpClient](#) instances, where each instance is configured appropriately, and then requests are issued on the relevant client.

[HttpClient](#) only resolves DNS entries when a connection is created. It does not track any time to live (TTL) durations specified by the DNS server. If DNS entries change regularly, which can happen in some container scenarios, the client won't respect those updates. To solve this issue, you can limit the lifetime of the connection by setting the [SocketsHttpHandler.PooledConnectionLifetime](#) property, so that DNS lookup is required when the connection is replaced.

C#

```
public class GoodController : ApiController
{
    private static readonly HttpClient httpClient;

    static GoodController()
```

```

    {
        var socketsHandler = new SocketsHttpHandler
        {
            PooledConnectionLifetime = TimeSpan.FromMinutes(2)
        };

        httpClient = new HttpClient(socketsHandler);
    }
}

```

As an alternative to creating only one `HttpClient` instance, you can also use [IHttpClientFactory](#) to manage the `HttpClient` instances for you. For more information, see [Guidelines for using HttpClient](#).

Derivation

The `HttpClient` also acts as a base class for more specific HTTP clients. An example would be a `FacebookHttpClient` that provides additional methods specific to a Facebook web service (for example, a `GetFriends` method). Derived classes should not override the virtual methods on the class. Instead, use a constructor overload that accepts `HttpMessageHandler` to configure any pre-request or post-request processing.

Transports

The `HttpClient` is a high-level API that wraps the lower-level functionality available on each platform where it runs.

On each platform, `HttpClient` tries to use the best available transport:

[] [Expand table](#)

| Host/Runtime | Backend |
|---------------------------|--|
| Windows/.NET Framework | HttpWebRequest |
| Windows/Mono | HttpWebRequest |
| Windows/UWP | Windows native WinHttpHandler (HTTP 2.0 capable) |
| Windows/.NET Core 1.0-2.0 | Windows native WinHttpHandler (HTTP 2.0 capable) |
| Android/Xamarin | Selected at build-time. Can either use HttpWebRequest or be configured to use Android's native HttpURLConnection ↗ |

| Host/Runtime | Backend |
|-------------------------------|---|
| iOS, tvOS, watchOS/Xamarin | Selected at build-time. Can either use HttpWebRequest or be configured to use Apple's NSURLSession (HTTP 2.0 capable) |
| macOS/Xamarin | Selected at build-time. Can either use HttpWebRequest or be configured to use Apple's NSURLSession (HTTP 2.0 capable) |
| macOS/Mono | HttpWebRequest |
| macOS/.NET Core 1.0- 2.0 | <code>libcurl</code> -based HTTP transport (HTTP 2.0 capable) |
| Linux/Mono | HttpWebRequest |
| Linux/.NET Core 1.0- 2.0 | <code>libcurl</code> -based HTTP transport (HTTP 2.0 capable) |
| .NET Core 2.1 and later | System.Net.Http.SocketsHttpHandler |

Users can also configure a specific transport for [HttpClient](#) by invoking the [HttpClient](#) constructor that takes an [HttpMessageHandler](#).

.NET Framework & Mono

By default on .NET Framework and Mono, [HttpWebRequest](#) is used to send requests to the server. This behavior can be modified by specifying a different handler in one of the constructor overloads with an [HttpMessageHandler](#) parameter. If you require features like authentication or caching, you can use [WebRequestHandler](#) to configure settings and the instance can be passed to the constructor. The returned handler can be passed to a constructor overload that has an [HttpMessageHandler](#) parameter.

.NET Core

Starting with .NET Core 2.1, the [System.Net.Http.SocketsHttpHandler](#) class instead of [HttpClientHandler](#) provides the implementation used by higher-level HTTP networking classes such as [HttpClient](#). The use of [SocketsHttpHandler](#) offers a number of advantages:

- A significant performance improvement when compared with the previous implementation.
- The elimination of platform dependencies, which simplifies deployment and servicing. For example, `libcurl` is no longer a dependency on .NET Core for macOS and .NET Core for Linux.

- Consistent behavior across all .NET platforms.

If this change is undesirable, on Windows you can continue to use [WinHttpHandler](#) by referencing its [NuGet package](#) and passing it to [HttpClient's constructor](#) manually.

Configure behavior using runtime configuration options

Certain aspects of [HttpClient](#)'s behavior are customizable through [Runtime configuration options](#). However, the behavior of these switches differs through .NET versions. For example, in .NET Core 2.1 - 3.1, you can configure whether [SocketsHttpHandler](#) is used by default, but that option is no longer available starting in .NET 5.0.

Connection pooling

[HttpClient](#) pools HTTP connections where possible and uses them for more than one request. This can have a significant performance benefit, especially for HTTPS requests, as the connection handshake is only done once.

Connection pool properties can be configured on a [HttpClientHandler](#) or [SocketsHttpHandler](#) passed in during construction, including [MaxConnectionsPerServer](#), [PooledConnectionIdleTimeout](#), and [PooledConnectionLifetime](#).

Disposing of the [HttpClient](#) instance closes the open connections and cancels any pending requests.

Note

If you concurrently send HTTP/1.1 requests to the same server, new connections can be created. Even if you reuse the `HttpClient` instance, if the rate of requests is high, or if there are any firewall limitations, that can exhaust the available sockets because of default TCP cleanup timers. To limit the number of concurrent connections, you can set the `MaxConnectionsPerServer` property. By default, the number of concurrent HTTP/1.1 connections is unlimited.

Buffering and request lifetime

By default, `HttpClient` methods (except `GetStreamAsync`) buffer the responses from the server, reading all the response body into memory before returning the async result. Those requests will continue until one of the following occurs:

- The `Task<TResult>` succeeds and returns a result.
- The `Timeout` is reached, in which case the `Task<TResult>` will be cancelled.
- The `CancellationToken` passable to some method overloads is fired.
- `CancelPendingRequests()` is called.
- The `HttpClient` is disposed.

You can change the buffering behavior on a per-request basis using the `HttpCompletionOption` parameter available on some method overloads. This argument can be used to specify if the `Task<TResult>` should be considered complete after reading just the response headers, or after reading and buffering the response content.

If your app that uses `HttpClient` and related classes in the `System.Net.Http` namespace intends to download large amounts of data (50 megabytes or more), then the app should stream those downloads and not use the default buffering. If you use the default buffering, the client memory usage will get very large, potentially resulting in substantially reduced performance.

Thread safety

The following methods are thread safe:

- `CancelPendingRequests`
- `DeleteAsync`
- `GetAsync`
- `GetByteArrayAsync`
- `GetStreamAsync`
- `GetStringAsync`
- `PostAsync`
- `PutAsync`
- `SendAsync`

Proxies

By default, `HttpClient` reads proxy configuration from environment variables or user/system settings, depending on the platform. You can change this behavior by passing a `WebProxy` or `IWebProxy` to, in order of precedence:

- The [Proxy](#) property on a `HttpClientHandler` passed in during `HttpClient` construction
- The [DefaultProxy](#) static property (affects all instances)

You can disable the proxy using [UseProxy](#). The default configuration for Windows users is to try and detect a proxy using network discovery, which can be slow. For high throughput applications where it's known that a proxy isn't required, you should disable the proxy.

Proxy settings (like [Credentials](#)) should be changed only before the first request is made using the `HttpClient`. Changes made after using the `HttpClient` for the first time may not be reflected in subsequent requests.

Timeouts

You can use [Timeout](#) to set a default timeout for all HTTP requests from the `HttpClient` instance. The timeout only applies to the `xxxAsync` methods that cause a request/response to be initiated. If the timeout is reached, the [Task<TResult>](#) for that request is cancelled.

You can set some additional timeouts if you pass in a [SocketsHttpHandler](#) instance when constructing the `HttpClient` object:

[\[\]](#) [Expand table](#)

| Property | Description |
|---|--|
| ConnectTimeout | Specifies a timeout that's used when a request requires a new TCP connection to be created. If the timeout occurs, the request Task<TResult> is cancelled. |
| PooledConnectionLifetime | Specifies a timeout to be used for each connection in the connection pool. If the connection is idle, the connection is immediately closed; otherwise, the connection is closed at the end of the current request. |
| PooledConnectionIdleTimeout | If a connection in the connection pool is idle for this long, the connection is closed. |
| Expect100ContinueTimeout | If request has an "Expect: 100-continue" header, it delays sending content until the timeout or until a "100-continue" response is received. |

`HttpClient` only resolves DNS entries when the connections are created. It does not track any time to live (TTL) durations specified by the DNS server. If DNS entries are changing

regularly, which can happen in some container scenarios, you can use the [PooledConnectionLifetime](#) to limit the lifetime of the connection so that DNS lookup is required when replacing the connection.

System.Net.Http.HttpClientHandler class

Article • 01/08/2024

This article provides supplementary remarks to the reference documentation for this API.

The [HttpClientHandler](#) class and classes derived from it enable developers to configure a variety of options ranging from proxies to authentication.

HttpClientHandler in .NET Core

Starting in .NET Core 2.1, the implementation of the `HttpClientHandler` class was changed to be based on the cross-platform HTTP protocol stack used by the [System.Net.Http.SocketsHttpHandler](#) class. Prior to .NET Core 2.1, the `HttpClientHandler` class used older HTTP protocol stacks ([WinHttpHandler](#) on Windows and `CurlHandler`, an internal class implemented on top of Linux's native `libcurl` component, on Linux).

On .NET Core 2.1 - 3.1 only, you can configure your app to use the older HTTP protocol stacks in one of the following three ways:

- Call the [AppContext.SetSwitch](#) method:

C#

```
AppContext.SetSwitch("System.Net.Http.UseSocketsHttpHandler", false);
```

VB

```
AppContext.SetSwitch("System.Net.Http.UseSocketsHttpHandler", False)
```

- Define the `System.Net.Http.UseSocketsHttpHandler` switch in the `.netcore.runtimeconfig.json` configuration file:

JSON

```
"runtimeOptions": {
    "configProperties": {
        "System.Net.Http.UseSocketsHttpHandler": false
    }
}
```

- Define an environment variable named `DOTNET_SYSTEM_NET_HTTP_USESOCKETSHTTPHANDLER` and set it to either `false` or `0`.

These configuration options are not available starting with .NET 5.

System.Net.HttpListener class

Article • 01/08/2024

This article provides supplementary remarks to the reference documentation for this API.

Using the [HttpListener](#) class, you can create a simple HTTP protocol listener that responds to HTTP requests. The listener is active for the lifetime of the [HttpListener](#) object and runs within your application with its permissions.

To use [HttpListener](#), create a new instance of the class using the [HttpListener](#) constructor and use the [Prefixes](#) property to gain access to the collection that holds the strings that specify which Uniform Resource Identifier (URI) prefixes the [HttpListener](#) should process.

A URI prefix string is composed of a scheme (http or https), a host, an optional port, and an optional path. An example of a complete prefix string is

`http://www.contoso.com:8080/customerData/`. Prefixes must end in a forward slash ("/").

The [HttpListener](#) object with the prefix that most closely matches a requested URI responds to the request. Multiple [HttpListener](#) objects cannot add the same prefix; a [Win32Exception](#) exception is thrown if a [HttpListener](#) adds a prefix that is already in use.

When a port is specified, the host element can be replaced with "*" to indicate that the [HttpListener](#) accepts requests sent to the port if the requested URI does not match any other prefix. For example, to receive all requests sent to port 8080 when the requested URI is not handled by any [HttpListener](#), the prefix is `http://*:8080/`. Similarly, to specify that the [HttpListener](#) accepts all requests sent to a port, replace the host element with the "+" character. For example, `https://+:8080`. The "*" and "+" characters can be present in prefixes that include paths.

Starting with .NET Core 2.0 or .NET Framework 4.6 on Windows 10, wildcard subdomains are supported in URI prefixes that are managed by an [HttpListener](#) object. To specify a wildcard subdomain, use the "*" character as part of the hostname in a URI prefix. For example, `http://*.foo.com/`. Pass this as the argument to the [Add](#) method.

⚠ Warning

Top-level wildcard bindings (`http://*:8080/` and `http://+:8080`) should **not** be used. Top-level wildcard bindings can open up your app to security vulnerabilities. This applies to both strong and weak wildcards. Use explicit host names rather than wildcards. Subdomain wildcard binding (for example, `*.mysub.com`) doesn't have

this security risk if you control the entire parent domain (as opposed to `*.com`, which is vulnerable). See [rfc7230 section-5.4](#) for more information.

To begin listening for requests from clients, add the URI prefixes to the collection and call the [Start](#) method. [HttpListener](#) offers both synchronous and asynchronous models for processing client requests. Requests and their associated responses are accessed using the [HttpListenerContext](#) object returned by the [GetContext](#) method or its asynchronous counterparts, the [BeginGetContext](#) and [EndGetContext](#) methods.

The synchronous model is appropriate if your application should block while waiting for a client request and if you want to process only one request at a time. Using the synchronous model, call the [GetContext](#) method, which waits for a client to send a request. The method returns an [HttpListenerContext](#) object to you for processing when one occurs.

In the more complex asynchronous model, your application does not block while waiting for requests and each request is processed in its own execution thread. Use the [BeginGetContext](#) method to specify an application-defined method to be called for each incoming request. Within that method, call the [EndGetContext](#) method to obtain the request, process it, and respond.

In either model, incoming requests are accessed using the [HttpListenerContext.Request](#) property and are represented by [HttpListenerRequest](#) objects. Similarly, responses are accessed using the [HttpListenerContext.Response](#) property and are represented by [HttpListenerResponse](#) objects. These objects share some functionality with the [HttpWebRequest](#) and [HttpWebResponse](#) objects, but the latter objects cannot be used in conjunction with [HttpListener](#) because they implement client, not server, behaviors.

An [HttpListener](#) can require client authentication. You can either specify a particular scheme to use for authentication, or you can specify a delegate that determines the scheme to use. You must require some form of authentication to obtain information about the client's identity. For additional information, see the [User](#), [AuthenticationSchemes](#), and [AuthenticationSchemeSelectorDelegate](#) properties.

① Note

If you create an [HttpListener](#) using `https`, you must select a Server Certificate for that listener. Otherwise, requests to this [HttpListener](#) will fail with an unexpected close of the connection.

① Note

You can configure Server Certificates and other listener options by using Network Shell (netsh.exe). See [Network Shell \(Netsh\)](#) for more details. The executable began shipping with Windows Server 2008 and Windows Vista.

Note

If you specify multiple authentication schemes for the [HttpListener](#), the listener will challenge clients in the following order: `Negotiate`, `NTLM`, `Digest`, and then `Basic`.

HTTP.sys

The [HttpListener](#) class is built on top of `HTTP.sys`, which is the kernel mode listener that handles all HTTP traffic for Windows. `HTTP.sys` provides connection management, bandwidth throttling, and web server logging. Use the [HttpCfg.exe](#) tool to add SSL certificates.

Sockets in .NET

Article • 08/27/2022

The [System.Net.Sockets](#) namespace contains a managed, cross-platform socket networking implementation. All other network-access classes in the [System.Net](#) namespace are built on top of this implementation of sockets.

The [Socket](#) class is a managed-code version of the socket services provided relying on native interoperability with Linux, macOS, or Windows. In most cases, the `Socket` class methods simply marshal data into their native counterparts and handle any necessary security checks.

The `Socket` class supports two basic modes, synchronous and asynchronous. In synchronous mode, calls to functions that perform network operations (such as [SendAsync](#) and [ReceiveAsync](#)) wait until the operation completes before returning control to the calling program. In asynchronous mode, these calls return immediately.

Use Sockets to send and receive data over TCP

Article • 12/01/2022

Before you can use a socket to communicate with remote devices, the socket must be initialized with protocol and network address information. The constructor for the [Socket](#) class has parameters that specify the address family, socket type, and protocol type that the socket uses to make connections. When connecting a client socket to a server socket, the client will use an [IPEndPoint](#) object to specify the network address of the server.

Create an IP endpoint

When working with [System.Net.Sockets](#), you represent a network endpoint as an [IPEndPoint](#) object. The [IPEndPoint](#) is constructed with an [IPAddress](#) and its corresponding port number. Before you can initiate a conversation through a [Socket](#), you create a data pipe between your app and the remote destination.

TCP/IP uses a network address and a service port number to uniquely identify a service. The network address identifies a specific network destination; the port number identifies the specific service on that device to connect to. The combination of network address and service port is called an endpoint, which is represented in the .NET by the [EndPoint](#) class. A descendant of [EndPoint](#) is defined for each supported address family; for the IP address family, the class is [IPEndPoint](#).

The [Dns](#) class provides domain-name services to apps that use TCP/IP internet services. The [GetHostEntryAsync](#) method queries a DNS server to map a user-friendly domain name (such as "host.contoso.com") to a numeric Internet address (such as `192.168.1.1`). [GetHostEntryAsync](#) returns a [Task<IPHostEntry>](#) that when awaited contains a list of addresses and aliases for the requested name. In most cases, you can use the first address returned in the [AddressList](#) array. The following code gets an [IPAddress](#) containing the IP address for the server `host.contoso.com`.

C#

```
IPHostEntry ipHostInfo = await Dns.GetHostEntryAsync("host.contoso.com");
IPAddress ipAddress = ipHostInfo.AddressList[0];
```

Tip

For manual testing and debugging purposes, you can typically use the `GetHostEntryAsync` method to get given the `Dns.GetHostName()` value to resolve the localhost name to an IP address.

The Internet Assigned Numbers Authority (IANA) defines port numbers for common services. For more information, see [IANA: Service Name and Transport Protocol Port Number Registry](#). Other services can have registered port numbers in the range 1,024 to 65,535. The following code combines the IP address for `host.contoso.com` with a port number to create a remote endpoint for a connection.

C#

```
IPEndPoint ipEndPoint = new(ipAddress, 11_000);
```

After determining the address of the remote device and choosing a port to use for the connection, the app can establish a connection with the remote device.

Create a `Socket` client

With the `endPoint` object created, create a client socket to connect to the server. Once the socket is connected, it can send and receive data from the server socket connection.

C#

```
using Socket client = new(
    ipEndPoint.AddressFamily,
    SocketType.Stream,
    ProtocolType.Tcp);

await client.ConnectAsync(ipEndPoint);
while (true)
{
    // Send message.
    var message = "Hi friends 🤙!<|EOM|>";
    var messageBytes = Encoding.UTF8.GetBytes(message);
    _ = await client.SendAsync(messageBytes, SocketFlags.None);
    Console.WriteLine($"Socket client sent message: \"{message}\"");

    // Receive ack.
    var buffer = new byte[1_024];
    var received = await client.ReceiveAsync(buffer, SocketFlags.None);
    var response = Encoding.UTF8.GetString(buffer, 0, received);
    if (response == "<|ACK|>")
    {
        Console.WriteLine(
            $"Socket client received acknowledgment: \"{response}\"");
```

```

        break;
    }
    // Sample output:
    //     Socket client sent message: "Hi friends 🙌!<|EOM|>"
    //     Socket client received acknowledgment: "<|ACK|>"
}

client.Shutdown(SocketShutdown.Both);

```

The preceding C# code:

- Instantiates a new `Socket` object with a given `endPoint` instances address family, the `SocketType.Stream`, and `ProtocolType.Tcp`.
- Calls the `Socket.ConnectAsync` method with the `endPoint` instance as an argument.
- In a `while` loop:
 - Encodes and sends a message to the server using `Socket.SendAsync`.
 - Writes the sent message to the console.
 - Initializes a buffer to receive data from the server using `Socket.ReceiveAsync`.
 - When the `response` is an acknowledgment, it is written to the console and the loop is exited.
- Finally, the `client` socket calls `Socket.Shutdown` given `SocketShutdown.Both`, which shuts down both send and receive operations.

Create a `Socket` server

To create the server socket, the `endPoint` object can listen for incoming connections on any IP address but the port number must be specified. Once the socket is created, the server can accept incoming connections and communicate with clients.

C#

```

using Socket listener = new(
    ipEndPoint.AddressFamily,
    SocketType.Stream,
    ProtocolType.Tcp);

listener.Bind(ipEndPoint);
listener.Listen(100);

var handler = await listener.AcceptAsync();
while (true)
{
    // Receive message.
    var buffer = new byte[1_024];

```

```

    var received = await handler.ReceiveAsync(buffer, SocketFlags.None);
    var response = Encoding.UTF8.GetString(buffer, 0, received);

    var eom = "<|EOM|>";
    if (response.IndexOf(eom) > -1 /* is end of message */)
    {
        Console.WriteLine(
            $"Socket server received message: \'{response.Replace(eom,
            "")}\'{\"}");
    }

    var ackMessage = "<|ACK|>";
    var echoBytes = Encoding.UTF8.GetBytes(ackMessage);
    await handler.SendAsync(echoBytes, 0);
    Console.WriteLine(
        $"Socket server sent acknowledgment: \'{ackMessage}\'{\"}");

    break;
}
// Sample output:
//     Socket server received message: "Hi friends 🙌!"
//     Socket server sent acknowledgment: "<|ACK|>"
}

```

The preceding C# code:

- Instantiates a new `Socket` object with a given `endPoint` instances address family, the `SocketType.Stream`, and `ProtocolType.Tcp`.
- The `listener` calls the `Socket.Bind` method with the `endPoint` instance as an argument to associate the socket with the network address.
- The `Socket.Listen()` method is called to listen for incoming connections.
- The `listener` calls the `Socket.AcceptAsync` method to accept an incoming connection on the `handler` socket.
- In a `while` loop:
 - Calls `Socket.ReceiveAsync` to receive data from the client.
 - When the data is received, it's decoded and written to the console.
 - If the `response` message ends with `<|EOM|>`, an acknowledgment is sent to the client using the `Socket.SendAsync`.

Run the sample client and server

Start the server application first, and then start the client application.

.NET CLI

```
dotnet run --project socket-server
Socket server starting...
Found: 172.23.64.1 available on port 9000.
Socket server received message: "Hi friends 🤙 !"
Socket server sent acknowledgment: "<|ACK|>"
Press ENTER to continue...
```

The client application will send a message to the server, and the server will respond with an acknowledgment.

.NET CLI

```
dotnet run --project socket-client
Socket client starting...
Found: 172.23.64.1 available on port 9000.
Socket client sent message: "Hi friends 🤙 !<|EOM|>"
Socket client received acknowledgment: "<|ACK|>"
Press ENTER to continue...
```

TCP overview

Article • 12/06/2022

ⓘ Important

The [Socket](#) class is highly recommended for advanced users, instead of [TcpClient](#) and [TcpListener](#).

To work with Transmission Control Protocol (TCP), you have two options: either use [Socket](#) for maximum control and performance, or use the [TcpClient](#) and [TcpListener](#) helper classes. [TcpClient](#) and [TcpListener](#) are built on top of the [System.Net.Sockets.Socket](#) class and take care of the details of transferring data for ease of use.

The protocol classes use the underlying [Socket](#) class to provide simple access to network services without the overhead of maintaining state information or knowing the details of setting up protocol-specific sockets. To use asynchronous [Socket](#) methods, you can use the asynchronous methods supplied by the [NetworkStream](#) class. To access features of the [Socket](#) class not exposed by the protocol classes, you must use the [Socket](#) class.

[TcpClient](#) and [TcpListener](#) represent the network using the [NetworkStream](#) class. You use the [GetStream](#) method to return the network stream, and then call the stream's [NetworkStream.ReadAsync](#) and [NetworkStream.WriteAsync](#) methods. The [NetworkStream](#) does not own the protocol classes' underlying socket, so closing it does not affect the socket.

Use [TcpClient](#) and [TcpListener](#)

The [TcpClient](#) class requests data from an internet resource using TCP. The methods and properties of [TcpClient](#) abstract the details for creating a [Socket](#) for requesting and receiving data using TCP. Because the connection to the remote device is represented as a stream, data can be read and written with .NET Framework stream-handling techniques.

The TCP protocol establishes a connection with a remote endpoint and then uses that connection to send and receive data packets. TCP is responsible for ensuring that data packets are sent to the endpoint and assembled in the correct order when they arrive.

Create an IP endpoint

When working with [System.Net.Sockets](#), you represent a network endpoint as an [IPEndPoint](#) object. The [IPEndPoint](#) is constructed with an [IPAddress](#) and its corresponding port number. Before you can initiate a conversation through a [Socket](#), you create a data pipe between your app and the remote destination.

TCP/IP uses a network address and a service port number to uniquely identify a service. The network address identifies a specific network destination; the port number identifies the specific service on that device to connect to. The combination of network address and service port is called an endpoint, which is represented in the .NET by the [EndPoint](#) class. A descendant of [EndPoint](#) is defined for each supported address family; for the IP address family, the class is [IPEndPoint](#).

The [Dns](#) class provides domain-name services to apps that use TCP/IP internet services. The [GetHostEntryAsync](#) method queries a DNS server to map a user-friendly domain name (such as "host.contoso.com") to a numeric Internet address (such as [192.168.1.1](#)). [GetHostEntryAsync](#) returns a [Task<IPHostEntry>](#) that when awaited contains a list of addresses and aliases for the requested name. In most cases, you can use the first address returned in the [AddressList](#) array. The following code gets an [IPAddress](#) containing the IP address for the server [host.contoso.com](#).

C#

```
IPHostEntry ipHostInfo = await Dns.GetHostEntryAsync("host.contoso.com");
IPAddress ipAddress = ipHostInfo.AddressList[0];
```

Tip

For manual testing and debugging purposes, you can typically use the [GetHostEntryAsync](#) method to get given the [Dns.GetHostName\(\)](#) value to resolve the localhost name to an IP address.

The Internet Assigned Numbers Authority (IANA) defines port numbers for common services. For more information, see [IANA: Service Name and Transport Protocol Port Number Registry](#). Other services can have registered port numbers in the range 1,024 to 65,535. The following code combines the IP address for [host.contoso.com](#) with a port number to create a remote endpoint for a connection.

C#

```
IPEndPoint ipEndPoint = new(ipAddress, 11_000);
```

After determining the address of the remote device and choosing a port to use for the connection, the app can establish a connection with the remote device.

Create a `TcpClient`

The `TcpClient` class provides TCP services at a higher level of abstraction than the `Socket` class. `TcpClient` is used to create a client connection to a remote host. Knowing how to get an `IPPEndPoint`, let's assume you have an `IPAddress` to pair with your desired port number. The following example demonstrates setting up a `TcpClient` to connect to a time server on TCP port 13:

C#

```
var ipEndPoint = new IPPEndPoint(ipAddress, 13);

using TcpClient client = new();
await client.ConnectAsync(ipEndPoint);
await using NetworkStream stream = client.GetStream();

var buffer = new byte[1_024];
int received = await stream.ReadAsync(buffer);

var message = Encoding.UTF8.GetString(buffer, 0, received);
Console.WriteLine($"Message received: \"{message}\"");
// Sample output:
//     Message received: "📅 8/22/2022 9:07:17 AM ⏳"
```

The preceding C# code:

- Creates an `IPPEndPoint` from a known `IPAddress` and port.
- Instantiate a new `TcpClient` object.
- Connects the `client` to the remote TCP time server on port 13 using `TcpClient.ConnectAsync`.
- Uses a `NetworkStream` to read data from the remote host.
- Declares a read buffer of `1_024` bytes.
- Reads data from the `stream` into the read buffer.
- Writes the results as a string to the console.

Since the client knows that the message is small, the entire message can be read into the read buffer in one operation. With larger messages, or messages with an

indeterminate length, the client should use the buffer more appropriately and read in a `while` loop.

ⓘ Important

When sending and receiving messages, the [Encoding](#) should be known ahead of time to both server and client. For example, if the server communicates using [ASCIIEncoding](#) but the client attempts to use [UTF8Encoding](#), the messages will be malformed.

Create a `TcpListener`

The [TcpListener](#) type is used to monitor a TCP port for incoming requests and then create either a [Socket](#) or a [TcpClient](#) that manages the connection to the client. The [Start](#) method enables listening, and the [Stop](#) method disables listening on the port. The [AcceptTcpClientAsync](#) method accepts incoming connection requests and creates a [TcpClient](#) to handle the request, and the [AcceptSocketAsync](#) method accepts incoming connection requests and creates a [Socket](#) to handle the request.

The following example demonstrates creating a network time server using a `TcpListener` to monitor TCP port 13. When an incoming connection request is accepted, the time server responds with the current date and time from the host server.

C#

```
var ipEndPoint = new IPEndPoint(IPAddress.Any, 13);
TcpListener listener = new(ipEndPoint);

try
{
    listener.Start();

    using TcpClient handler = await listener.AcceptTcpClientAsync();
    await using NetworkStream stream = handler.GetStream();

    var message = $"📅 {DateTime.Now} ⏰";
    var dateTimeBytes = Encoding.UTF8.GetBytes(message);
    await stream.WriteAsync(dateTimeBytes);

    Console.WriteLine($"Sent message: \'{message}\'");
    // Sample output:
    //      Sent message: "📅 8/22/2022 9:07:17 AM ⏰"
}
finally
{}
```

```
    listener.Stop();
}
```

The preceding C# code:

- Creates an `IPPEndPoint` with `IPAddress.Any` and port.
- Instantiate a new `TcpListener` object.
- Calls the `Start` method to start listening on the port.
- Uses a `TcpClient` from the `AcceptTcpClientAsync` method to accept incoming connection requests.
- Encodes the current date and time as a string message.
- Uses a `NetworkStream` to write data to the connected client.
- Writes the sent message to the console.
- Finally, calls the `Stop` method to stop listening on the port.

Finite TCP control with the `Socket` class

Both `TcpClient` and `TcpListener` internally rely on the `Socket` class, meaning anything you can do with these classes can be achieved using sockets directly. This section demonstrates several `TcpClient` and `TcpListener` use cases, along with their `Socket` counterpart that is functionally equivalent.

Create a client socket

`TcpClient`'s default constructor tries to create a *dual-stack socket* via the `Socket(SocketType, ProtocolType)` constructor. This constructor creates a dual-stack socket if [IPv6 is supported](#), otherwise, it falls back to IPv4.

Consider the following TCP client code:

```
C#
```

```
using var client = new TcpClient();
```

The preceding TCP client code is functionally equivalent to the following socket code:

```
C#
```

```
using var socket = new Socket(SocketType.Stream, ProtocolType.Tcp);
```

The [TcpClient\(AddressFamily\)](#) constructor

This constructor accepts only three `AddressFamily` values, otherwise it will throw a `ArgumentException`. Valid values are:

- `AddressFamily.InterNetwork`: for IPv4 socket.
- `AddressFamily.InterNetworkV6`: for IPv6 socket.
- `AddressFamily.Unknown`: this will attempt to create a dual-stack socket, similarly to the default constructor.

Consider the following TCP client code:

C#

```
using var client = new TcpClient(AddressFamily.InterNetwork);
```

The preceding TCP client code is functionally equivalent to the following socket code:

C#

```
using var socket = new Socket(AddressFamily.InterNetwork, SocketType.Stream,  
ProtocolType.Tcp);
```

The [TcpClient\(IPEndPoint\)](#) constructor

Upon creating the socket, this constructor will also **bind** to the provided `local IPEndPoint`. The `IPEndPoint.AddressFamily` property is used to determine the address family of the socket.

Consider the following TCP client code:

C#

```
var endPoint = new IPEndPoint(IPAddress.Parse("127.0.0.1"), 5001);  
using var client = new TcpClient(endPoint);
```

The preceding TCP client code is functionally equivalent to the following socket code:

C#

```
// Example IPEndPoint object  
var endPoint = new IPEndPoint(IPAddress.Parse("127.0.0.1"), 5001);  
using var socket = new Socket(endPoint.AddressFamily, SocketType.Stream,
```

```
ProtocolType.Tcp);  
socket.Bind(endPoint);
```

The `TcpClient(String, Int32)` constructor

This constructor will attempt to create a dual-stack similar to the default constructor and connect it to the **remote** DNS endpoint defined by the `hostname` and `port` pair.

Consider the following TCP client code:

C#

```
using var client = new TcpClient("www.example.com", 80);
```

The preceding TCP client code is functionally equivalent to the following socket code:

C#

```
using var socket = new Socket(SocketType.Stream, ProtocolType.Tcp);  
socket.Connect("www.example.com", 80);
```

Connect to server

All `Connect`, `ConnectAsync`, `BeginConnect` and `EndConnect` overloads in `TcpClient` are functionally equivalent to the corresponding `Socket` methods.

Consider the following TCP client code:

C#

```
using var client = new TcpClient();  
client.Connect("www.example.com", 80);
```

The above `TcpClient` code is equivalent to the following socket code:

C#

```
using var socket = new Socket(SocketType.Stream, ProtocolType.Tcp);  
socket.Connect("www.example.com", 80);
```

Create a server socket

Much like `TcpClient` instances having functional equivalency with their raw `Socket` counterparts, this section maps `TcpListener` constructors to their corresponding socket code. The first constructor to consider is the `TcpListener(IPAddress localaddr, int port)`.

```
C#
```

```
var listener = new TcpListener(IPAddress.Loopback, 5000);
```

The preceding TCP listener code is functionally equivalent to the following socket code:

```
C#
```

```
var ep = new IPEndPoint(IPAddress.Loopback, 5000);
using var socket = new Socket(ep.AddressFamily, SocketType.Stream,
ProtocolType.Tcp);
```

Start listening on the server

The `Start()` method is a wrapper combining `Socket`'s `Bind` and `Listen()` functionality.

Consider the following TCP listener code:

```
C#
```

```
var listener = new TcpListener(IPAddress.Loopback, 5000);
listener.Start(10);
```

The preceding TCP listener code is functionally equivalent to the following socket code:

```
C#
```

```
var endPoint = new IPEndPoint(IPAddress.Loopback, 5000);
using var socket = new Socket(endPoint.AddressFamily, SocketType.Stream,
ProtocolType.Tcp);
socket.Bind(endPoint);
try
{
    socket.Listen(10);
}
catch (SocketException)
{
    socket.Dispose();
}
```

Accept a server connection

Under the hood, incoming TCP connections are always creating a new socket when accepted. `TcpListener` can accept a `Socket` instance directly (via `AcceptSocket()` or `AcceptSocketAsync()`) or it can accept a `TcpClient` (via `AcceptTcpClient()` and `AcceptTcpClientAsync()`).

Consider the following `TcpListener` code:

C#

```
var listener = new TcpListener(IPAddress.Loopback, 5000);
using var acceptedSocket = await listener.AcceptSocketAsync();

// Synchronous alternative.
// var acceptedSocket = listener.AcceptSocket();
```

The preceding TCP listener code is functionally equivalent to the following socket code:

C#

```
var endPoint = new IPEndPoint(IPAddress.Loopback, 5000);
using var socket = new Socket(endPoint.AddressFamily, SocketType.Stream,
ProtocolType.Tcp);
using var acceptedSocket = await socket.AcceptAsync();

// Synchronous alternative
// var acceptedSocket = socket.Accept();
```

Create a `NetworkStream` to send and receive data

With `TcpClient` you need to instantiate a `NetworkStream` with the `GetStream()` method to be able to send and receive data . With `Socket`, you have to do the `NetworkStream` creation manually.

Consider the following `TcpClient` code:

C#

```
using var client = new TcpClient();
using NetworkStream stream = client.GetStream();
```

Which is equivalent to the following socket code:

C#

```
using var socket = new Socket(SocketType.Stream, ProtocolType.Tcp);

// Be aware that transferring the ownership means that closing/disposing the
// stream will also close the underlying socket.
using var stream = new NetworkStream(socket, ownsSocket: true);
```

💡 Tip

If your code doesn't need to work with a `Stream` instance, you can rely on `Socket`'s Send/Receive methods (`Send`, `SendAsync`, `Receive` and `ReceiveAsync`) directly instead of creating a `NetworkStream`.

System.Net.Sockets.Socket class

Article • 01/08/2024

This article provides supplementary remarks to the reference documentation for this API.

The [Socket](#) class provides a rich set of methods and properties for network communications. The [Socket](#) class allows you to perform both synchronous and asynchronous data transfer using any of the communication protocols listed in the [ProtocolType](#) enumeration.

The [Socket](#) class follows the .NET naming pattern for asynchronous methods. For example, the synchronous [Receive](#) method corresponds to the asynchronous [ReceiveAsync](#) variants.

Use the following methods for synchronous operation mode:

- If you are using a connection-oriented protocol such as TCP, your server can listen for connections using the [Listen](#) method. The [Accept](#) method processes any incoming connection requests and returns a [Socket](#) that you can use to communicate data with the remote host. Use this returned [Socket](#) to call the [Send](#) or [Receive](#) method. Call the [Bind](#) method prior to calling the [Listen](#) method if you want to specify the local IP address and port number. Use a port number of zero if you want the underlying service provider to assign a free port for you. If you want to connect to a listening host, call the [Connect](#) method. To communicate data, call the [Send](#) or [Receive](#) method.
- If you are using a connectionless protocol such as UDP, you do not need to listen for connections at all. Call the [ReceiveFrom](#) method to accept any incoming datagrams. Use the [SendTo](#) method to send datagrams to a remote host.

To process communications asynchronously, use the following methods:

- If you are using a connection-oriented protocol such as TCP, use [ConnectAsync](#) to connect with a listening host. Use [SendAsync](#) or [ReceiveAsync](#) to communicate data asynchronously. Incoming connection requests can be processed using [AcceptAsync](#).
- If you are using a connectionless protocol such as UDP, you can use [SendToAsync](#) to send datagrams, and [ReceiveFromAsync](#) to receive datagrams.

If you perform multiple asynchronous operations on a socket, they do not necessarily complete in the order in which they are started.

When you are finished sending and receiving data, use the [Shutdown](#) method to disable the [Socket](#). After calling [Shutdown](#), call the [Close](#) method to release all resources associated with the [Socket](#).

The [Socket](#) class allows you to configure your [Socket](#) using the [SetSocketOption](#) method. Retrieve these settings using the [GetSocketOption](#) method.

WebSockets support in .NET

Article • 03/25/2023

The WebSocket protocol enables two-way communication between a client and a remote host. The [System.Net.WebSockets.ClientWebSocket](#) exposes the ability to establish WebSocket connection via an opening handshake, it is created and sent by the `ConnectAsync` method.

Differences in HTTP/1.1 and HTTP/2 WebSockets

WebSockets over HTTP/1.1 uses a single TCP connection, therefore it is managed by connection-wide headers, for more information, see [RFC 6455](#). Consider the following example of how to establish WebSocket over HTTP/1.1:

```
c#  
  
Uri uri = new("ws://corefx-net-  
http11.azurewebsites.net/WebSocket/EchoWebSocket.ashx");  
  
using ClientWebSocket ws = new();  
await ws.ConnectAsync(uri, default);  
  
var bytes = new byte[1024];  
var result = await ws.ReceiveAsync(bytes, default);  
string res = Encoding.UTF8.GetString(bytes, 0, result.Count);  
  
await ws.CloseAsync(WebSocketCloseStatus.NormalClosure, "Client closed",  
default);
```

A different approach must be taken with HTTP/2 due to its multiplexing nature. WebSockets are established per stream, for more information, see [RFC 8441](#). With HTTP/2 it is possible to use one connection for multiple web socket streams together with ordinary HTTP streams and extend HTTP/2's more efficient use of the network to WebSockets. There is a special overload of [ConnectAsync\(Uri, HttpMessageInvoker, CancellationToken\)](#) which accepts an [HttpMessageInvoker](#) to allow reusing existing pooled connections:

```
c#  
  
using SocketsHttpHandler handler = new();  
using ClientWebSocket ws = new();
```

```
await ws.ConnectAsync(uri, new HttpMessageInvoker(handler),  
cancellationToken);
```

Set up HTTP version and policy

By default, `ClientWebSocket` uses HTTP/1.1 to send an opening handshake and allows downgrade. In .NET 7 web sockets over HTTP/2 are available. It can be changed before calling `ConnectAsync`:

```
c#  
  
using SocketsHttpHandler handler = new();  
using ClientWebSocket ws = new();  
  
ws.Options.HttpVersion = HttpVersion.Version20;  
ws.Options.HttpVersionPolicy = HttpVersionPolicy.RequestVersionOrHigher;  
  
await ws.ConnectAsync(uri, new HttpMessageInvoker(handler),  
cancellationToken);
```

Incompatible options

`ClientWebSocket` has properties `System.Net.WebSockets.ClientWebSocketOptions` that the user can set up before the connection is established. However, when `HttpMessageInvoker` is provided, it also has these properties. To avoid ambiguity, in that case, properties should be set on `HttpMessageInvoker`, and `ClientWebSocketOptions` should have default values. Otherwise, if `ClientWebSocketOptions` are changed, overload of `ConnectAsync` will throw an [ArgumentException](#).

```
c#  
  
using HttpClientHandler handler = new()  
{  
    CookieContainer = cookies;  
    UseCookies = cookies != null;  
    ServerCertificateCustomValidationCallback =  
    remoteCertificateValidationCallback;  
    Credentials = useDefaultCredentials  
        ? CredentialCache.DefaultCredentials  
        : credentials;  
};  
if (proxy is null)  
{  
    handler.UseProxy = false;  
}
```

```
else
{
    handler.Proxy = proxy;
}
if (clientCertificates?.Count > 0)
{
    handler.ClientCertificates.AddRange(clientCertificates);
}
HttpMessageInvoker invoker = new(handler);
using ClientWebSocket cws = new();
await cws.ConnectAsync(uri, invoker, cancellationToken);
```

Compression

The WebSocket protocol supports per-message deflate as defined in [RFC 7692](#). It is controlled by

[System.Net.WebSockets.ClientWebSocketOptions.DangerousDeflateOptions](#). When present, the options are sent to the server during the handshake phase. If the server supports per-message-deflate and the options are accepted, the `ClientWebSocket` instance will be created with compression enabled by default for all messages.

```
c#

using ClientWebSocket ws = new()
{
    Options =
    {
        DangerousDeflateOptions = new WebSocketDeflateOptions()
        {
            ClientMaxWindowBits = 10,
            ServerMaxWindowBits = 10
        }
    }
};
```

ⓘ Important

Before using compression, please be aware that enabling it makes the application subject to CRIME/BREACH type of attacks, for more information, see [CRIME](#) and [BREACH](#). It is strongly advised to turn off compression when sending data containing secrets by specifying the `DisableCompression` flag for such messages.

TLS/SSL best practices

Article • 03/18/2023

TLS (Transport Layer Security) is a cryptographic protocol designed to secure communication between two computers over the internet. The TLS protocol is exposed in .NET via the [SslStream](#) class.

This article presents best practices for setting up secure communication between client and server and assumes use of .NET. For best practices with .NET Framework, see [Transport Layer Security \(TLS\) best practices with the .NET Framework](#).

Select TLS version

While it is possible to specify the version of the TLS protocol to be used via the [EnabledSslProtocols](#) property, it is recommended to defer to the operating system settings by using [None](#) value (this is the default).

Deferring the decision to the OS automatically uses the most recent version of TLS available and lets the application pick up changes after OS upgrades. The operating system may also prevent use of TLS versions which are no longer considered secure.

Select cipher suites

`SslStream` allows users to specify which cipher suites can be negotiated by the TLS handshake via the [CipherSuitesPolicy](#) class. As with TLS versions, it's recommended to let the OS decide which are the best cipher suites to negotiate with, and, therefore, it's recommended to avoid using [CipherSuitesPolicy](#).

Note

`CipherSuitesPolicy` is not supported on Windows and attempts to instantiate it will cause `NotSupportedException` to be thrown.

Specify a server certificate

When authenticating as a server, `SslStream` requires an [X509Certificate2](#) instance. It is recommended to always use an [X509Certificate2](#) instance which also contains the private key.

There are multiple ways that a server certificate can be passed to `SslStream`:

- Directly as a parameter to `SslStream.AuthenticateAsServerAsync` or via `SslServerAuthenticationOptions.ServerCertificate` property
- From a selection callback in `SslServerAuthenticationOptions.ServerCertificateSelectionCallback` property
- By passing a `SslStreamCertificateContext` in the `SslServerAuthenticationOptions.ServerCertificateContext` property

The recommended approach is to use the `SslServerAuthenticationOptions.ServerCertificateContext` property. When the certificate is obtained by one of the other two ways, a `SslStreamCertificateContext` instance is created internally by the `SslStream` implementation. Creating a `SslStreamCertificateContext` involves building an `X509Chain` which is a CPU intensive operation. It is more efficient to create a `SslStreamCertificateContext` once and reuse it for multiple `SslStream` instances.

Reusing `SslStreamCertificateContext` instances also enables additional features such as [TLS session resumption](#) on Linux servers.

Custom X509Certificate validation

There are certain scenarios in which the default certificate validation procedure isn't adequate and some custom validation logic is required. Parts of the validation logic can be customized by specifying `SslClientAuthenticationOptions.CertificateChainPolicy` or `SslServerAuthenticationOptions.CertificateChainPolicy`. Alternatively, completely custom logic can be provided via the `<System.Net.Security.SslClientAuthenticationOptions.RemoteCertificateValidationCallback>` property. For more information, see [Custom certificate trust](#).

Custom certificate trust

When encountering a certificate that wasn't issued by any of the certificate authorities trusted by the machine (including self-signed certificates), the default certificate validation procedure will fail. One possible way to resolve this is to add the necessary issuer certificates to the machine's trusted store. That, however, might affect other applications on the system and is not always possible.

The alternative solution is to specify custom trusted root certificates via an `X509ChainPolicy`. To specify a custom trust list that will be used instead of the system trust list during validation, consider the following example:

C#

```
SslClientAuthenticationOptions clientOptions = new();

clientOptions.CertificateChainPolicy = new X509ChainPolicy()
{
    TrustMode = X509ChainTrustMode.CustomRootTrust,
    CustomTrustStore =
    {
        customIssuerCert
    }
};
```

Clients configured with the preceding policy would only accept certificates trusted by `customIssuerCert`.

Ignore specific validation errors

Consider an IoT device without a persistent clock. After powering on, the clock of the device would start many years in the past and, therefore, all certificates would be considered "not yet valid". Consider the following code that shows a validation callback implementation ignoring validity period violations.

C#

```
static bool CustomCertificateValidationCallback(
    object sender,
    X509Certificate? certificate,
    X509Chain? chain,
    SslPolicyErrors sslPolicyErrors)
{
    // Anything that would have been accepted by default is OK
    if (sslPolicyErrors == SslPolicyErrors.None)
    {
        return true;
    }

    // If there is something wrong other than a chain processing error,
    // don't trust it.
    if (sslPolicyErrors != SslPolicyErrors.RemoteCertificateChainErrors)
    {
        return false;
    }

    Debug.Assert(chain is not null);

    foreach (X509ChainStatus status in chain.ChainStatus)
    {
        // If an error other than `NotTimeValid` (or `NoError`) is present,
        // don't trust it.
```

```

    if ((status.Status & ~X509ChainStatusFlags.NotTimeValid) != X509ChainStatusFlags.NoError)
    {
        return false;
    }
}

return true;
}

```

Certificate pinning

Another situation where custom certificate validation is necessary is when clients expect servers to use a specific certificate, or a certificate from a small set of known certificates. This practice is known as [certificate pinning](#). The following code snippet shows a validation callback which checks that the server presents a certificate with a specific known public key.

C#

```

static bool CustomCertificateValidationCallback(
    object sender,
    X509Certificate? certificate,
    X509Chain? chain,
    SslPolicyErrors sslPolicyErrors)
{
    // If there is something wrong other than a chain processing error,
    // don't trust it.
    if ((sslPolicyErrors & ~SslPolicyErrors.RemoteCertificateChainErrors) != 0)
    {
        return false;
    }

    Debug.Assert(certificate is not null);

    const string ExpectedPublicKey =
        "3082010A0282010100C204ECF88CEE04C2B3D850D57058CC9318EB5C" +
        "A86849B022B5F9959EB12B2C763E6CC04B604C4CEAB2B4C00F80B6B0" +
        "F972C98602F95C415D132B7F71C44BBC9942E5037A6671C618CF641" +
        "42C546D31687279F74EB0A9D11522621736C844C7955E4D16BE8063D" +
        "481552ADB328DBAAFF6EFF60954A776B39F124D131B6DD4DC0C4FC53" +
        "B96D42ADB57CFEAFF515D23348E72271C7C2147A6C28EA374ADFEA6C" +
        "B572B47E5AA216DC69B15744DB0A12ABDEC30F47745C4122E19AF91B" +
        "93E6AD2206292EB1BA491C0C279EA3FB8BF7407200AC9208D98C5784" +
        "538105CBE6FE6B5498402785C710BB7370EF6918410745557CF9643F" +
        "3D2CC3A97CEB931A4C86D1CA850203010001";

    return certificate.GetPublicKeyString().Equals(ExpectedPublicKey);
}

```

Considerations for client certificate validation

Server applications need to be careful when requiring and validating client certificates. Certificates may contain the [AIA \(Authority Information Access\)](#) ↗ extension which specifies where the issuer certificate can be downloaded. The server may therefore attempt to download the issuer certificate from external server when building the [X509Chain](#) for the client certificate. Similarly, servers may need to contact external servers to ensure that the client certificate has not been revoked.

The need to contact external servers when building and validating the [X509Chain](#) may expose the application to denial of service attacks if the external servers are slow to respond. Therefore, server applications should configure the [X509Chain](#) building behavior using the [CertificateChainPolicy](#).

Troubleshoot `SslStream` authentication issues

Article • 03/18/2023

This article presents the most frequent authentication issues when using `SslStream` cryptography- and security-related functionalities in .NET are implemented by interop with either the OS API (such as Schannel on Windows) or low-level system libraries (like OpenSSL on Linux). The behavior of .NET application, including exception messages and error codes may therefore change depending on which platform it is run.

Some issues may be easier to investigate and troubleshoot by observing the actual messages exchanged over the wire using tools such as [Wireshark](#) or [tcpdump](#). These tools can be used to inspect the `ClientHello`, `ServerHello`, and other messages for advertised supported TLS versions allowed and negotiated cipher suites and the certificates exchanged for authentication.

Intermediate certificates are not sent

During the TLS handshake, the server (and the client too, if client authentication is requested) sends its certificate to prove its identity to the client. In order to validate the authenticity of the certificate, a chain of certificates needs to be built and verified. The root of the chain must be one of the trusted root certificate authority (CA), the certificate of which is stored in the machine certificate store.

If the peer certificate hasn't been issued by one of the trusted CAs an intermediate CA certificate is necessary to build the certificate chain. However, if the intermediate certificate isn't available, it isn't possible to validate the certificate and the TLS handshake may fail.

This issue is most frequently encountered on Windows. Even though the application provided intermediate certificates via the authentication options, they will not be sent to the peer unless they are stored in the Windows certificate store. This limitation is due to the fact that the actual TLS handshake occurs outside of the application process.

For server applications, it is possible to pass an `SslStreamCertificateContext` as `SslServerAuthenticationOptions.ServerCertificateContext`. During construction of the `SslStreamCertificateContext` instance, you can pass additional intermediate certificates and these will be temporarily added into the certificate store.

Unfortunately, for client application the only solution is to add the certificates to the certificate store manually.

Handshake failed with ephemeral keys

On Windows, you may encounter the `(0x8009030E): No credentials are available in the security package` error message when attempting to use certificates with ephemeral keys. This behavior is due to a bug in the underlying OS API (Schannel). More relevant info and workarounds can be found on the associated [GitHub issue](#).

Client and server do not possess a common algorithm

When inspecting the `ClientHello` and `ServerHello` messages, you may find out that there is no cipher suite offered by both client and server or even that some ciphers are not offered even if explicitly configured via `CipherSuitesPolicy` (available on Linux only). The underlying TLS library may disable TLS versions and cipher suites which are considered insecure.

On many Linux distributions, the relevant configuration file is located at `/etc/ssl/openssl.cnf`.

On Windows, the `Enable-TlsCipherSuite` and `Disable-TlsCipherSuite` PowerShell cmdlets can be used to configure cipher suites. Individual TLS versions can be enabled/disable by configuring the

`HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Control\SecurityProviders\SCHANNEL\Protocols\TLS <version>\{Client|Server}\Enabled` registry key.

Migrate SslStream code from .NET Framework to .NET

Article • 03/18/2023

.NET Core brought many improvements as well as breaking changes to how [SslStream](#) works. The most important change related to network security is that the [ServicePointManager](#) class has been mostly obsoleted and affects only the legacy [WebRequest](#) interface.

For each [SslStream](#) instance, you must configure the allowed TLS protocols and certificate validation callbacks separately via [SslServerAuthenticationOptions](#) or [SslClientAuthenticationOptions](#). To configure network security options used in HTTPS in [HttpClient](#), you need to configure the security options in the underlying handler. The default handler used by [HttpClient](#) is [SocketsHttpHandler](#), which has an [SslOptions](#) property that accepts [SslClientAuthenticationOptions](#).

Consider the following example that demonstrates how to create an [HttpClient](#) with a custom certificate validation callback:

C#

```
bool CustomCertificateValidator(
    object sender,
    X509Certificate? certificate,
    X509Chain? chain,
    SslPolicyErrors sslPolicyErrors)
{
    // TODO: Always returns false.
    // Need to implement certificate evaluation logic.
    return false;
}

HttpClient httpClient = new(
    new SocketsHttpHandler
    {
        SslOptions =
        {
            RemoteCertificateValidationCallback = CustomCertificateValidator
        }
    });

```

The following table shows how to migrate individual [ServicePointManager](#) properties related to TLS.

| Source API | Target API |
|-------------------------------------|---|
| CheckCertificateRevocationList | Set appropriate X509RevocationMode on SslClientAuthenticationOptions.CertificateRevocationCheckMode . |
| EncryptionPolicy | Use SslClientAuthenticationOptions.EncryptionPolicy . |
| SecurityProtocol | Use SslClientAuthenticationOptions.EnabledSslProtocols . |
| ServerCertificateValidationCallback | Use SslClientAuthenticationOptions.RemoteCertificateValidationCallback . |

QUIC protocol

Article • 12/30/2023

QUIC is a network transport layer protocol standardized in [RFC 9000](#). It uses UDP as an underlying protocol and it's inherently secure as it mandates TLS 1.3 usage. For more information, see [RFC 9001](#). Another interesting difference from well-known transport protocols such as TCP and UDP is that it has stream multiplexing built-in on the transport layer. This allows having multiple, concurrent, independent data streams that don't affect each other.

QUIC itself doesn't define any semantics for the exchanged data as it's a transport protocol. It's rather used in application layer protocols, for example in [HTTP/3](#) or in [SMB over QUIC](#). It can also be used for any custom-defined protocol.

The protocol offers many advantages over TCP with TLS, here are a few:

- Faster connection establishment as it doesn't require as many round trips as TCP with TLS on top.
- Avoidance of head-of-line blocking problem where one lost packet doesn't block data of all the other streams.

On the other hand, there are potential disadvantages to consider when using QUIC. As a newer protocol, its adoption is still growing and limited. Apart from that, QUIC traffic may be even blocked by some networking components.

QUIC in .NET

The QUIC implementation was introduced in .NET 5 as the `System.Net.Quic` library. However, up until .NET 7.0 the library was strictly internal and served only as an implementation of HTTP/3. With .NET 7, the library was made public thus exposing its APIs.

ⓘ Note

In .NET 7.0, the APIs are published as [preview features](#).

From the implementation perspective, `System.Net.Quic` depends on [MsQuic](#), the native implementation of QUIC protocol. As a result, `System.Net.Quic` platform support and dependencies are inherited from MsQuic and documented in the [Platform dependencies](#) section. In short, the MsQuic library is shipped as part of .NET for Windows. But for Linux, you must manually install `libmsquic` via an appropriate package manager. For the other platforms, it's still possible to build MsQuic manually, whether against SChannel or OpenSSL, and use it with `System.Net.Quic`. However, these scenarios are not part of our testing matrix and unforeseen problems might occur.

Platform dependencies

The following sections describe the platform dependencies for QUIC in .NET.

Windows

- Windows 11, Windows Server 2022, or later. (Earlier Windows versions are missing the cryptographic APIs required to support QUIC.)

On Windows, msquic.dll is distributed as part of the .NET runtime, and no other steps are required to install it.

Linux

Note

.NET 7+ is only compatible with 2.2+ versions of libmsquic.

The `libmsquic` package is required on Linux. This package is published in Microsoft's official Linux package repository, <https://packages.microsoft.com>. You must add this repository to your package manager before installing the package. For more information, see [Linux Software Repository for Microsoft Products](#).

Caution

Adding the Microsoft pacakge repository may conflict with your distribution's repository when your distribution's repository provides .NET and other Microsoft packages. To avoid or troubleshoot package mixups, review [Troubleshoot .NET errors related to missing files on Linux](#).

Examples

Here are some examples of using a package manager to install `libmsquic`:

- APT

```
Bash
```

```
sudo apt-get libmsquic
```

- APK

```
Bash
```

```
sudo apk add libmsquic
```

- DNF

```
Bash
```

```
sudo dnf install libmsquic
```

- zypper

```
Bash
```

```
sudo zypper install libmsquic
```

- YUM

```
Bash
```

```
sudo yum install libmsquic
```

Dependencies of libmsquic

All the following dependencies are stated in the `libmsquic` package manifest and are automatically installed by the package manager:

- OpenSSL 3+ or 1.1 - depends on the default OpenSSL version for the distribution version, for example, OpenSSL 3 for [Ubuntu 22](#) and OpenSSL 1.1 for [Ubuntu 20](#).
- libnuma 1

macOS

QUIC isn't currently supported on macOS but may be available in a future release.

API overview

[System.Net.Quic](#) brings three major classes that enable the usage of QUIC protocol:

- [QuicListener](#) - server side class for accepting incoming connections.
- [QuicConnection](#) - QUIC connection, corresponding to [RFC 9000 Section 5](#).
- [QuicStream](#) - QUIC stream, corresponding to [RFC 9000 Section 2](#).

But before using these classes, your code should check whether QUIC is currently supported, as `libmsquic` might be missing, or TLS 1.3 might not be supported. For that, both `QuicListener` and `QuicConnection` expose a static property `IsSupported`:

```
C#
```

```
if (QuicListener.IsSupported)
{
    // Use QuicListener
}
else
{
    // Fallback/Error
}

if (QuicConnection.IsSupported)
{
    // Use QuicConnection
}
else
{
    // Fallback/Error
}
```

These properties will report the same value, but that might change in the future. It's recommended to check [IsSupported](#) for server-scenarios and [IsSupported](#) for the client ones.

QuicListener

[QuicListener](#) represents a server side class that accepts incoming connections from the clients. The listener is constructed and started with a static method [ListenAsync\(QuicListenerOptions, CancellationToken\)](#). The method accepts an instance of [QuicListenerOptions](#) class with all the settings necessary to start the listener and accept incoming connections. After that, listener is ready to hand out connections via [AcceptConnectionAsync\(CancellationToken\)](#). Connections returned by this method are always fully connected, meaning that the TLS handshake is finished and the connection is ready to be used. Finally, to stop listening and release all resources, [DisposeAsync\(\)](#) must be called.

Consider the following [QuicListener](#) example code:

C#

```
using System.Net.Quic;

// First, check if QUIC is supported.
if (!QuicListener.IsSupported)
{
    Console.WriteLine("QUIC is not supported, check for presence of libmsquic and support of
TLS 1.3.");
    return;
}

// Share configuration for each incoming connection.
// This represents the minimal configuration necessary.
var serverConnectionOptions = new QuicServerConnectionOptions
{
    // Used to abort stream if it's not properly closed by the user.
    // See https://www.rfc-editor.org/rfc/rfc9000#section-20.2
    DefaultStreamErrorCode = 0x0A, // Protocol-dependent error code.

    // Used to close the connection if it's not done by the user.
    // See https://www.rfc-editor.org/rfc/rfc9000#section-20.2
    DefaultCloseErrorCode = 0x0B, // Protocol-dependent error code.

    // Same options as for server side SslStream.
    ServerAuthenticationOptions = new SslServerAuthenticationOptions
    {
        // List of supported application protocols, must be the same or subset of
        QuicListenerOptions.ApplicationProtocols.
        ApplicationProtocols = new List<SslApplicationProtocol>() { "protocol-name" },
        // Server certificate, it can also be provided via ServerCertificateContext or
        ServerCertificateSelectionCallback.
        ServerCertificate = serverCertificate
    }
};

// Initialize, configure the listener and start listening.
var listener = await QuicListener.ListenAsync(new QuicListenerOptions
{
    // Listening endpoint, port 0 means any port.
    ListenEndPoint = new IPPEndPoint(IPAddress.Loopback, 0),
    // List of all supported application protocols by this listener.
    ApplicationProtocols = new List<SslApplicationProtocol>() { "protocol-name" },
    // Callback to provide options for the incoming connections, it gets called once per each
    connection.
});
```

```

    ConnectionOptionsCallback = (_, _, _) => ValueTask.FromResult(serverConnectionOptions)
});

// Accept and process the connections.
while (isRunning)
{
    // Accept will propagate any exceptions that occurred during the connection
    // establishment,
    // including exceptions thrown from ConnectionOptionsCallback, caused by invalid
    QuicServerConnectionOptions or TLS handshake failures.
    var connection = await listener.AcceptConnectionAsync();

    // Process the connection...
}

// When finished, dispose the listener.
await listener.DisposeAsync();

```

For more information about how the `QuicListener` was designed, see the [API proposal ↗](#).

QuicConnection

`QuicConnection` is a class used for both server and client side QUIC connections. Server side connections are created internally by the listener and handed out via `AcceptConnectionAsync(CancellationToken)`. Client side connections must be opened and connected to the server. As with the listener, there's a static method `ConnectAsync(QuicClientConnectionOptions, CancellationToken)` that instantiates and connects the connection. It accepts an instance of `QuicClientConnectionOptions`, an analogous class to `QuicServerConnectionOptions`. After that, the work with the connection doesn't differ between client and server. It can open outgoing streams and accept incoming ones. It also provides properties with information about the connection, like `LocalEndPoint`, `RemoteEndPoint`, or `RemoteCertificate`.

When the work with the connection is done, it needs to be closed and disposed. QUIC protocol mandates using an application layer code for immediate closure, see [RFC 9000 Section 10.2 ↗](#). For that, `CloseAsync(Int64, CancellationToken)` with application layer code can be called or if not, `DisposeAsync()` will use the code provided in `DefaultCloseErrorCode`. Either way, `DisposeAsync()` must be called at the end of the work with the connection to fully release all the associated resources.

Consider the following `QuicConnection` example code:

```

C#

using System.Net.Quic;

// First, check if QUIC is supported.
if (!QuicConnection.IsSupported)
{
    Console.WriteLine("QUIC is not supported, check for presence of libmsquic and support of
TLS 1.3.");
    return;
}

// This represents the minimal configuration necessary to open a connection.
var clientConnectionOptions = new QuicClientConnectionOptions
{
    // End point of the server to connect to.
    RemoteEndPoint = listener.LocalEndPoint,
}

```

```

// Used to abort stream if it's not properly closed by the user.
// See https://www.rfc-editor.org/rfc/rfc9000#section-20.2
DefaultStreamErrorCode = 0x0A, // Protocol-dependent error code.

// Used to close the connection if it's not done by the user.
// See https://www.rfc-editor.org/rfc/rfc9000#section-20.2
DefaultCloseErrorCode = 0x0B, // Protocol-dependent error code.

// Optionally set limits for inbound streams.
MaxInboundUnidirectionalStreams = 10,
MaxInboundBidirectionalStreams = 100,

// Same options as for client side SslStream.
ClientAuthenticationOptions = new SslClientAuthenticationOptions
{
    // List of supported application protocols.
    ApplicationProtocols = new List<SslApplicationProtocol>() { "protocol-name" }
}
};

// Initialize, configure and connect to the server.
var connection = await QuicConnection.ConnectAsync(clientConnectionOptions);

Console.WriteLine($"Connected {connection.LocalEndPoint} --> {connection.RemoteEndPoint}");

// Open a bidirectional (can both read and write) outbound stream.
var outgoingStream = await connection.OpenOutboundStreamAsync(QuicStreamType.Bidirectional);

// Work with the outgoing stream ...

// To accept any stream on a client connection, at least one of
// MaxInboundBidirectionalStreams or MaxInboundUnidirectionalStreams of QuicConnectionOptions
// must be set.
while (isRunning)
{
    // Accept an inbound stream.
    var incomingStream = await connection.AcceptInboundStreamAsync();

    // Work with the incoming stream ...
}

// Close the connection with the custom code.
await connection.CloseAsync(0x0C);

// Dispose the connection.
await connection.DisposeAsync();

```

or more information about how the `QuicConnection` was designed, see the [API proposal ↗](#).

QuicStream

[QuicStream](#) is the actual type that is used to send and receive data in QUIC protocol. It derives from ordinary [Stream](#) and can be used as such, but it also offers several features that are specific to QUIC protocol. Firstly, a QUIC stream can either be unidirectional or bidirectional, see [RFC 9000 Section 2.1 ↗](#). A bidirectional stream is able to send and receive data on both sides, whereas unidirectional stream can only write from the initiating side and read on the accepting one. Each peer can limit how many concurrent stream of each type is willing to accept, see [MaxInboundBidirectionalStreams](#) and [MaxInboundUnidirectionalStreams](#).

Another particularity of QUIC stream is ability to explicitly close the writing side in the middle of work with the stream, see [CompleteWrites\(\)](#) or [WriteAsync\(ReadOnlyMemory<Byte>, Boolean, CancellationToken\)](#) overload with `completeWrites` argument. Closing of the writing side lets the peer know that no more data will arrive, yet the peer still can continue sending (in case of a bidirectional stream). This is useful in scenarios like HTTP request/response exchange when the client sends the request and closes the writing side to let the server know that this is the end of the request content. Server is still able to send the response after that, but knows that no more data will arrive from the client. And for erroneous cases, either writing or reading side of the stream can be aborted, see [Abort\(QuicAbortDirection, Int64\)](#). The behavior of the individual methods for each stream type is summarized in the following table (note that both client and server can open and accept streams):

[] [Expand table](#)

| Method | Peer opening stream | Peer accepting stream |
|--|--|---|
| <code>CanRead</code> | <code>bidirectional: true</code> <code>unidirectional: false</code> | <code>true</code> |
| <code>CanWrite</code> | <code>true</code> | <code>bidirectional: true</code> <code>unidirectional: false</code> |
| <code>ReadAsync</code> | <code>bidirectional: reads data</code> <code>unidirectional: InvalidOperationException</code> | <code>reads data</code> |
| <code>WriteAsync</code> | <code>sends data => peer read returns the data</code> | <code>bidirectional: sends data => peer read returns the data</code> <code>unidirectional: InvalidOperationException</code> |
| <code>CompleteWrites</code> | <code>closes writing side => peer read returns 0</code> | <code>bidirectional: closes writing side => peer read returns 0</code> <code>unidirectional: no-op</code> |
| <code>Abort(QuicAbortDirection.Read)</code> | <code>bidirectional: STOP_SENDING ↗ => peer write throws</code> <code>QuicException(QuicError.OperationAborted)</code> <code>unidirectional: no-op</code> | <code>STOP_SENDING ↗ => peer write throws</code> <code>QuicException(QuicError.OperationAborted)</code> |
| <code>Abort(QuicAbortDirection.Write)</code> | <code>RESET_STREAM ↗ => peer read throws</code> <code>QuicException(QuicError.OperationAborted)</code> | <code>bidirectional: RESET_STREAM ↗ => peer read throws</code> <code>QuicException(QuicError.OperationAborted)</code> <code>unidirectional: no-op</code> |

On top of these methods, `QuicStream` offers two specialized properties to get notified whenever either reading or writing side of the stream has been closed: `ReadsClosed` and `WritesClosed`. Both return a `Task` that completes with its corresponding side getting closed, whether it be success or abort, in which case the `Task` will contain appropriate exception. These properties are useful when the user code needs to know about stream side getting closed without issuing call to `ReadAsync` or `WriteAsync`.

Finally, when the work with the stream is done, it needs to be disposed with [DisposeAsync\(\)](#). The dispose will make sure that both reading and/or writing side - depending on the stream type - is closed. If stream hasn't been properly read till the end, dispose will issue an equivalent of [Abort\(QuicAbortDirection.Read\)](#). However, if stream writing side hasn't been closed, it will be gracefully closed as it would be with `CompleteWrites`. The reason for this difference is to make sure that scenarios working with an ordinary `Stream` behave as expected and lead to a successful path. Consider the following example:

C#

```
// Work done with all different types of streams.
async Task WorkWithStreamAsync(Stream stream)
{
    // This will dispose the stream at the end of the scope.
    await using (stream)
    {
        // Simple echo, read data and send them back.
        byte[] buffer = new byte[1024];
        int count = 0;
        // The loop stops when read returns 0 bytes as is common for all streams.
        while ((count = await stream.ReadAsync(buffer)) > 0)
        {
            await stream.WriteAsync(buffer.AsMemory(0, count));
        }
    }
}

// Open a QuicStream and pass to the common method.
var quicStream = await connection.OpenOutboundStreamAsync(QuicStreamType.Bidirectional);
await WorkWithStreamAsync(quicStream);
```

The sample usage of `QuicStream` in client scenario:

C#

```
// Consider connection from the connection example, open a bidirectional stream.
await using var stream = await connection.OpenStreamAsync(QuicStreamType.Bidirectional,
cancellationToken);

// Send some data.
await stream.WriteAsync(data, cancellationToken);
await stream.WriteAsync(data, cancellationToken);

// End the writing-side together with the last data.
await stream.WriteAsync(data, endStream: true, cancellationToken);
// Or separately.
stream.CompleteWrites();

// Read data until the end of stream.
while (await stream.ReadAsync(buffer, cancellationToken) > 0)
{
    // Handle buffer data...
}

// DisposeAsync called by await using at the top.
```

And the sample usage of `QuicStream` in server scenario:

C#

```
// Consider connection from the connection example, accept a stream.
await using var stream = await connection.AcceptStreamAsync(cancellationToken);

if (stream.Type != QuicStreamType.Bidirectional)
{
    Console.WriteLine($"Expected bidirectional stream, got {stream.Type}");
    return;
}
```

```

// Read the data.
while (stream.ReadAsync(buffer, cancellationToken) > 0)
{
    // Handle buffer data...

    // Client completed the writes, the loop might be exited now without another ReadAsync.
    if (stream.ReadsCompleted.IsCompleted)
    {
        break;
    }
}

// Listen for Abort(QuicAbortDirection.Read) from the client.
var writesClosedTask = WritesClosedAsync(stream);
async ValueTask WritesClosedAsync(QuicStream stream)
{
    try
    {
        await stream.WritesClosed;
    }
    catch (Exception ex)
    {
        // Handle peer aborting our writing side ...
    }
}

// DisposeAsync called by await using at the top.

```

For more information about how the `QuicStream` was designed, see the [API proposal](#).

Troubleshoot QUIC issues in .NET

Article • 05/22/2023

In this article, you'll learn how to diagnose the most common issues with QUIC in .NET.

The `System.Net.Quic` library is based on the open source QUIC implementation [MsQuic](#). Because of this, the behavior differs from ordinary sockets, sometimes by design. Moreover, it's based on UDP protocol, and it doesn't provide the exact same experience as with TCP.

Listener is running but doesn't receive any data

If a listener is running but never receives data, it might be caused by other process listening on the same port. To verify which process is using which port run:

```
Bash
```

```
sudo ss -tulpw
```

This behavior is by design as `MsQuic` uses `SO_REUSEPORT` to achieve better performance. For more information, see [ListenerStart](#) documentation and the original issue [dotnet/runtime#59382](#).

ⓘ Note

This problem doesn't occur on Windows, where MsQuic will attempt to do a port reservation. This causes the application trying to open second listener on the same port fail to start.

Client receives unexpected ALPN error

Client attempts to connect, but receives `Application layer protocol negotiation error was encountered` despite using the same ALPN as the server.

What happens is that listener always binds to dual-mode wildcard address, regardless of what the application specified. Then it matches incoming connections by IP address and ALPN. If no match is found, it reports the above mentioned error. As a result, mismatch between listening IP address and connecting one will result in an ALPN error.

To avoid this error, make sure you're connecting to the same address for which the listener was started. For example, print the listening address for your listener:

```
C#
```

```
await using var listener = QuicListener.ListenAsync(new() /* appropriate
options */);
Console.WriteLine(listener.LocalEndPoint);
```

This issue might happen in several different scenarios, such as in this issue [dotnet/runtime#85412](#). The server was started for `Loopback` address (`127.0.0.1`) and everything worked when ran on the same machine. But when the client tried to connect from a different one, the address would not match the server loopback address and was rejected with ALPN error.

ⓘ Note

This happens when the listener is using MsQuic, for example via .NET `QuicListener`.

Listener succeeds to start for IPv6 despite it being disabled

Despite IPv6 being disabled, `QuicListener.ListenAsync` succeeds with an IPv6 address. This is related to the previous problem as `MsQuic` binds to wildcard address and thus succeeds in doing so. As a result, the listener is started but no connection can be made to it. This is behavioral difference from sockets, which throw in such case.

There are many ways to check if IPv6 is enable, for example on Linux check the state of IPv6 module:

```
Bash
```

```
cat /sys/module/ipv6/parameters/disable

# 0 - IPv6 is enable
# 1 - IPv6 is disabled
```

As stated above, MsQuic behavior here is intentional. However, this particular problem might be mitigated on the .NET side in the future. For more details, see [dotnet/runtime#75343](#).

Listener fails to start with QUIC_STATUS_ADDRESS_IN_USE error

This a Windows specific problem. Listener throws `QuicException` with `QUIC_STATUS_ADDRESS_IN_USE` error despite no other process running on particular address and port. The error is caused by port exclusion range defined for the same port as the listener is trying to listen on. To check for the exclusion ranges run:

```
batch
```

```
netsh.exe int ip show excludedportrange protocol=udp
```

Getting failure for attempt to bind on a port that is from excluded range is expected behavior. For that reason, there are no immediate plans to fix this. More details can be found in [dotnet/runtime#71518](#).

Networking telemetry in .NET

Article • 11/30/2023

The .NET networking stack is instrumented at various layers. .NET gives you the option to collect accurate timings throughout the lifetime of an HTTP request using metrics, event counters, and events.

- **Networking metrics:** Starting with .NET 8, the HTTP and the name resolution (DNS) components are instrumented using the modern [System.Diagnostics.Metrics API](#). These metrics were designed in cooperation with [OpenTelemetry](#).
- **Networking events:** Events provide debug and trace information with accurate timestamps.
- **Networking event counters:** All networking components are instrumented to publish real-time performance metrics using the EventCounters API.

💡 Tip

If you're looking for information on tracking HTTP operations across different services, see the [distributed tracing documentation](#).

Networking metrics in .NET

Article • 11/30/2023

Metrics are numerical measurements reported over time. They are typically used to monitor the health of an app and generate alerts.

Starting with .NET 8, the `System.Net.Http` and the `System.Net.NameResolution` components are instrumented to publish metrics using .NET's new `System.Diagnostics.Metrics API`. These metrics were designed in cooperation with [OpenTelemetry](#) to make sure they're consistent with the standard and work well with popular tools like [Prometheus](#) and [Grafana](#). They are also [multi-dimensional](#), meaning that measurements are associated with key-value pairs called tags (a.k.a. attributes or labels) that allow data to be categorized for analysis.

💡 Tip

For a comprehensive list of all built-in instruments together with their attributes, see [System.Net metrics](#).

Collect System.Net metrics

There are two parts to using metrics in a .NET app:

- **Instrumentation:** Code in .NET libraries takes measurements and associates these measurements with a metric name. .NET and ASP.NET Core include many built-in metrics.
- **Collection:** A .NET app configures named metrics to be transmitted from the app for external storage and analysis. Some tools might perform configuration outside the app using configuration files or a UI tool.

This section demonstrates various methods to collect and view System.Net metrics.

Example app

For the sake of this tutorial, create a simple app that sends HTTP requests to various endpoints in parallel.

.NET CLI

```
dotnet new console -o HelloBuiltinMetrics
```

```
cd ..\HelloBuiltinMetrics
```

Replace the contents of `Program.cs` with the following sample code:

C#

```
using System.Net;

string[] uris = ["http://example.com", "http://httpbin.org/get",
"https://example.com", "https://httpbin.org/get"];
using HttpClient client = new()
{
    DefaultRequestVersion = HttpVersion.Version20
};

Console.WriteLine("Press any key to start.");
Console.ReadKey();

while (!Console.KeyAvailable)
{
    await Parallel.ForAsync(0, Random.Shared.Next(20), async (_, ct) =>
    {
        string uri = uris[Random.Shared.Next(uris.Length)];
        byte[] bytes = await client.GetByteArrayAsync(uri, ct);
        await Console.Out.WriteLineAsync($"{uri} - received {bytes.Length}
bytes.");
    });
}
```

View metrics with dotnet-counters

[dotnet-counters](#) is a cross-platform performance monitoring tool for ad-hoc health monitoring and first-level performance investigation.

.NET CLI

```
dotnet tool install --global dotnet-counters
```

When running against a .NET 8+ process, `dotnet-counters` enables the instruments defined by the `--counters` argument and displays the measurements. It continuously refreshes the console with the latest numbers:

Console

```
dotnet-counters monitor --counters System.Net.Http,System.Net.NameResolution
-n HelloBuiltinMetrics
```

View metrics in Grafana with OpenTelemetry and Prometheus

Overview

[OpenTelemetry](#):

- Is a vendor-neutral, open-source project supported by the [Cloud Native Computing Foundation](#).
- Standardizes generating and collecting telemetry for cloud-native software.
- Works with .NET using the .NET metric APIs.
- Is endorsed by [Azure Monitor](#) and many APM vendors.

This tutorial shows one of the integrations available for OpenTelemetry metrics using the OSS [Prometheus](#) and [Grafana](#) projects. The metrics data flow consists of the following steps:

1. The .NET metric APIs record measurements from the example app.
2. The OpenTelemetry library running in the app aggregates the measurements.
3. The Prometheus exporter library makes the aggregated data available via an HTTP metrics endpoint. 'Exporter' is what OpenTelemetry calls the libraries that transmit telemetry to vendor-specific backends.
4. A Prometheus server:
 - Polls the metrics endpoint.
 - Reads the data.
 - Stores the data in a database for long-term persistence. Prometheus refers to reading and storing data as *scraping* an endpoint.
 - Can run on a different machine.
5. The Grafana server:
 - Queries the data stored in Prometheus and displays it on a web-based monitoring dashboard.
 - Can run on a different machine.

Configure the example app to use OpenTelemetry's Prometheus exporter

Add a reference to the OpenTelemetry Prometheus exporter to the example app:

.NET CLI

```
dotnet add package OpenTelemetry.Exporter.Prometheus.HttpListener --  
prerelease
```

ⓘ Note

This tutorial uses a pre-release build of OpenTelemetry's Prometheus support available at the time of writing.

Update `Program.cs` with OpenTelemetry configuration:

C#

```
using OpenTelemetry.Metrics;  
using OpenTelemetry;  
using System.Net;  
  
using MeterProvider meterProvider = Sdk.CreateMeterProviderBuilder()  
    .AddMeter("System.Net.Http", "System.Net.NameResolution")  
    .AddPrometheusHttpListener(options => options.UriPrefixes = new string[]  
{ "http://localhost:9184/" })  
    .Build();  
  
string[] uris = ["http://example.com", "http://httpbin.org/get",  
"https://example.com", "https://httpbin.org/get"];  
using HttpClient client = new()  
{  
    DefaultRequestVersion = HttpVersion.Version20  
};  
  
while (!Console.KeyAvailable)  
{  
    await Parallel.ForAsync(0, Random.Shared.Next(20), async (_, ct) =>  
    {  
        string uri = uris[Random.Shared.Next(uris.Length)];  
        byte[] bytes = await client.GetByteArrayAsync(uri, ct);  
        await Console.Out.WriteLineAsync($"{uri} - received {bytes.Length}  
bytes.");  
    });  
}
```

In the preceding code:

- `AddMeter("System.Net.Http", "System.Net.NameResolution")` configures OpenTelemetry to transmit all the metrics collected by the built-in `System.Net.Http` and `System.Net.NameResolution` meters.

- `AddPrometheusHttpListener` configures OpenTelemetry to expose Prometheus' metrics HTTP endpoint on port `9184`.

ⓘ Note

This configuration differs for ASP.NET Core apps, where metrics are exported with `OpenTelemetry.Exporter.Prometheus.AspNetCore` instead of `HttpListener`. See the [related ASP.NET Core example](#).

Run the app and leave it running so measurements can be collected:

.NET CLI

```
dotnet run
```

Set up and configure Prometheus

Follow the [Prometheus first steps](#) to set up a Prometheus server and confirm it is working.

Modify the `prometheus.yml` configuration file so that Prometheus scrapes the metrics endpoint that the example app is exposing. Add the following highlighted text in the `scrape_configs` section:

YAML

```
# my global config
global:
  scrape_interval: 15s # Set the scrape interval to every 15 seconds.
  # Default is every 1 minute.
  evaluation_interval: 15s # Evaluate rules every 15 seconds. The default is
  # every 1 minute.
  # scrape_timeout is set to the global default (10s).

# Alertmanager configuration
alerting:
  alertmanagers:
    - static_configs:
        - targets:
            # - alertmanager:9093

# Load rules once and periodically evaluate them according to the global
# 'evaluation_interval'.
rule_files:
  # - "first_rules.yml"
  # - "second_rules.yml"
```

```

# A scrape configuration containing exactly one endpoint to scrape:
# Here it's Prometheus itself.
scrape_configs:
  # The job name is added as a label `job=<job_name>` to any timeseries
  # scraped from this config.
  - job_name: "prometheus"

    # metrics_path defaults to '/metrics'
    # scheme defaults to 'http'.

  static_configs:
    - targets: ["localhost:9090"]

  - job_name: 'OpenTelemetryTest'
    scrape_interval: 1s # poll very quickly for a more responsive demo
    static_configs:
      - targets: ['localhost:9184']

```

Start prometheus

1. Reload the configuration or restart the Prometheus server.
2. Confirm that OpenTelemetryTest is in the UP state in the **Status > Targets** page of the Prometheus web portal.

The screenshot shows the Prometheus web interface with the following details:

- Header:** Prometheus Time Series Collector
- Toolbar:** Includes navigation icons, search bar, and user info (Guest).
- Navigation:** Prometheus > Status > Targets
- Status Selection:** The "Status" dropdown menu is highlighted with a yellow box.
- Targets Table:**

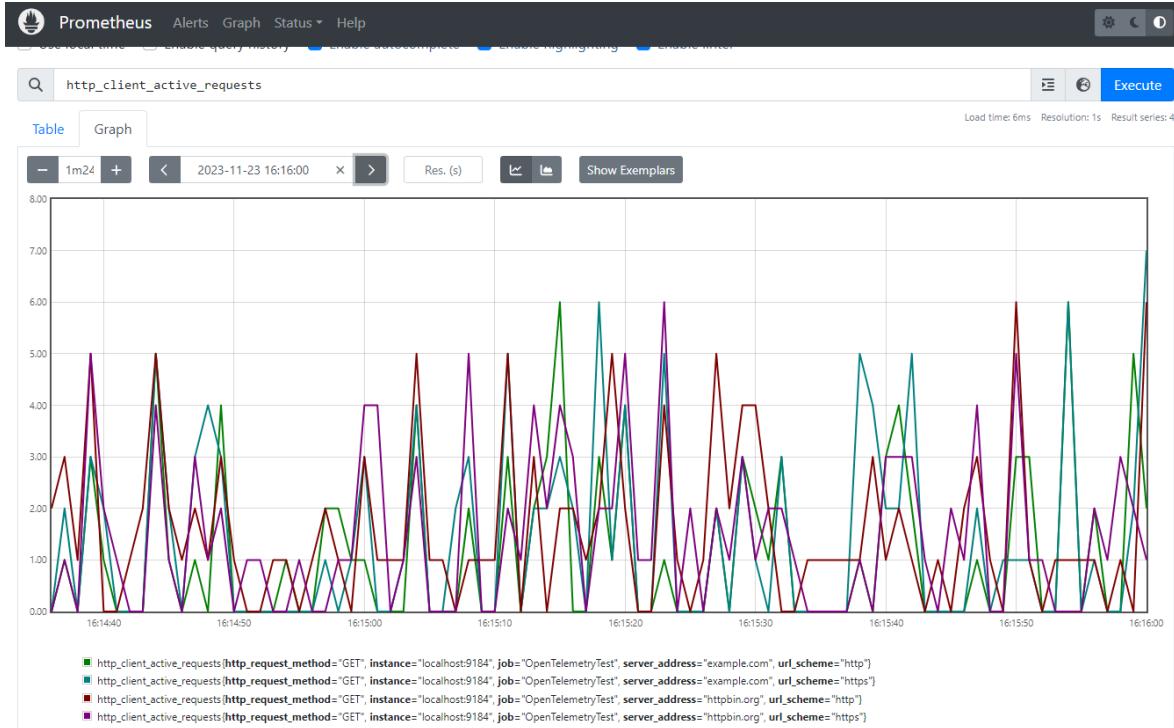

| Endpoint | State | Labels | Last Scrape | Scrape Duration | Error |
|-------------------------------|-------|--|----------------|-----------------|-------|
| http://localhost:9184/metrics | UP | instance="localhost:9184" job="OpenTelemetryTest" | 488.000 ms ago | 0.977ms | |
- prometheus Table:**

| Endpoint | State | Labels | Last Scrape | Scrape Duration | Error |
|-------------------------------|-------|---|-------------|-----------------|-------|
| http://localhost:9090/metrics | UP | instance="localhost:9090" job="prometheus" | 1.921s ago | 10.583ms | |

3. On the Graph page of the Prometheus web portal, enter `http` in the expression text box and select `http_client_active_requests`.

The screenshot shows the Prometheus web interface. At the top, there are several checkboxes: 'Use local time', 'Enable query history', 'Enable autocomplete' (which is checked), 'Enable highlighting' (which is checked), and 'Enable linter'. Below the search bar, a table lists metrics starting with 'http': `http_client_active_requests`, `http_client_open_connections`, `http_client_request_duration_seconds_bucket`, `http_client_request_duration_seconds_count`, and `http_client_request_duration_seconds_sum`. The first metric is highlighted. To its right, a detailed description box says: 'Number of outbound HTTP requests that are currently active on the client.' Below the table, the status bar indicates 'Load time: 6ms Resolution: 1s Result series: 8'.

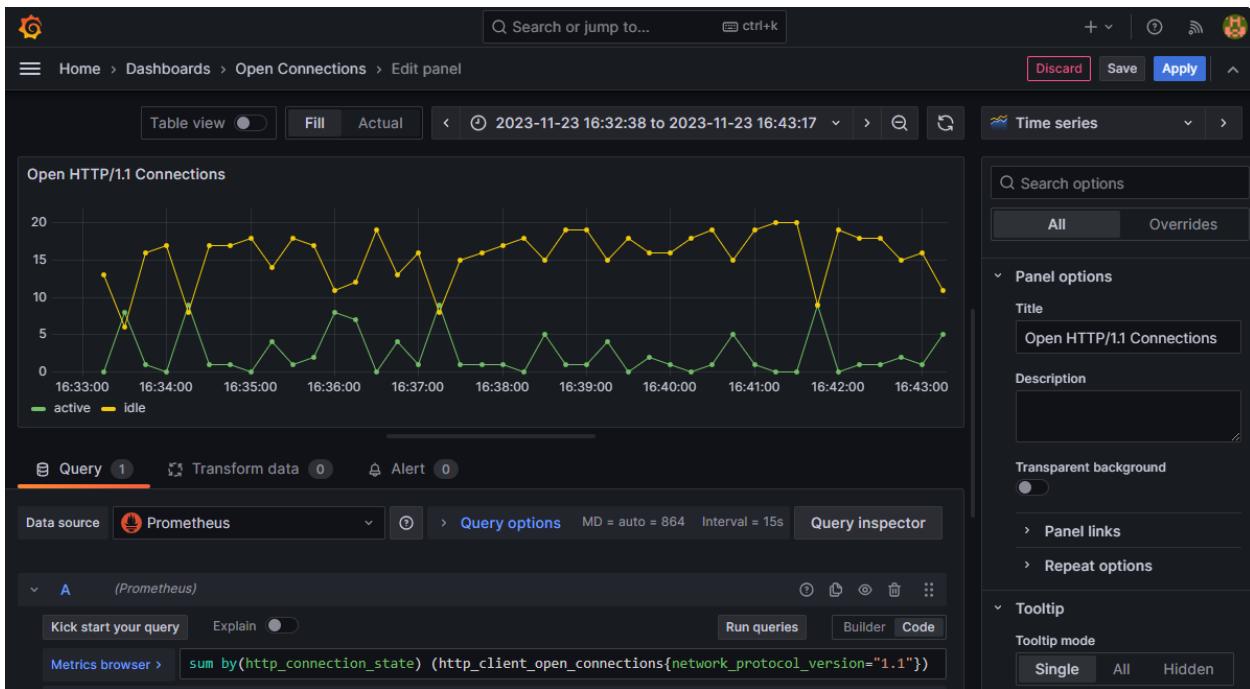

In the graph tab, Prometheus shows the value of the `http.client.active_requests` counter that's emitted by the example app.

Show metrics on a Grafana dashboard

- Follow the [standard instructions](#) to install Grafana and connect it to a Prometheus data source.
- Create a Grafana dashboard by selecting the + icon on the top toolbar then selecting **Dashboard**. In the dashboard editor that appears, enter **Open HTTP/1.1 Connections** in the **Title** box and the following query in the PromQL expression field:

```
sum by(http_connection_state)
(http_client_open_connections{network_protocol_version="1.1"})
```

1. Select **Apply** to save and view the new dashboard. It displays the number of active vs idle HTTP/1.1 connections in the pool.

Enrichment

Enrichment is the addition of custom tags (a.k.a. attributes or labels) to a metric. This is useful if an app wants to add a custom categorization to dashboards or alerts built with metrics. The `http.client.request.duration` instrument supports enrichment by registering callbacks with the `HttpMetricsEnrichmentContext`. Note that this is a low-level API and a separate callback registration is needed for each `HttpRequestMessage`.

A simple way to do the callback registration at a single place is to implement a custom `DelegatingHandler`. This will allow you to intercept and modify the requests before they are forwarded to the inner handler and sent to the server:

C#

```
using System.Net.Http.Metrics;

using HttpClient client = new(new EnrichmentHandler() { InnerHandler = new
HttpClientHandler() });

await client.GetStringAsync("https://httpbin.org/response-headers?
Enrichment-Value=A");
await client.GetStringAsync("https://httpbin.org/response-headers?
Enrichment-Value=B");

sealed class EnrichmentHandler : DelegatingHandler
{
    protected override Task<HttpResponseMessage>
```

```

SendAsync(HttpRequestMessage request, CancellationToken cancellationToken)
{
    HttpMetricsEnrichmentContext.AddCallback(request, static context =>
    {
        if (context.Response is not null) // Response is null when an
        exception occurs.
        {
            // Use any information available on the request or the
            response to emit custom tags.
            string? value =
context.Response.Headers.GetValues("Enrichment-Value").FirstOrDefault();
            if (value != null)
            {
                context.AddCustomTag("enrichment_value", value);
            }
        }
    });
    return base.SendAsync(request, cancellationToken);
}
}

```

If you're working with [IHttpClientFactory](#), you can use [AddHttpMessageHandler](#) to register the `EnrichmentHandler`:

C#

```

using Microsoft.Extensions.DependencyInjection;
using Microsoft.Extensions.Options;
using System.Net.Http.Metrics;

ServiceCollection services = new();
services.AddHttpClient(Options.DefaultName).AddHttpMessageHandler(() => new
EnrichmentHandler());

ServiceProvider serviceProvider = services.BuildServiceProvider();
HttpClient client = serviceProvider.GetRequiredService<HttpClient>();

await client.GetStringAsync("https://httpbin.org/response-headers?
Enrichment-Value=A");
await client.GetStringAsync("https://httpbin.org/response-headers?
Enrichment-Value=B");

```

ⓘ Note

For performance reasons, the enrichment callback is only invoked when the `http.client.request.duration` instrument is enabled, meaning that something should be collecting the metrics. This can be `dotnet-monitor`, Prometheus exporter, a `MeterListener`, or a `MetricCollector<T>`.

IMeterFactory and **IHttpClientFactory** integration

HTTP metrics were designed with isolation and testability in mind. These aspects are supported by the use of [IMeterFactory](#), which enables publishing metrics by a custom [Meter](#) instance in order to keep Meters isolated from each other. By default, all metrics are emitted by a global [Meter](#) internal to the [System.Net.Http](#) library. This behavior can be overridden by assigning a custom [IMeterFactory](#) instance to [SocketsHttpHandler.MeterFactory](#) or [HttpClientHandler.MeterFactory](#).

ⓘ Note

The [Meter.Name](#) is [System.Net.Http](#) for all metrics emitted by [HttpClientHandler](#) and [SocketsHttpHandler](#).

When working with [Microsoft.Extensions.Http](#) and [IHttpClientFactory](#) on .NET 8+, the default [IHttpClientFactory](#) implementation automatically picks the [IMeterFactory](#) instance registered in the [IServiceCollection](#) and assigns it to the primary handler it creates internally.

ⓘ Note

Starting with .NET 8, the [AddHttpClient](#) method automatically calls [AddMetrics](#) to initialize the metrics services and register the default [IMeterFactory](#) implementation with [IServiceCollection](#). The default [IMeterFactory](#) caches [Meter](#) instances by name, meaning that there will be one [Meter](#) with the name [System.Net.Http](#) per [IServiceCollection](#).

Test metrics

The following example demonstrates how to validate built-in metrics in unit tests using [xUnit](#), [IHttpClientFactory](#), and [MetricCollector<T>](#) from the [Microsoft.Extensions.Diagnostics.Testing](#) NuGet package:

C#

```
[Fact]
public async Task RequestDurationTest()
{
    // Arrange
```

```

ServiceCollection services = new();
services.AddHttpClient();
ServiceProvider serviceProvider = services.BuildServiceProvider();
var meterFactory = serviceProvider.GetService<IMeterFactory>();
var collector = new MetricCollector<double>(meterFactory,
    "System.Net.Http", "http.client.request.duration");
var client = serviceProvider.GetRequiredService<HttpClient>();

// Act
await client.GetStringAsync("http://example.com");

// Assert
await collector.WaitForMeasurementsAsync(minCount:
1).WaitAsync(TimeSpan.FromSeconds(5));
Assert.Collection(collector.GetMeasurementSnapshot(),
    measurement =>
{
    Assert.Equal("http", measurement.Tags["url.scheme"]);
    Assert.Equal("GET", measurement.Tags["http.request.method"]);
});
}

```

Metrics vs. EventCounters

Metrics are [more feature-rich](#) than EventCounters, most notably because of their multi-dimensional nature. This multi-dimensionality lets you create sophisticated queries in tools like Prometheus and get insights on a level that's not possible with EventCounters.

Nevertheless, as of .NET 8, only the `System.Net.Http` and the `System.Net.NameResolutions` components are instrumented using Metrics, meaning that if you need counters from the lower levels of the stack such as `System.Net.Sockets` or `System.Net.Security`, you must use EventCounters.

Moreover, there are some semantical differences between Metrics and their matching EventCounters. For example, when using `HttpCompletionOption.ResponseContentRead`, the [current-requests](#) EventCounter considers a request to be active until the moment when the last byte of the request body has been read. Its metrics counterpart `http.client.active_requests` doesn't include the time spent reading the response body when counting the active requests.

Need more metrics?

If you have suggestions for other useful information that could be exposed via metrics, create a [dotnet/runtime issue ↗](#).

Networking events in .NET

Article • 11/30/2023

Events give you access to:

- Accurate timestamps throughout the lifetime of an operation. For example, how long it took to connect to the server and how long it took an HTTP request to receive response headers.
- Debug/trace information that may not be obtainable by other means. For example, what kind of decisions the connection pool made and why.

The instrumentation is based on [EventSource](#), allowing you to collect this information from both inside and outside the process.

Event providers

Networking information is split across the following event providers:

- `System.Net.Http` (`HttpClient` and `SocketsHttpHandler`)
- `System.Net.NameResolution` (`Dns`)
- `System.Net.Security` (`SslStream`)
- `System.Net.Sockets`
- `Microsoft.AspNetCore.Hosting`
- `Microsoft.AspNetCore.Server.Kestrel`

The telemetry has some performance overhead when enabled, so make sure to subscribe only to event providers you're actually interested in.

Consume events in-process

Prefer in-process collection when possible for easier event correlation and analysis.

EventListener

[EventListener](#) is an API that allows you to listen to [EventSource](#) events from within the same process that produced them.

C#

```
using System.Diagnostics.Tracing;
```

```

using var listener = new MyListener();

using var client = new HttpClient();
await client.GetStringAsync("https://httpbin.org/get");

public sealed class MyListener : EventListener
{
    protected override void OnEventSourceCreated(EventSource eventSource)
    {
        if (eventSource.Name == "System.Net.Http")
        {
            EnableEvents(eventSource, EventLevel.Informational);
        }
    }

    protected override void OnEventWritten(EventWrittenEventArgs eventData)
    {
        Console.WriteLine($"{DateTime.UtcNow:ss:fff} {eventData.EventName}:
" +
            string.Join(' ', eventData.PayloadNames!.Zip(eventData.Payload!).Select(pair => $"{{pair.First}}={{pair.Second}}")));
    }
}

```

The preceding code prints output similar to the following:

Output

```

00:598 RequestStart: scheme=https host=httpbin.org port=443
pathAndQuery=/get versionMajor=1 versionMinor=1 versionPolicy=0
01:470 ConnectionEstablished: versionMajor=1 versionMinor=1
01:474 RequestLeftQueue: timeOnQueueMilliseconds=470,6214 versionMajor=1
versionMinor=1
01:476 RequestHeadersStart:
01:477 RequestHeadersStop:
01:592 ResponseHeadersStart:
01:593 ResponseHeadersStop:
01:633 ResponseContentStart:
01:635 ResponseContentStop:
01:635 RequestStop:
01:637 ConnectionClosed: versionMajor=1 versionMinor=1

```

Yarp.Telemetry.Consumption

While the `EventListener` approach outlined above is useful for quick experimentation and debugging, the APIs aren't strongly typed and force you to depend on implementation details of the instrumented library.

To address this, .NET created a library that makes it easy to consume networking events in-process: [Yarp.Telemetry.Consumption](#). While the package is currently maintained as part of the [YARP](#) project, it can be used in any .NET application.

To use it, implement the interfaces and methods (events) that you're interested in:

C#

```
public sealed class MyTelemetryConsumer : IHttpTelemetryConsumer,
INetSecurityTelemetryConsumer
{
    public void OnRequestStart(DateTime timestamp, string scheme, string
host, int port, string pathAndQuery, int versionMajor, int versionMinor,
HttpVersionPolicy versionPolicy)
    {
        Console.WriteLine($"Request to {host} started at {timestamp}");
    }

    public void OnHandshakeStart(DateTime timestamp, bool isServer, string
targetHost)
    {
        Console.WriteLine($"Starting TLS handshake with {targetHost}");
    }
}
```

And register the implementations with your DI container:

C#

```
services.AddTelemetryConsumer<MyTelemetryConsumer>();
```

The library provides the following strongly typed interfaces:

- [IHttpTelemetryConsumer](#)
- [INameResolutionTelemetryConsumer](#)
- [INetSecurityTelemetryConsumer](#)
- [ISocketsTelemetryConsumer](#)
- [IKestrelTelemetryConsumer](#)

These callbacks are called as part of the instrumented operation, so the general logging guidance applies. You should avoid blocking or performing any expensive calculations as part of the callback. Offload any post-processing work to different threads to avoid adding latency to the underlying operation.

Consume events from outside the process

dotnet-trace

[dotnet-trace](#) is a cross-platform tool that enables the collection of .NET Core traces of a running process without a native profiler.

```
Console
```

```
dotnet tool install --global dotnet-trace
```

```
Console
```

```
dotnet-trace collect --providers  
System.Net.Http, System.Net.Security, System.Threading.Tasks.TplEventSource:0x  
80:4 --process-id 1234
```

For all the available commands and parameters, see the [dotnet-trace docs](#).

You can analyze the captured `.nettrace` file in Visual Studio or [PerfView](#). For more information, see the [dotnet-trace analysis docs](#).

PerfView

[PerfView](#) is a free, advanced performance analysis tool. It runs on Windows but can also analyze traces captured on Linux.

To configure the list of events to capture, specify them under `Advanced Options / Additional Providers`:

```
txt
```

```
*System.Net.Sockets, *System.Net.NameResolution, *System.Net.Http, *System.Net.  
Security
```

TraceEvent

[TraceEvent](#) is a library that allows you to consume events from different processes in real time. `dotnet-trace` and `PerfView` both rely on it.

If you want to process events programmatically and in real time, see the [TraceEvent docs](#).

Start and Stop events

Larger operations often start with a `Start` event and end with a `Stop` event. For example, you'll see `RequestStart`/`RequestStop` events from `System.Net.Http` or `ConnectStart`/`ConnectStop` events from `System.Net.Sockets`.

While large operations such as these often guarantee that a `Stop` event will always be present, this is not always the case. For example, seeing the `RequestHeadersStart` event from `System.Net.Http` does not guarantee that `RequestHeadersStop` will also be logged.

Event correlation

Now that you know how to observe these events, you often need to correlate them together, generally to the originating HTTP request.

Prefer in-process collection when possible for easier event correlation and analysis.

In-process correlation

As networking uses asynchronous I/O, you can't assume that the thread that completed a given request is also the thread that started it. This means you can't use `[ThreadLocal]` statics to correlate events, but you can use an `AsyncLocal`. Get familiar with `AsyncLocal` as this type is key to correlating work across different threads.

`AsyncLocal` allows you to access the same state deeper into the async flow of an operation. `AsyncLocal` values only flow down (deeper into the async call stack), and don't propagate changes up to the caller.

Consider the following example:

C#

```
AsyncLocal<int> asyncLocal = new();
asyncLocal.Value = 1;

await WorkAsync();
Console.WriteLine($"Value after WorkAsync: {asyncLocal.Value}");

async Task WorkAsync()
{
    Console.WriteLine($"Value in WorkAsync: {asyncLocal.Value}");
    asyncLocal.Value = 2;
    Console.WriteLine($"Value in WorkAsync: {asyncLocal.Value}");
}
```

This code produces the following output:

Output

```
Value in WorkAsync: 1
Value in WorkAsync: 2
Value after WorkAsync: 1
```

The value 1 flowed down from the caller into `WorkAsync`, but the modification in `WorkAsync` (2) did not flow back up to the caller.

As telemetry events (and their corresponding callbacks) occur as part of the underlying operation, they happen within the same async scope as the caller that initiated the request. This means that you can observe `asyncLocal.Value` from within the callback, but if you set the value in the callback, nothing will be able to observe it further up the stack.

The following steps show the general pattern.

1. Create a mutable class that can be updated from inside event callbacks.

C#

```
public sealed class RequestInfo
{
    public DateTime StartTime, HeadersSent;
}
```

2. Set the `AsyncLocal.Value` before the main operation so that the state will flow into the operation.

C#

```
private static readonly AsyncLocal<RequestInfo> _requestInfo = new();

public async Task SendRequestAsync(string url)
{
    var info = new RequestInfo();
    _requestInfo.Value = info;

    info.StartTime = DateTime.UtcNow;
    await _client.GetStringAsync(url);
```

3. Inside the event callbacks, check if the shared state is available and update it.

`AsyncLocal.Value` will be `null` if the request was sent by a component that didn't set the `AsyncLocal.Value` in the first place.

C#

```
public void OnRequestHeadersStop(DateTime timestamp)
{
    if (_requestInfo.Value is { } info) info.HeadersSent = timestamp;
}
```

4. Process the collected information after finishing the operation.

C#

```
await _client.GetStringAsync(url);

Log($"Time until headers were sent {url} was {info.HeadersSent - info.StartTime}");
```

For more ways to do this, see the [samples section](#).

Correlation outside the process

Every event has a piece of data attached to it called `ActivityID`. This ID encodes the async hierarchy at the time the event was produced.

If you look at a trace file in PerfView, you'll see events like:

txt

| | |
|---------------------------------------|-----------------------------|
| System.Net.Http/Request/Start | ActivityID="/#14396/1/1/" |
| System.Net.Http/RequestHeaders/Start | ActivityID="/#14396/1/1/2/" |
| System.Net.Http/RequestHeaders/Stop | ActivityID="/#14396/1/1/2/" |
| System.Net.Http/ResponseHeaders/Start | ActivityID="/#14396/1/1/3/" |
| System.Net.Http/ResponseHeaders/Stop | ActivityID="/#14396/1/1/3/" |
| System.Net.Http/Request/Stop | ActivityID="/#14396/1/1/" |

You'll know that these events belong to the same request because they share the `/#14396/1/1/` prefix.

When doing manual investigations, a useful trick is to look for the `System.Net.Http/Request/Start` event of a request you're interested in, then paste its `ActivityID` in the `Text Filter` text box. If you now select all available providers, you'll see the list of all events that were produced as part of that request.

PerfView automatically collects the `ActivityID`, but if you use tools like `dotnet-trace`, you must explicitly enable the `System.Threading.Tasks.TplEventSource:0x80:4` provider (see `dotnet-trace` example above).

HttpClient request vs. connection lifetime

Since .NET 6, an HTTP request is no longer tied to a specific connection. Instead, the request will be serviced as soon as any connection is available.

This means you may see the following order of events:

1. Request start
2. Dns start
3. Request stop
4. Dns stop

This indicates that the request did trigger a DNS resolution, but was processed by a different connection before the DNS call completed. The same goes for socket connects or TLS handshakes - the originating request may complete before they do.

You should think about such events separately. Monitor DNS resolutions or TLS handshakes on their own without tying them to the timeline of a specific request.

Internal diagnostics

Some components in .NET are instrumented with additional debug-level events that provide more insight into exactly what's happening internally. These events come with high performance overhead and their shape is constantly changing. As the name suggests, they are not part of the public API and you should therefore not rely on their behavior or existence.

Regardless, these events can offer a lot of insights when all else fails. The `System.Net` stack emits such events from `Private.InternalDiagnostics.System.Net.*` namespaces.

If you change the condition in the `EventListener` example above to
`eventSource.Name.Contains("System.Net")`, you will see 100+ events from different layers in the stack. For more information, see the [full example ↗](#).

Samples

- [Measure DNS resolutions for a given endpoint](#)
- [Measure time-to-headers when using HttpClient](#)
- [Time to process a request in ASP.NET Core running Kestrel](#)
- [Measure the latency of a .NET reverse proxy](#)

Measure DNS resolutions for a given endpoint

C#

```
services.AddTelemetryConsumer(new DnsMonitor("httpbin.org"));

public sealed class DnsMonitor : INameResolutionTelemetryConsumer
{
    private static readonly AsyncLocal<DateTime?> _startTimestamp = new();
    private readonly string _hostname;

    public DnsMonitor(string hostname) => _hostname = hostname;

    public void OnResolutionStart(DateTime timestamp, string hostNameOrAddress)
    {
        if (hostNameOrAddress.Equals(_hostname,
StringComparison.OrdinalIgnoreCase))
        {
            _startTimestamp.Value = timestamp;
        }
    }

    public void OnResolutionStop(DateTime timestamp)
    {
        if (_startTimestamp.Value is { } start)
        {
            Console.WriteLine($"DNS resolution for {_hostname} took
{((timestamp - start).TotalMilliseconds} ms");
        }
    }
}
```

Measure time-to-headers when using HttpClient

C#

```
var info = RequestState.Current; // Initialize the AsyncLocal's value ahead
of time

var response = await client.GetStringAsync("http://httpbin.org/get");

var requestTime = (info.RequestStop - info.RequestStart).TotalMilliseconds;
var serverLatency = (info.HeadersReceived -
info.HeadersSent).TotalMilliseconds;
Console.WriteLine($"Request took {requestTime:N2} ms, server request latency
was {serverLatency:N2} ms");

public sealed class RequestState
{
    private static readonly AsyncLocal<RequestState> _asyncLocal = new();
```

```

    public static RequestState Current => _asyncLocal.Value ??= new();

    public DateTime RequestStart;
    public DateTime HeadersSent;
    public DateTime HeadersReceived;
    public DateTime RequestStop;
}

public sealed class TelemetryConsumer : IHttpTelemetryConsumer
{
    public void OnRequestStart(DateTime timestamp, string scheme, string
host, int port, string pathAndQuery, int versionMajor, int versionMinor,
HttpVersionPolicy versionPolicy) =>
        RequestState.Current.RequestStart = timestamp;

    public void OnRequestStop(DateTime timestamp) =>
        RequestState.Current.RequestStop = timestamp;

    public void OnRequestHeadersStop(DateTime timestamp) =>
        RequestState.Current.HeadersSent = timestamp;

    public void OnResponseHeadersStop(DateTime timestamp) =>
        RequestState.Current.HeadersReceived = timestamp;
}

```

Time to process a request in ASP.NET Core running Kestrel

This is currently the most accurate way to measure the duration of a given request.

```

C#

public sealed class KestrelTelemetryConsumer : IKestrelTelemetryConsumer
{
    private static readonly AsyncLocal<DateTime?> _startTimestamp = new();
    private readonly ILogger<KestrelTelemetryConsumer> _logger;

    public KestrelTelemetryConsumer(ILogger<KestrelTelemetryConsumer>
logger) => _logger = logger;

    public void OnRequestStart(DateTime timestamp, string connectionId,
string requestId, string httpVersion, string path, string method)
    {
        _startTimestamp.Value = timestamp;
    }

    public void OnRequestStop(DateTime timestamp, string connectionId,
string requestId, string httpVersion, string path, string method)
    {
        if (_startTimestamp.Value is { } startTime)
        {

```

```
        var elapsed = timestamp - startTime;
        _logger.LogInformation("Request {requestId} to {path} took
{elapsedMs} ms", requestId, path, elapsed.TotalMilliseconds);
    }
}
```

Measure the latency of a .NET reverse proxy

This sample is applicable if you have a reverse proxy that receives inbound requests via Kestrel and makes outbound requests via HttpClient (for example, [YARP](#)).

This sample measures the time from receiving the request headers until they're sent out to the backend server.

C#

```
public sealed class InternalLatencyMonitor : IKestrelTelemetryConsumer,
IHttpTelemetryConsumer
{
    private record RequestInfo(DateTime StartTimestamp, string RequestId,
string Path);

    private static readonly AsyncLocal<RequestInfo> _requestInfo = new();
    private readonly ILogger<InternalLatencyMonitor> _logger;

    public InternalLatencyMonitor(ILogger<InternalLatencyMonitor> logger) =>
        _logger = logger;

    public void OnRequestStart(DateTime timestamp, string connectionId,
string requestId, string httpVersion, string path, string method)
    {
        _requestInfo.Value = new RequestInfo(timestamp, requestId, path);
    }

    public void OnRequestHeadersStop(DateTime timestamp)
    {
        if (_requestInfo.Value is { } requestInfo)
        {
            var elapsed = (timestamp -
requestInfo.StartTimestamp).TotalMilliseconds;
            _logger.LogInformation("Internal latency for {requestId} to
{path} was {duration} ms", requestInfo.RequestId, requestInfo.Path,
elapsed);
        }
    }
}
```

Need more telemetry?

If you have suggestions for other useful information that could be exposed via events or metrics, create a [dotnet/runtime issue ↗](#).

If you're using the [Yarp.Telemetry.Consumption ↗](#) library and have any suggestions, create a [microsoft/reverse-proxy issue ↗](#).

Networking event counters in .NET

Article • 11/30/2023

[EventCounters](#) are .NET APIs used for lightweight, cross-platform, and near real-time performance metric collection.

Networking components are instrumented to publish basic diagnostic information using EventCounters. They include information like the following:

- `System.Net.Http > requests-started`
- `System.Net.Http > requests-failed`
- `System.Net.Http > http11-connections-current-total`
- `System.Net.Security > all-tls-sessions-open`
- `System.Net.Sockets > outgoing-connections-established`
- `System.Net.NameResolution > dns-lookups-duration`

💡 Tip

For the full list, see [well-known counters](#).

💡 Tip

On projects targeting .NET 8+, consider using the newer and more feature-rich [networking metrics](#) instead of EventCounters.

Providers

Networking information is split across the following providers:

- `System.Net.Http` (`HttpClient` and `SocketsHttpHandler`)
- `System.Net.NameResolution` (`Dns`)
- `System.Net.Security` (`SslStream`)
- `System.Net.Sockets`
- `Microsoft.AspNetCore.Hosting`
- `Microsoft.AspNetCore.Server.Kestrel`

The telemetry has some performance overhead when enabled, so make sure to subscribe only to providers you're actually interested in.

Monitor event counters from outside the process

dotnet-counters

[dotnet-counters](#) is a cross-platform performance monitoring tool for ad-hoc health monitoring and first-level performance investigation.

.NET CLI

```
dotnet tool install --global dotnet-counters
```

.NET CLI

```
dotnet-counters monitor --counters System.Net.Http,System.Net.Security --process-id 1234
```

The command continually refreshes the console with the latest numbers.

txt

| [System.Net.Http] | |
|---------------------------------------|-----|
| Current Http 1.1 Connections | 3 |
| Current Http 2.0 Connections | 1 |
| Current Http 3.0 Connections | 0 |
| Current Requests | 4 |
| HTTP 1.1 Requests Queue Duration (ms) | 0 |
| HTTP 2.0 Requests Queue Duration (ms) | 0 |
| HTTP 3.0 Requests Queue Duration (ms) | 0 |
| Requests Failed | 0 |
| Requests Failed Rate (Count / 1 sec) | 0 |
| Requests Started | 470 |
| Requests Started Rate (Count / 1 sec) | 18 |

For all the available commands and parameters, see the [dotnet-counter docs](#).

Application Insights

Application Insights does not collect event counters by default. For information on customizing the set of counters you're interested in, see the [AppInsights EventCounters docs](#).

For example:

C#

```
services.ConfigureTelemetryModule<EventCounterCollectionModule>((module,
options) =>
{
    module.Counters.Add(new EventCounterCollectionRequest("System.Net.Http",
"current-requests"));
    module.Counters.Add(new EventCounterCollectionRequest("System.Net.Http",
"requests-failed"));
    module.Counters.Add(new EventCounterCollectionRequest("System.Net.Http",
"http11-connections-current-total"));
    module.Counters.Add(new
EventCounterCollectionRequest("System.Net.Security", "all-tls-sessions-
open"));
});
```

For an example of how to subscribe to many runtime and ASP.NET event counters, see the [RuntimeEventCounters sample](#). Simply add an `EventCounterCollectionRequest` for every entry.

C#

```
foreach (var (eventSource, counters) in RuntimeEventCounters.EventCounters)
{
    foreach (string counter in counters)
    {
        module.Counters.Add(new EventCounterCollectionRequest(eventSource,
counter));
    }
}
```

Consume event counters in-process

The [Yarp.Telemetry.Consumption](#) library makes it easy to consume event counters from within the process. While the package is currently maintained as part of the [YARP](#) project, it can be used in any .NET application.

To use it, implement the `IMetricsConsumer<TMetrics>` interface:

C#

```
public sealed class MyMetricsConsumer : IMetricsConsumer<SocketsMetrics>
{
    public void OnMetrics(SocketsMetrics previous, SocketsMetrics current)
    {
        var elapsedTime = (current.Timestamp -
previous.Timestamp).TotalMilliseconds;
        Console.WriteLine($"Received {current.BytesReceived -
```

```
previous.BytesReceived} bytes in the last {elapsedTime:N2} ms");
    }
}
```

Then register the implementations with your DI container:

C#

```
services.AddSingleton<IMetricsConsumer<SocketsMetrics>, MyMetricsConsumer>();
services.AddTelemetryListeners();
```

The library provides the following strongly typed metrics types:

- [HttpMetrics ↗](#)
- [NameResolutionMetrics ↗](#)
- [NetSecurityMetrics ↗](#)
- [SocketsMetrics ↗](#)
- [KestrelMetrics ↗](#)

Need more telemetry?

If you have suggestions for other useful information that could be exposed via events or metrics, create a [dotnet/runtime issue ↗](#).

If you're using the [Yarp.Telemetry.Consumption ↗](#) library and have any suggestions, create a [microsoft/reverse-proxy issue ↗](#).

 Collaborate with us on
GitHub

File globbing in .NET

Article • 03/18/2023

In this article, you'll learn how to use file globbing with the [Microsoft.Extensions.FileSystemGlobbing](#) NuGet package. A *glob* is a term used to define patterns for matching file and directory names based on wildcards. Globbing is the act of defining one or more glob patterns, and yielding files from either inclusive or exclusive matches.

Patterns

To match files in the file system based on user-defined patterns, start by instantiating a `Matcher` object. A `Matcher` can be instantiated with no parameters, or with a `System.StringComparison` parameter, which is used internally for comparing patterns to file names. The `Matcher` exposes the following additive methods:

- `Matcher.AddExclude`
- `Matcher.AddInclude`

Both `AddExclude` and `AddInclude` methods can be called any number of times, to add various file name patterns to either exclude or include from results. Once you've instantiated a `Matcher` and added patterns, it's then used to evaluate matches from a starting directory with the `Matcher.Execute` method.

Extension methods

The `Matcher` object has several extension methods.

Multiple exclusions

To add multiple exclude patterns, you can use:

C#

```
Matcher matcher = new();
matcher.AddExclude("*.txt");
matcher.AddExclude("*.asciidoc");
matcher.AddExclude("*.md");
```

Alternatively, you can use the [MatcherExtensions.AddExcludePatterns\(Matcher, IEnumerable<String>\[\]\)](#) to add multiple exclude patterns in a single call:

C#

```
Matcher matcher = new();
matcher.AddExcludePatterns(new [] { "*.txt", "*.asciidoc", "*.md" });
```

This extension method iterates over all of the provided patterns calling [AddExclude](#) on your behalf.

Multiple inclusions

To add multiple include patterns, you can use:

C#

```
Matcher matcher = new();
matcher.AddInclude("*.txt");
matcher.AddInclude("*.asciidoc");
matcher.AddInclude("*.md");
```

Alternatively, you can use the [MatcherExtensions.AddIncludePatterns\(Matcher, IEnumerable<String>\[\]\)](#) to add multiple include patterns in a single call:

C#

```
Matcher matcher = new();
matcher.AddIncludePatterns(new[] { "*.txt", "*.asciidoc", "*.md" });
```

This extension method iterates over all of the provided patterns calling [AddInclude](#) on your behalf.

Get all matching files

To get all matching files, you have to call [Matcher.Execute\(DirectoryInfoBase\)](#) either directly or indirectly. To call it directly, you need a search directory:

C#

```
Matcher matcher = new();
matcher.AddIncludePatterns(new[] { "*.txt", "*.asciidoc", "*.md" });

string searchDirectory = "../starting-folder/";
```

```

PatternMatchingResult result = matcher.Execute(
    new DirectoryInfoWrapper(
        new DirectoryInfo(searchDirectory)));

// Use result.HasMatches and results.Files.
// The files in the results object are file paths relative to the search
directory.

```

The preceding C# code:

- Instantiates a `Matcher` object.
- Calls `AddIncludePatterns(Matcher, IEnumerable<String>[])` to add several file name patterns to include.
- Declares and assigns the search directory value.
- Instantiates a `DirectoryInfo` from the given `searchDirectory`.
- Instantiates a `DirectoryInfoWrapper` from the `DirectoryInfo` it wraps.
- Calls `Execute` given the `DirectoryInfoWrapper` instance to yield a `PatternMatchingResult` object.

ⓘ Note

The `DirectoryInfoWrapper` type is defined in the `Microsoft.Extensions.FileSystemGlobbing.Abstractions` namespace, and the `DirectoryInfo` type is defined in the `System.IO` namespace. To avoid unnecessary `using` statements, you can use the provided extension methods.

There is another extension method that yields an `IEnumerable<string>` representing the matching files:

C#

```

Matcher matcher = new();
matcher.AddIncludePatterns(new[] { ".txt", ".asciidoc", ".md" });

string searchDirectory = "../starting-folder/";

IEnumerable<string> matchingFiles =
    matcher.GetResultsInFullPath(searchDirectory);

// Use matchingFiles if there are any found.
// The files in this collection are fully qualified file system paths.

```

The preceding C# code:

- Instantiates a `Matcher` object.

- Calls `AddIncludePatterns(Matcher, IEnumerable<String>[])` to add several file name patterns to include.
- Declares and assigns the search directory value.
- Calls `GetResultsInFullPath` given the `searchDirectory` value to yield all matching files as a `IEnumerable<string>`.

Match overloads

The `PatternMatchingResult` object represents a collection of `FilePatternMatch` instances, and exposes a `boolean` value indicating whether the result has matches—`PatternMatchingResult.HasMatches`.

With a `Matcher` instance, you can call any of the various `Match` overloads to get a pattern matching result. The `Match` methods invert the responsibility on the caller to provide a file or a collection of files in which to evaluate for matches. In other words, the caller is responsible for passing the file to match on.

ⓘ Important

When using any of the `Match` overloads, there is no file system I/O involved. All of the file globbing is done in memory with the include and exclude patterns of the `matcher` instance. The parameters of the `Match` overloads do not have to be fully qualified paths. The current directory (`Directory.GetCurrentDirectory()`) is used when not specified.

To match a single file:

```
C#
Matcher matcher = new();
matcher.AddInclude("/**/*.md");

PatternMatchingResult result = matcher.Match("file.md");
```

The preceding C# code:

- Matches any file with the `.md` file extension, at an arbitrary directory depth.
- If a file named `file.md` exists in a subdirectory from the current directory:
 - `result.HasMatches` would be `true`.
 - and `result.Files` would have one match.

The additional `Match` overloads work in similar ways.

Pattern formats

The patterns that are specified in the `AddExclude` and `AddInclude` methods can use the following formats to match multiple files or directories.

- Exact directory or file name
 - `some-file.txt`
 - `path/to/file.txt`
- Wildcards `*` in file and directory names that represent zero to many characters not including separator characters.

| Value | Description |
|---------------------------|---|
| <code>*.txt</code> | All files with <code>.txt</code> file extension. |
| <code>*.*</code> | All files with an extension. |
| <code>*</code> | All files in top-level directory. |
| <code>.*</code> | File names beginning with <code>'.'</code> . |
| <code>*word*</code> | All files with 'word' in the filename. |
| <code>readme.*</code> | All files named 'readme' with any file extension. |
| <code>styles/*.css</code> | All files with extension <code>'.css'</code> in the directory <code>'styles/'</code> . |
| <code>scripts/**/*</code> | All files in <code>'scripts/'</code> or one level of subdirectory under <code>'scripts/'</code> . |
| <code>images*/*</code> | All files in a folder with name that is or begins with <code>'images'</code> . |

- Arbitrary directory depth (`/**/`).

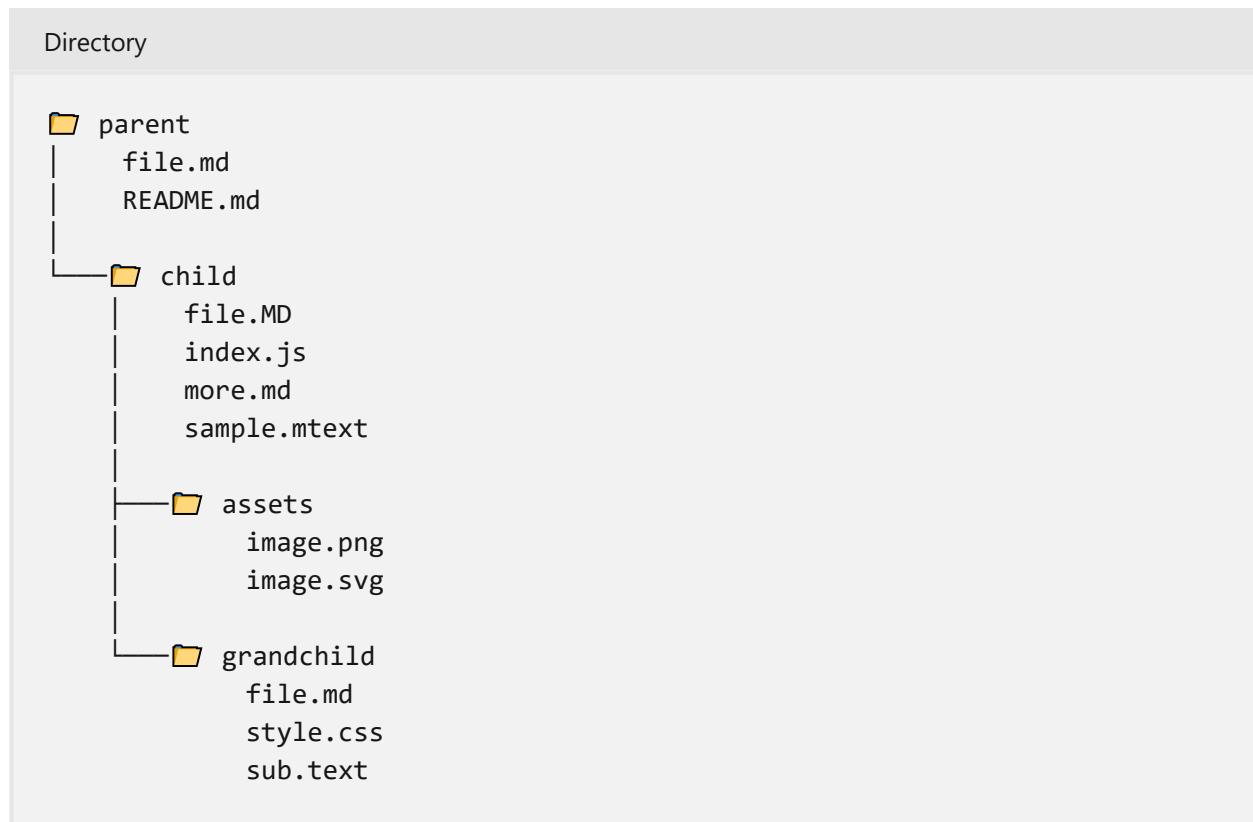

| Value | Description |
|-----------------------|---|
| <code>**/*</code> | All files in any subdirectory. |
| <code>dir/</code> | All files in any subdirectory under <code>'dir/'</code> . |
| <code>dir/**/*</code> | All files in any subdirectory under <code>'dir/'</code> . |

- Relative paths.

To match all files in a directory named "shared" at the sibling level to the base directory given to `Matcher.Execute(DirectoryInfoBase)`, use `../shared/*`.

Examples

Consider the following example directory, and each file within its corresponding folder.

💡 Tip

Some file extensions are in uppercase, while others are in lowercase. By default, **StringComparer.OrdinalIgnoreCase** is used. To specify different string comparison behavior, use the **Matcher.Matcher(StringComparison)** constructor.

To get all of the markdown files, where the file extension is either `.md` or `.mtext`, regardless of character case:

C#

```
Matcher matcher = new();
matcher.AddIncludePatterns(new[] { "**/*.md", "**/*.mtext" });

foreach (string file in matcher.GetResultsInFullPath("parent"))
{
    Console.WriteLine(file);
}
```

Running the application would output results similar to the following:

Console

```
C:\app\parent\file.md
C:\app\parent\README.md
C:\app\parent\child\file.MD
C:\app\parent\child\more.md
C:\app\parent\child\sample.mtext
C:\app\parent\child\grandchild\file.md
```

To get any files in an *assets* directory at an arbitrary depth:

C#

```
Matcher matcher = new();
matcher.AddInclude("**/assets/**/*");

foreach (string file in matcher.GetResultsInFullPath("parent"))
{
    Console.WriteLine(file);
}
```

Running the application would output results similar to the following:

Console

```
C:\app\parent\child\assets\image.png
C:\app\parent\child\assets\image.svg
```

To get any files where the directory name contains the word *child* at an arbitrary depth, and the file extensions are not *.md*, *.text*, or *.mtext*:

C#

```
Matcher matcher = new();
matcher.AddInclude("**/*child/**/*");
matcher.AddExcludePatterns(
    new[]
    {
        "**/*.md", "**/*.text", "**/*.mtext"
    });

foreach (string file in matcher.GetResultsInFullPath("parent"))
{
    Console.WriteLine(file);
}
```

Running the application would output results similar to the following:

Console

```
C:\app\parent\child\index.js  
C:\app\parent\child\assets\image.png  
C:\app\parent\child\assets\image.svg  
C:\app\parent\child\grandchild\style.css
```

Primitives: The extensions library for .NET

Article • 03/18/2023

In this article, you'll learn about the [Microsoft.Extensions.Primitives](#) library. The primitives in this article are *not* to be confused with .NET primitive types from the BCL, or that of the C# language. Instead, the types within the primitive's library serve as building blocks for some of the peripheral .NET NuGet packages, such as:

- [Microsoft.Extensions.Configuration](#)
- [Microsoft.Extensions.Configuration.FileExtensions](#)
- [Microsoft.Extensions.FileProviders.Composite](#)
- [Microsoft.Extensions.FileProviders.Physical](#)
- [Microsoft.Extensions.Logging.EventSource](#)
- [Microsoft.Extensions.Options](#)
- [System.Text.Json](#)

Change notifications

Propagating notifications when a change occurs is a fundamental concept in programming. The observed state of an object more often than not can change. When change occurs, implementations of the [Microsoft.Extensions.Primitives.IChangeToken](#) interface can be used to notify interested parties of said change. The implementations available are as follows:

- [CancellationChangeToken](#)
- [CompositeChangeToken](#)

As a developer, you're also free to implement your own type. The [IChangeToken](#) interface defines a few properties:

- [IChangeToken.HasChanged](#): Gets a value that indicates if a change has occurred.
- [IChangeToken.ActiveChangeCallbacks](#): Indicates if the token will proactively raise callbacks. If `false`, the token consumer must poll `HasChanged` to detect changes.

Instance-based functionality

Consider the following example usage of the `CancellationChangeToken`:

C#

```

CancellationTokenSource cancellationTokenSource = new();
CancellationChangeToken cancellationChangeToken =
new(cancellationTokenSource.Token);

Console.WriteLine($"HasChanged: {cancellationChangeToken.HasChanged}");

static void callback(object? _) =>
    Console.WriteLine("The callback was invoked.");

using (IDisposable subscription =
    cancellationChangeToken.RegisterChangeCallback(callback, null))
{
    cancellationTokenSource.Cancel();
}

Console.WriteLine($"HasChanged: {cancellationChangeToken.HasChanged}\n");

// Outputs:
//     HasChanged: False
//     The callback was invoked.
//     HasChanged: True

```

In the preceding example, a [CancellationTokenSource](#) is instantiated and its [Token](#) is passed to the [CancellationChangeToken](#) constructor. The initial state of [HasChanged](#) is written to the console. An [Action<object?>](#) [callback](#) is created that writes when the callback is invoked to the console. The token's [RegisterChangeCallback\(Action<Object>, Object\)](#) method is called, given the [callback](#). Within the [using](#) statement, the [cancellationTokenSource](#) is cancelled. This triggers the callback, and the state of [HasChanged](#) is again written to the console.

When you need to take action from multiple sources of change, use the [CompositeChangeToken](#). This implementation aggregates one or more change tokens and fires each registered callback exactly one time regardless of the number of times a change is triggered. Consider the following example:

C#

```

CancellationTokenSource firstCancellationTokenSource = new();
CancellationChangeToken firstCancellationChangeToken =
new(firstCancellationTokenSource.Token);

CancellationTokenSource secondCancellationTokenSource = new();
CancellationChangeToken secondCancellationChangeToken =
new(secondCancellationTokenSource.Token);

CancellationTokenSource thirdCancellationTokenSource = new();
CancellationChangeToken thirdCancellationChangeToken =
new(thirdCancellationTokenSource.Token);

```

```

var compositeChangeToken =
    new CompositeChangeToken(
        new IChangeToken[]
    {
        firstCancellationChangeToken,
        secondCancellationChangeToken,
        thirdCancellationChangeToken
    });

static void callback(object? state) =>
    Console.WriteLine($"The {state} callback was invoked.");

// 1st, 2nd, 3rd, and 4th.
compositeChangeToken.RegisterChangeCallback(callback, "1st");
compositeChangeToken.RegisterChangeCallback(callback, "2nd");
compositeChangeToken.RegisterChangeCallback(callback, "3rd");
compositeChangeToken.RegisterChangeCallback(callback, "4th");

// It doesn't matter which cancellation source triggers the change.
// If more than one trigger the change, each callback is only fired once.
Random random = new();
int index = random.Next(3);
CancellationTokenSource[] sources = new[]
{
    firstCancellationTokenSource,
    secondCancellationTokenSource,
    thirdCancellationTokenSource
};
sources[index].Cancel();

Console.WriteLine();

// Outputs:
//      The 4th callback was invoked.
//      The 3rd callback was invoked.
//      The 2nd callback was invoked.
//      The 1st callback was invoked.

```

In the preceding C# code, three `CancellationTokenSource` objects instances are created and paired with corresponding `CancellationChangeToken` instances. The composite token is instantiated by passing an array of the tokens to the `CompositeChangeToken` constructor. The `Action<object?> callback` is created, but this time the `state` object is used and written to console as a formatted message. The callback is registered four times, each with a slightly different state object argument. The code uses a pseudo-random number generator to pick one of the change token sources (doesn't matter which one) and call its `Cancel()` method. This triggers the change, invoking each registered callback exactly once.

Alternative static approach

As an alternative to calling `RegisterChangeCallback`, you could use the `Microsoft.Extensions.Primitives.ChangeToken` static class. Consider the following consumption pattern:

C#

```
CancellationTokenSource cancellationTokenSource = new();
CancellationChangeToken cancellationChangeToken =
    new(cancellationTokenSource.Token);

IChangeToken producer()
{
    // The producer factory should always return a new change token.
    // If the token's already fired, get a new token.
    if (cancellationTokenSource.IsCancellationRequested)
    {
        cancellationTokenSource = new();
        cancellationChangeToken = new(cancellationTokenSource.Token);
    }

    return cancellationChangeToken;
}

void consumer() => Console.WriteLine("The callback was invoked.");

using (ChangeToken.OnChange(producer, consumer))
{
    cancellationTokenSource.Cancel();
}

// Outputs:
//      The callback was invoked.
```

Much like previous examples, you'll need an implementation of `IChangeToken` that is produced by the `changeTokenProducer`. The producer is defined as a `Func<IChangeToken>` and it's expected that this will return a new token every invocation. The `consumer` is either an `Action` when not using `state`, or an `Action<TState>` where the generic type `TState` flows through the change notification.

String tokenizers, segments, and values

Interacting with strings is commonplace in application development. Various representations of strings are parsed, split, or iterated over. The primitives library offers

a few choice types that help to make interacting with strings more optimized and efficient. Consider the following types:

- **StringSegment**: An optimized representation of a substring.
- **StringTokenizer**: Tokenizes a `string` into `StringSegment` instances.
- **StringValues**: Represents `null`, zero, one, or many strings in an efficient way.

The `StringSegment` type

In this section, you'll learn about an optimized representation of a substring known as the `StringSegment` `struct` type. Consider the following C# code example showing some of the `StringSegment` properties and the `AsSpan` method:

C#

```
var segment =
    new StringSegment(
        "This a string, within a single segment representation.",
        14, 25);

Console.WriteLine($"Buffer: \'{segment.Buffer}\'");
Console.WriteLine($"Offset: {segment.Offset}");
Console.WriteLine($"Length: {segment.Length}");
Console.WriteLine($"Value: \'{segment.Value}\');

Console.Write("Span: \");
foreach (char @char in segment.AsSpan())
{
    Console.Write(@char);
}
Console.Write("\n");

// Outputs:
//     Buffer: "This a string, within a single segment representation."
//     Offset: 14
//     Length: 25
//     Value: " within a single segment "
//             " within a single segment "
```

The preceding code instantiates the `StringSegment` given a `string` value, an `offset`, and a `length`. The `StringSegment.Buffer` is the original string argument, and the `StringSegment.Value` is the substring based on the `StringSegment.Offset` and `StringSegment.Length` values.

The `StringSegment` struct provides [many methods](#) for interacting with the segment.

The `StringTokenizer` type

The `StringTokenizer` object is a struct type that tokenizes a `string` into `StringSegment` instances. The tokenization of large strings usually involves splitting the string apart and iterating over it. With that said, `String.Split` probably comes to mind. These APIs are similar, but in general, `StringTokenizer` provides better performance. First, consider the following example:

C#

```
var tokenizer =
    new StringTokenizer(
        s_nineHundredAutoGeneratedParagraphsOfLoremIpsum,
        new[] { ' ' });

foreach (StringSegment segment in tokenizer)
{
    // Interact with segment
}
```

In the preceding code, an instance of the `StringTokenizer` type is created given 900 auto-generated paragraphs of Lorem Ipsum text and an array with a single value of a white-space character `' '`. Each value within the tokenizer is represented as a `StringSegment`. The code iterates the segments, allowing the consumer to interact with each `segment`.

Benchmark comparing `StringTokenizer` to `string.Split`

With the various ways of slicing and dicing strings, it feels appropriate to compare two methods with a benchmark. Using the [BenchmarkDotNet](#) NuGet package, consider the following two benchmark methods:

1. Using `StringTokenizer`:

C#

```
StringBuilder buffer = new();

var tokenizer =
    new StringTokenizer(
        s_nineHundredAutoGeneratedParagraphsOfLoremIpsum,
        new[] { ' ', '.' });

foreach (StringSegment segment in tokenizer)
{
```

```
        buffer.Append(segment.Value);  
    }
```

2. Using `String.Split`:

C#

```
StringBuilder buffer = new();  
  
string[] tokenizer =  
    s_nineHundredAutoGeneratedParagraphsOfLoremIpsum.Split(  
        new[] { ' ', '.' });  
  
foreach (string segment in tokenizer)  
{  
    buffer.Append(segment);  
}
```

Both methods look similar on the API surface area, and they're both capable of splitting a large string into chunks. The benchmark results below show that the `StringTokenizer` approach is nearly three times faster, but *results may vary*. As with all performance considerations, you should evaluate your specific use case.

| Method | Mean | Error | StdDev | Ratio |
|-----------|-----------|-----------|-----------|-------|
| Tokenizer | 3.315 ms | 0.0659 ms | 0.0705 ms | 0.32 |
| Split | 10.257 ms | 0.2018 ms | 0.2552 ms | 1.00 |

Legend

- Mean: Arithmetic mean of all measurements
- Error: Half of 99.9% confidence interval
- Standard deviation: Standard deviation of all measurements
- Median: Value separating the higher half of all measurements (50th percentile)
- Ratio: Mean of the ratio distribution (Current/Baseline)
- Ratio standard deviation: Standard deviation of the ratio distribution (Current/Baseline)
- 1 ms: 1 Millisecond (0.001 sec)

For more information on benchmarking with .NET, see [BenchmarkDotNet](#).

The `StringValues` type

The `StringValues` object is a `struct` type that represents `null`, zero, one, or many strings in an efficient way. The `StringValues` type can be constructed with either of the following syntaxes: `string?` or `string?[]?`. Using the text from the previous example, consider the following C# code:

C#

```
StringValues values =
    new(s_nineHundredAutoGeneratedParagraphsOfLoremIpsum.Split(
        new[] { '\n' }));

Console.WriteLine($"Count = {values.Count:#,#}");

foreach (string? value in values)
{
    // Interact with the value
}
// Outputs:
//      Count = 1,799
```

The preceding code instantiates a `StringValues` object given an array of string values. The `StringValues.Count` is written to the console.

The `StringValues` type is an implementation of the following collection types:

- `IList<string>`
- `ICollection<string>`
- `IEnumerable<string>`
- `IEnumerable`
- `IReadOnlyList<string>`
- `IReadOnlyCollection<string>`

As such, it can be iterated over and each `value` can be interacted with as needed.

Globalize and localize .NET applications

Article • 03/18/2023

Developing a world-ready application, including an application that can be localized into one or more languages, involves three steps: globalization, localizability review, and localization.

Globalization

This step involves designing and coding an application that is culture-neutral and language-neutral, and that supports localized user interfaces and regional data for all users. It involves making design and programming decisions that are not based on culture-specific assumptions. While a globalized application is not localized, it nevertheless is designed and written so that it can be subsequently localized into one or more languages with relative ease.

Localizability review

This step involves reviewing an application's code and design to ensure that it can be localized easily and to identify potential roadblocks for localization, and verifying that the application's executable code is separated from its resources. If the globalization stage was effective, the localizability review will confirm the design and coding choices made during globalization. The localizability stage may also identify any remaining issues so that an application's source code doesn't have to be modified during the localization stage.

Localization

This step involves customizing an application for specific cultures or regions. If the globalization and localizability steps have been performed correctly, localization consists primarily of translating the user interface.

Following these three steps provides two advantages:

- It frees you from having to retrofit an application that is designed to support a single culture, such as U.S. English, to support additional cultures.
- It results in localized applications that are more stable and have fewer bugs.

.NET provides extensive support for the development of world-ready and localized applications. In particular, many type members in the .NET class library aid globalization by returning values that reflect the conventions of either the current user's culture or a

specified culture. Also, .NET supports satellite assemblies, which facilitate the process of localizing an application.

In this section

[Globalization](#)

Discusses the first stage of creating a world-ready application, which involves designing and coding an application that is culture-neutral and language-neutral.

[.NET globalization and ICU](#)

Describes how .NET globalization uses [International Components for Unicode \(ICU\)](#).

[Localizability review](#)

Discusses the second stage of creating a localized application, which involves identifying potential roadblocks to localization.

[Localization](#)

Discusses the final stage of creating a localized application, which involves customizing an application's user interface for specific regions or cultures.

[Culture-insensitive string operations](#)

Describes how to use .NET methods and classes that are culture-sensitive by default to obtain culture-insensitive results.

[Best practices for developing world-ready applications](#)

Describes the best practices to follow for globalization, localization, and developing world-ready ASP.NET applications.

Reference

- [System.Globalization](#) namespace

Contains classes that define culture-related information, including the language, the country/region, the calendars in use, the format patterns for dates, currency, and numbers, and the sort order for strings.

- [System.Resources](#) namespace

Provides classes for creating, manipulating, and using resources.

- [System.Text namespace](#)

Contains classes representing ASCII, ANSI, Unicode, and other character encodings.

- [Resgen.exe \(Resource File Generator\)](#)

Describes how to use Resgen.exe to convert .txt files and XML-based resource format (.resx) files to common language runtime binary .resources files.

- [Winres.exe \(Windows Forms Resource Editor\)](#)

Describes how to use Winres.exe to localize Windows Forms forms.

Globalization

Article • 03/18/2023

Globalization involves designing and developing a world-ready app that supports localized interfaces and regional data for users in multiple cultures. Before beginning the design phase, you should determine which cultures your app will support. Although an app targets a single culture or region as its default, you can design and write it so that it can easily be extended to users in other cultures or regions.

As developers, we all have assumptions about user interfaces and data that are formed by our cultures. For example, for an English-speaking developer in the United States, serializing date and time data as a string in the format `MM/dd/yyyy hh:mm:ss` seems perfectly reasonable. However, deserializing that string on a system in a different culture is likely to throw a [FormatException](#) exception or produce inaccurate data. Globalization enables us to identify such culture-specific assumptions and ensure that they do not affect our app's design or code.

This article discusses some of the major issues you should consider and the best practices you can follow when handling strings, date and time values, and numeric values in a globalized app.

Strings

The handling of characters and strings is a central focus of globalization, because each culture or region may use different characters and character sets and sort them differently. This section provides recommendations for using strings in globalized apps.

Use Unicode internally

By default, .NET uses Unicode strings. A Unicode string consists of zero, one, or more [Char](#) objects, each of which represents a UTF-16 code unit. There is a Unicode representation for almost every character in every character set in use throughout the world.

Many applications and operating systems, including the Windows operating system, can also use code pages to represent character sets. Code pages typically contain the standard ASCII values from 0x00 through 0x7F and map other characters to the remaining values from 0x80 through 0xFF. The interpretation of values from 0x80 through 0xFF depends on the specific code page. Because of this, you should avoid using code pages in a globalized app if possible.

The following example illustrates the dangers of interpreting code page data when the default code page on a system is different from the code page on which the data was saved. (To simulate this scenario, the example explicitly specifies different code pages.) First, the example defines an array that consists of the uppercase characters of the Greek alphabet. It encodes them into a byte array by using code page 737 (also known as MS-DOS Greek) and saves the byte array to a file. If the file is retrieved and its byte array is decoded by using code page 737, the original characters are restored. However, if the file is retrieved and its byte array is decoded by using code page 1252 (or Windows-1252, which represents characters in the Latin alphabet), the original characters are lost.

C#

```
using System;
using System.IO;
using System.Text;

public class Example
{
    public static void CodePages()
    {
        // Represent Greek uppercase characters in code page 737.
        char[] greekChars =
        {
            'Α', 'Β', 'Γ', 'Δ', 'Ε', 'Ζ', 'Η', 'Θ',
            'Ι', 'Κ', 'Λ', 'Μ', 'Ν', 'Ξ', 'Ο', 'Π',
            'Ρ', 'Σ', 'Τ', 'Υ', 'Φ', 'Χ', 'Ψ', 'Ω'
        };

        Encoding.RegisterProvider(CodePagesEncodingProvider.Instance);

        Encoding cp737 = Encoding.GetEncoding(737);
        int nBytes = cp737.GetByteCount(greekChars);
        byte[] bytes737 = new byte[nBytes];
        bytes737 = cp737.GetBytes(greekChars);
        // Write the bytes to a file.
        FileStream fs = new FileStream(@".\\CodePageBytes.dat",
        FileMode.Create);
        fs.Write(bytes737, 0, bytes737.Length);
        fs.Close();

        // Retrieve the byte data from the file.
        fs = new FileStream(@".\\CodePageBytes.dat", FileMode.Open);
        byte[] bytes1 = new byte[fs.Length];
        fs.Read(bytes1, 0, (int)fs.Length);
        fs.Close();

        // Restore the data on a system whose code page is 737.
        string data = cp737.GetString(bytes1);
        Console.WriteLine(data);
        Console.WriteLine();
```

```
// Restore the data on a system whose code page is 1252.
Encoding cp1252 = Encoding.GetEncoding(1252);
data = cp1252.GetString(bytes1);
Console.WriteLine(data);
}

// The example displays the following output:
//      ΑΒΓΔΕΖΗΘΙΚΛΜΝΞΟΠΡΣΤΥΦΧΨΩ
//      €,ƒ,,...†‡^%Š<ŒŽ‘”•—
```

The use of Unicode ensures that the same code units always map to the same characters, and that the same characters always map to the same byte arrays.

Use resource files

Even if you are developing an app that targets a single culture or region, you should use resource files to store strings and other resources that are displayed in the user interface. You should never add them directly to your code. Using resource files has a number of advantages:

- All the strings are in a single location. You don't have to search throughout your source code to identify strings to modify for a specific language or culture.
- There's no need to duplicate strings. Developers who don't use resource files often define the same string in multiple source code files. This duplication increases the probability that one or more instances will be overlooked when a string is modified.
- You can include non-string resources, such as images or binary data, in the resource file instead of storing them in a separate standalone file, so they can be retrieved easily.

Using resource files has particular advantages if you are creating a localized app. When you deploy resources in satellite assemblies, the common language runtime automatically selects a culture-appropriate resource based on the user's current UI culture as defined by the [CultureInfo.CurrentCulture](#) property. As long as you provide an appropriate culture-specific resource and correctly instantiate a [ResourceManager](#) object or use a strongly typed resource class, the runtime handles the details of retrieving the appropriate resources.

For more information about creating resource files, see [Creating resource files](#). For information about creating and deploying satellite assemblies, see [Create satellite assemblies](#) and [Package and Deploy resources](#).

Search and compare strings

Whenever possible, you should handle strings as entire strings instead of handling them as a series of individual characters. This is especially important when you sort or search for substrings, to prevent problems associated with parsing combined characters.

Tip

You can use the [StringInfo](#) class to work with the text elements rather than the individual characters in a string.

In string searches and comparisons, a common mistake is to treat the string as a collection of characters, each of which is represented by a [Char](#) object. In fact, a single character may be formed by one, two, or more [Char](#) objects. Such characters are found most frequently in strings from cultures whose alphabets consist of characters outside the Unicode Basic Latin character range (U+0021 through U+007E). The following example tries to find the index of the LATIN CAPITAL LETTER A WITH GRAVE character (U+00C0) in a string. However, this character can be represented in two different ways: as a single code unit (U+00C0) or as a composite character (two code units: U+0041 and U+0300). In this case, the character is represented in the string instance by two [Char](#) objects, U+0041 and U+0300. The example code calls the [String.IndexOf\(Char\)](#) and [String.IndexOf\(String\)](#) overloads to find the position of this character in the string instance, but these return different results. The first method call has a [Char](#) argument; it performs an ordinal comparison and therefore cannot find a match. The second call has a [String](#) argument; it performs a culture-sensitive comparison and therefore finds a match.

C#

```
using System;
using System.Globalization;
using System.Threading;

public class Example17
{
    public static void Main17()
    {
        Thread.CurrentThread.CurrentCulture =
CultureInfo.CreateSpecificCulture("pl-PL");
        string composite = "\u0041\u0300";
        Console.WriteLine("Comparing using Char: {0}",
composite.IndexOf('\u00C0'));
        Console.WriteLine("Comparing using String: {0}",
composite.IndexOf("\u00C0"));
    }
}
```

```
}
```

```
// The example displays the following output:
//      Comparing using Char: -1
//      Comparing using String: 0
```

You can avoid some of the ambiguity of this example (calls to two similar overloads of a method returning different results) by calling an overload that includes a [StringComparison](#) parameter, such as the [String.IndexOf\(String, StringComparison\)](#) or [String.LastIndexOf\(String, StringComparison\)](#) method.

However, searches are not always culture-sensitive. If the purpose of the search is to make a security decision or to allow or disallow access to some resource, the comparison should be ordinal, as discussed in the next section.

Test strings for equality

If you want to test two strings for equality rather than determine how they compare in the sort order, use the [String.Equals](#) method instead of a string comparison method such as [String.Compare](#) or [CompareInfo.Compare](#).

Comparisons for equality are typically performed to access some resource conditionally. For example, you might perform a comparison for equality to verify a password or to confirm that a file exists. Such non-linguistic comparisons should always be ordinal rather than culture-sensitive. In general, you should call the instance [String.Equals\(String, StringComparison\)](#) method or the static [String.Equals\(String, String, StringComparison\)](#) method with a value of [StringComparison.Ordinal](#) for strings such as passwords, and a value of [StringComparison.OrdinalIgnoreCase](#) for strings such as file names or URIs.

Comparisons for equality sometimes involve searches or substring comparisons rather than calls to the [String.Equals](#) method. In some cases, you may use a substring search to determine whether that substring equals another string. If the purpose of this comparison is non-linguistic, the search should also be ordinal rather than culture-sensitive.

The following example illustrates the danger of a culture-sensitive search on non-linguistic data. The `AccessesFileSystem` method is designed to prohibit file system access for URIs that begin with the substring "FILE". To do this, it performs a culture-sensitive, case-insensitive comparison of the beginning of the URI with the string "FILE". Because a URI that accesses the file system can begin with either "FILE:" or "file:", the implicit assumption is that "i" (U+0069) is always the lowercase equivalent of "I" (U+0049). However, in Turkish and Azerbaijani, the uppercase version of "i" is "İ".

(U+0130). Because of this discrepancy, the culture-sensitive comparison allows file system access when it should be prohibited.

C#

```
using System;
using System.Globalization;
using System.Threading;

public class Example10
{
    public static void Main10()
    {
        Thread.CurrentThread.CurrentCulture =
CultureInfo.CreateSpecificCulture("tr-TR");
        string uri = @"file:\\c:\\users\\username\\Documents\\bio.txt";
        if (!AccessesFileSystem(uri))
            // Permit access to resource specified by URI
            Console.WriteLine("Access is allowed.");
        else
            // Prohibit access.
            Console.WriteLine("Access is not allowed.");
    }

    private static bool AccessesFileSystem(string uri)
    {
        return uri.StartsWith("FILE", true, CultureInfo.CurrentCulture);
    }
}

// The example displays the following output:
//       Access is allowed.
```

You can avoid this problem by performing an ordinal comparison that ignores case, as the following example shows.

C#

```
using System;
using System.Globalization;
using System.Threading;

public class Example11
{
    public static void Main11()
    {
        Thread.CurrentThread.CurrentCulture =
CultureInfo.CreateSpecificCulture("tr-TR");
        string uri = @"file:\\c:\\users\\username\\Documents\\bio.txt";
        if (!AccessesFileSystem(uri))
            // Permit access to resource specified by URI
            Console.WriteLine("Access is allowed.");
```

```

        else
            // Prohibit access.
            Console.WriteLine("Access is not allowed.");
    }

    private static bool AccessesFileSystem(string uri)
    {
        return uri.StartsWith("FILE", StringComparison.OrdinalIgnoreCase);
    }
}

// The example displays the following output:
//       Access is not allowed.

```

Order and sort strings

Typically, ordered strings that are to be displayed in the user interface should be sorted based on culture. For the most part, such string comparisons are handled implicitly by .NET when you call a method that sorts strings, such as [Array.Sort](#) or [List<T>.Sort](#). By default, strings are sorted by using the sorting conventions of the current culture. The following example illustrates the difference when an array of strings is sorted by using the conventions of the English (United States) culture and the Swedish (Sweden) culture.

C#

```

using System;
using System.Globalization;
using System.Threading;

public class Example18
{
    public static void Main18()
    {
        string[] values = { "able", "ångström", "apple", "Æble",
                           "Windows", "Visual Studio" };
        // Change thread to en-US.
        Thread.CurrentThread.CurrentCulture =
CultureInfo.CreateSpecificCulture("en-US");
        // Sort the array and copy it to a new array to preserve the order.
        Array.Sort(values);
        string[] enValues = (String[])values.Clone();

        // Change culture to Swedish (Sweden).
        Thread.CurrentThread.CurrentCulture =
CultureInfo.CreateSpecificCulture("sv-SE");
        Array.Sort(values);
        string[] svValues = (String[])values.Clone();

        // Compare the sorted arrays.
        Console.WriteLine("{0,-8} {1,-15} {2,-15}\n", "Position", "en-US",

```

```

"sv-SE");
    for (int ctr = 0; ctr <= values.GetUpperBound(0); ctr++)
        Console.WriteLine("{0,-8} {1,-15} {2,-15}", ctr, enValues[ctr],
svValues[ctr]);
}
}

// The example displays the following output:
//      Position en-US          sv-SE
//
//      0      able            able
//      1      Äble           Äble
//      2      ångström       apple
//      3      apple          Windows
//      4      Visual Studio  Visual Studio
//      5      Windows         ångström

```

Culture-sensitive string comparison is defined by the [CompareInfo](#) object, which is returned by each culture's [CultureInfo.CompareInfo](#) property. Culture-sensitive string comparisons that use the [String.Compare](#) method overloads also use the [CompareInfo](#) object.

.NET uses tables to perform culture-sensitive sorts on string data. The content of these tables, which contain data on sort weights and string normalization, is determined by the version of the Unicode standard implemented by a particular version of .NET. The following table lists the versions of Unicode implemented by the specified versions of .NET. This list of supported Unicode versions applies to character comparison and sorting only; it does not apply to classification of Unicode characters by category. For more information, see the "Strings and The Unicode Standard" section in the [String](#) article.

| .NET Framework version | Operating system | Unicode version |
|---|-------------------------|------------------------|
| .NET Framework 2.0 | All operating systems | Unicode 4.1 |
| .NET Framework 3.0 | All operating systems | Unicode 4.1 |
| .NET Framework 3.5 | All operating systems | Unicode 4.1 |
| .NET Framework 4 | All operating systems | Unicode 5.0 |
| .NET Framework 4.5 and later on Windows 7 | | Unicode 5.0 |

| .NET Framework version | Operating system | Unicode version |
|---|------------------|--|
| .NET Framework 4.5 and later on Windows 8 and later operating systems | | Unicode 6.3.0 |
| .NET Core and .NET 5+ | | Depends on the version of the Unicode Standard supported by the underlying operating system. |

Starting with .NET Framework 4.5 and in all versions of .NET Core and .NET 5+, string comparison and sorting depends on the operating system. .NET Framework 4.5 and later running on Windows 7 retrieves data from its own tables that implement Unicode 5.0. .NET Framework 4.5 and later running on Windows 8 and later retrieves data from operating system tables that implement Unicode 6.3. On .NET Core and .NET 5+, the supported version of Unicode depends on the underlying operating system. If you serialize culture-sensitive sorted data, you can use the [SortVersion](#) class to determine when your serialized data needs to be sorted so that it is consistent with .NET and the operating system's sort order. For an example, see the [SortVersion](#) class topic.

If your app performs extensive culture-specific sorts of string data, you can work with the [SortKey](#) class to compare strings. A sort key reflects the culture-specific sort weights, including the alphabetic, case, and diacritic weights of a particular string. Because comparisons using sort keys are binary, they are faster than comparisons that use a [CompareInfo](#) object either implicitly or explicitly. You create a culture-specific sort key for a particular string by passing the string to the [CompareInfo.GetSortKey](#) method.

The following example is similar to the previous example. However, instead of calling the [Array.Sort\(Array\)](#) method, which implicitly calls the [CompareInfo.Compare](#) method, it defines an [System.Collections.Generic.IComparer<T>](#) implementation that compares sort keys, which it instantiates and passes to the [Array.Sort<T>\(T\[\], IComparer<T>\)](#) method.

C#

```

using System;
using System.Collections.Generic;
using System.Globalization;
using System.Threading;

public class SortKeyComparer : IComparer<String>
{
    public int Compare(string? str1, string? str2)
    {
        return (str1, str2) switch
    }
}

```

```

        {
            (null, null) => 0,
            (null, _) => -1,
            (_, null) => 1,
            (var s1, var s2) => SortKey.Compare(
                CultureInfo.CurrentCulture.CompareInfo.GetSortKey(s1),
                CultureInfo.CurrentCulture.CompareInfo.GetSortKey(s1))
        };
    }
}

public class Example19
{
    public static void Main19()
    {
        string[] values = { "able", "ångström", "apple", "Æble",
                            "Windows", "Visual Studio" };
        SortKeyComparer comparer = new SortKeyComparer();

        // Change thread to en-US.
        Thread.CurrentThread.CurrentCulture =
CultureInfo.CreateSpecificCulture("en-US");
        // Sort the array and copy it to a new array to preserve the order.
        Array.Sort(values, comparer);
        string[] enValues = (String[])values.Clone();

        // Change culture to Swedish (Sweden).
        Thread.CurrentThread.CurrentCulture =
CultureInfo.CreateSpecificCulture("sv-SE");
        Array.Sort(values, comparer);
        string[] svValues = (String[])values.Clone();

        // Compare the sorted arrays.
        Console.WriteLine("{0,-8} {1,-15} {2,-15}\n", "Position", "en-US",
"sv-SE");
        for (int ctr = 0; ctr <= values.GetUpperBound(0); ctr++)
            Console.WriteLine("{0,-8} {1,-15} {2,-15}", ctr, enValues[ctr],
svValues[ctr]);
    }
}

// The example displays the following output:
//      Position en-US          sv-SE
//
//      0      able      able
//      1      Æble      Æble
//      2      ångström   apple
//      3      apple     Windows
//      4      Visual Studio  Visual Studio
//      5      Windows    ångström

```

Avoid string concatenation

If at all possible, avoid using composite strings that are built at run time from concatenated phrases. Composite strings are difficult to localize, because they often assume a grammatical order in the app's original language that does not apply to other localized languages.

Handle dates and times

How you handle date and time values depends on whether they are displayed in the user interface or persisted. This section examines both usages. It also discusses how you can handle time zone differences and arithmetic operations when working with dates and times.

Display dates and times

Typically, when dates and times are displayed in the user interface, you should use the formatting conventions of the user's culture, which is defined by the [CultureInfo.CurrentCulture](#) property and by the [DateTimeFormatInfo](#) object returned by the [CultureInfo.CurrentCulture.DateTimeFormat](#) property. The formatting conventions of the current culture are automatically used when you format a date by using any of these methods:

- The parameterless [DateTime.ToString\(\)](#) method
- The [DateTime.ToString\(String\)](#) method, which includes a format string
- The parameterless [DateTimeOffset.ToString\(\)](#) method
- The [DateTimeOffset.ToString\(String\)](#), which includes a format string
- The [composite formatting](#) feature, when it is used with dates

The following example displays sunrise and sunset data twice for October 11, 2012. It first sets the current culture to Croatian (Croatia), and then to English (United Kingdom). In each case, the dates and times are displayed in the format that is appropriate for that culture.

C#

```
using System;
using System.Globalization;
using System.Threading;

public class Example3
{
    static DateTime[] dates = { new DateTime(2012, 10, 11, 7, 06, 0),
```

```

        new DateTime(2012, 10, 11, 18, 19, 0) };

    public static void Main3()
    {
        Thread.CurrentThread.CurrentCulture =
CultureInfo.CreateSpecificCulture("hr-HR");
        ShowDayInfo();
        Console.WriteLine();
        Thread.CurrentThread.CurrentCulture =
CultureInfo.CreateSpecificCulture("en-GB");
        ShowDayInfo();
    }

    private static void ShowDayInfo()
    {
        Console.WriteLine("Date: {0:D}", dates[0]);
        Console.WriteLine("    Sunrise: {0:T}", dates[0]);
        Console.WriteLine("    Sunset: {0:T}", dates[1]);
    }
}

// The example displays the following output:
//      Date: 11. listopada 2012.
//          Sunrise: 7:06:00
//          Sunset: 18:19:00
//
//      Date: 11 October 2012
//          Sunrise: 07:06:00
//          Sunset: 18:19:00

```

Persist dates and times

You should never persist date and time data in a format that can vary by culture. This is a common programming error that results in either corrupted data or a run-time exception. The following example serializes two dates, January 9, 2013 and August 18, 2013, as strings by using the formatting conventions of the English (United States) culture. When the data is retrieved and parsed by using the conventions of the English (United States) culture, it is successfully restored. However, when it is retrieved and parsed by using the conventions of the English (United Kingdom) culture, the first date is wrongly interpreted as September 1, and the second fails to parse because the Gregorian calendar does not have an eighteenth month.

C#

```

using System;
using System.IO;
using System.Globalization;
using System.Threading;

```

```
public class Example4
{
    public static void Main4()
    {
        // Persist two dates as strings.
        Thread.CurrentThread.CurrentCulture =
CultureInfo.CreateSpecificCulture("en-US");
        DateTime[] dates = { new DateTime(2013, 1, 9),
                            new DateTime(2013, 8, 18) };
        StreamWriter sw = new StreamWriter("dateData.dat");
        sw.WriteLine("{0:d}|{1:d}", dates[0], dates[1]);
        sw.Close();

        // Read the persisted data.
        StreamReader sr = new StreamReader("dateData.dat");
        string dateData = sr.ReadToEnd();
        sr.Close();
        string[] dateStrings = dateData.Split('|');

        // Restore and display the data using the conventions of the en-US
culture.
        Console.WriteLine("Current Culture: {0}",
                           Thread.CurrentThread.CurrentCulture.DisplayName);
        foreach (var dateStr in dateStrings)
        {
            DateTime restoredDate;
            if (DateTime.TryParse(dateStr, out restoredDate))
                Console.WriteLine("The date is {0:D}", restoredDate);
            else
                Console.WriteLine("ERROR: Unable to parse {0}", dateStr);
        }
        Console.WriteLine();

        // Restore and display the data using the conventions of the en-GB
culture.
        Thread.CurrentThread.CurrentCulture =
CultureInfo.CreateSpecificCulture("en-GB");
        Console.WriteLine("Current Culture: {0}",
                           Thread.CurrentThread.CurrentCulture.DisplayName);
        foreach (var dateStr in dateStrings)
        {
            DateTime restoredDate;
            if (DateTime.TryParse(dateStr, out restoredDate))
                Console.WriteLine("The date is {0:D}", restoredDate);
            else
                Console.WriteLine("ERROR: Unable to parse {0}", dateStr);
        }
    }

    // The example displays the following output:
    //      Current Culture: English (United States)
    //      The date is Wednesday, January 09, 2013
    //      The date is Sunday, August 18, 2013
    //
}
```

```
//      Current Culture: English (United Kingdom)
//      The date is 01 September 2013
//      ERROR: Unable to parse 8/18/2013
```

You can avoid this problem in any of three ways:

- Serialize the date and time in binary format rather than as a string.
- Save and parse the string representation of the date and time by using a custom format string that is the same regardless of the user's culture.
- Save the string by using the formatting conventions of the invariant culture.

The following example illustrates the last approach. It uses the formatting conventions of the invariant culture returned by the static [CultureInfo.InvariantCulture](#) property.

C#

```
using System;
using System.IO;
using System.Globalization;
using System.Threading;

public class Example5
{
    public static void Main5()
    {
        // Persist two dates as strings.
        Thread.CurrentThread.CurrentCulture =
CultureInfo.CreateSpecificCulture("en-US");
        DateTime[] dates = { new DateTime(2013, 1, 9),
                           new DateTime(2013, 8, 18) };
        StreamWriter sw = new StreamWriter("dateData.dat");
        sw.WriteLine(String.Format(CultureInfo.InvariantCulture,
                               "{0:d}|{1:d}", dates[0], dates[1]));
        sw.Close();

        // Read the persisted data.
        StreamReader sr = new StreamReader("dateData.dat");
        string dateData = sr.ReadToEnd();
        sr.Close();
        string[] dateStrings = dateData.Split('|');

        // Restore and display the data using the conventions of the en-US
culture.
        Console.WriteLine("Current Culture: {0}",
                         Thread.CurrentThread.CurrentCulture.DisplayName);
        foreach (var dateStr in dateStrings)
        {
            DateTime restoredDate;
            if (DateTime.TryParse(dateStr, CultureInfo.InvariantCulture,
                                 DateTimeStyles.None, out restoredDate))
                Console.WriteLine("The date is {0:D}", restoredDate);
        }
    }
}
```

```

        else
            Console.WriteLine("ERROR: Unable to parse {0}", dateStr);
    }
    Console.WriteLine();

    // Restore and display the data using the conventions of the en-GB
    culture.
    Thread.CurrentThread.CurrentCulture =
CultureInfo.CreateSpecificCulture("en-GB");
    Console.WriteLine("Current Culture: {0}",
                      Thread.CurrentThread.CurrentCulture.DisplayName);
    foreach (var dateStr in dateStrings)
    {
        DateTime restoredDate;
        if (DateTime.TryParse(dateStr, CultureInfo.InvariantCulture,
                             DateTimeStyles.None, out restoredDate))
            Console.WriteLine("The date is {0:D}", restoredDate);
        else
            Console.WriteLine("ERROR: Unable to parse {0}", dateStr);
    }
}

// The example displays the following output:
//      Current Culture: English (United States)
//      The date is Wednesday, January 09, 2013
//      The date is Sunday, August 18, 2013
//
//      Current Culture: English (United Kingdom)
//      The date is 09 January 2013
//      The date is 18 August 2013

```

Serialization and time zone awareness

A date and time value can have multiple interpretations, ranging from a general time ("The stores open on January 2, 2013, at 9:00 A.M.") to a specific moment in time ("Date of birth: January 2, 2013 6:32:00 A.M."). When a time value represents a specific moment in time and you restore it from a serialized value, you should ensure that it represents the same moment in time regardless of the user's geographical location or time zone.

The following example illustrates this problem. It saves a single local date and time value as a string in three [standard formats](#):

- "G" for general date long time.
- "s" for sortable date/time.
- "o" for round-trip date/time.

```

using System;
using System.IO;

public class Example6
{
    public static void Main6()
    {
        DateTime dateOriginal = new DateTime(2023, 3, 30, 18, 0, 0);
        dateOriginal = DateTime.SpecifyKind(dateOriginal,
DateTimeKind.Local);

        // Serialize a date.
        if (!File.Exists("DateInfo.dat"))
        {
            StreamWriter sw = new StreamWriter("DateInfo.dat");
            sw.WriteLine("{0:G}|{0:s}|{0:o}", dateOriginal);
            sw.Close();
            Console.WriteLine("Serialized dates to DateInfo.dat");
        }
        Console.WriteLine();

        // Restore the date from string values.
        StreamReader sr = new StreamReader("DateInfo.dat");
        string datesToSplit = sr.ReadToEnd();
        string[] dateStrings = datesToSplit.Split('|');
        foreach (var dateStr in dateStrings)
        {
            DateTime newDate = DateTime.Parse(dateStr);
            Console.WriteLine('{0} --> {1} {2}',
                dateStr, newDate, newDate.Kind);
        }
    }
}

```

When the data is restored on a system in the same time zone as the system on which it was serialized, the deserialized date and time values accurately reflect the original value, as the output shows:

Console

```

'3/30/2013 6:00:00 PM' --> 3/30/2013 6:00:00 PM Unspecified
'2013-03-30T18:00:00' --> 3/30/2013 6:00:00 PM Unspecified
'2013-03-30T18:00:00.0000000-07:00' --> 3/30/2013 6:00:00 PM Local

```

However, if you restore the data on a system in a different time zone, only the date and time value that was formatted with the "o" (round-trip) standard format string preserves time zone information and therefore represents the same instant in time. Here's the output when the date and time data is restored on a system in the Romance Standard Time zone:

Console

```
'3/30/2023 6:00:00 PM' --> 3/30/2023 6:00:00 PM Unspecified
'2023-03-30T18:00:00' --> 3/30/2023 6:00:00 PM Unspecified
'2023-03-30T18:00:00.0000000-07:00' --> 3/31/2023 3:00:00 AM Local
```

To accurately reflect a date and time value that represents a single moment of time regardless of the time zone of the system on which the data is deserialized, you can do any of the following:

- Save the value as a string by using the "o" (round-trip) standard format string. Then deserialize it on the target system.
- Convert it to UTC and save it as a string by using the "r" (RFC1123) standard format string. Then deserialize it on the target system and convert it to local time.
- Convert it to UTC and save it as a string by using the "u" (universal sortable) standard format string. Then deserialize it on the target system and convert it to local time.

The following example illustrates each technique.

C#

```
using System;
using System.IO;

public class Example9
{
    public static void Main9()
    {
        // Serialize a date.
        DateTime dateOriginal = new DateTime(2023, 3, 30, 18, 0, 0);
        dateOriginal = DateTime.SpecifyKind(dateOriginal,
DateTimeKind.Local);

        // Serialize the date in string form.
        if (!File.Exists("DateInfo2.dat"))
        {
            StreamWriter sw = new StreamWriter("DateInfo2.dat");
            sw.WriteLine("{0:o}|{1:r}|{1:u}", dateOriginal,
                        dateOriginal.ToUniversalTime());
            sw.Close();
        }

        // Restore the date from string values.
        StreamReader sr = new StreamReader("DateInfo2.dat");
        string datesToSplit = sr.ReadToEnd();
        string[] dateStrings = datesToSplit.Split('|');
        for (int ctr = 0; ctr < dateStrings.Length; ctr++)
        {
```

```
DateTime newDate = DateTime.Parse(dateStrings[ctr]);
if (ctr == 1)
{
    Console.WriteLine($"'{dateStrings[ctr]}' --> {newDate}
{newDate.Kind}");
}
else
{
    DateTime newLocalDate = newDate.ToLocalTime();
    Console.WriteLine($"'{dateStrings[ctr]}' --> {newLocalDate}
{newLocalDate.Kind}");
}
}
```

When the data is serialized on a system in the Pacific Standard Time zone and deserialized on a system in the Romance Standard Time zone, the example displays the following output:

Console

```

```

For more information, see [Convert times between time zones](#).

Perform date and time arithmetic

Both the [DateTime](#) and [DateTimeOffset](#) types support arithmetic operations. You can calculate the difference between two date values, or you can add or subtract particular time intervals to or from a date value. However, arithmetic operations on date and time values do not take time zones and time zone adjustment rules into account. Because of this, date and time arithmetic on values that represent moments in time can return inaccurate results.

For example, the transition from Pacific Standard Time to Pacific Daylight Time occurs on the second Sunday of March, which is March 10 for the year 2013. As the following example shows, if you calculate the date and time that is 48 hours after March 9, 2013 at 10:30 A.M. on a system in the Pacific Standard Time zone, the result, March 11, 2013 at 10:30 A.M., does not take the intervening time adjustment into account.

C#

```

using System;

public class Example7
{
    public static void Main7()
    {
        DateTime date1 = DateTime.SpecifyKind(new DateTime(2013, 3, 9, 10,
30, 0),
                                            DateTimeKind.Local);
        TimeSpan interval = new TimeSpan(48, 0, 0);
        DateTime date2 = date1 + interval;
        Console.WriteLine("{0:g} + {1:N1} hours = {2:g}",
                          date1, interval.TotalHours, date2);
    }
}

// The example displays the following output:
//      3/9/2013 10:30 AM + 48.0 hours = 3/11/2013 10:30 AM

```

To ensure that an arithmetic operation on date and time values produces accurate results, follow these steps:

1. Convert the time in the source time zone to UTC.
2. Perform the arithmetic operation.
3. If the result is a date and time value, convert it from UTC to the time in the source time zone.

The following example is similar to the previous example, except that it follows these three steps to correctly add 48 hours to March 9, 2013 at 10:30 A.M.

C#

```

using System;

public class Example8
{
    public static void Main8()
    {
        TimeZoneInfo pst = TimeZoneInfo.FindSystemTimeZoneById("Pacific
Standard Time");
        DateTime date1 = DateTime.SpecifyKind(new DateTime(2013, 3, 9, 10,
30, 0),
                                            DateTimeKind.Local);
        DateTime utc1 = date1.ToUniversalTime();
        TimeSpan interval = new TimeSpan(48, 0, 0);
        DateTime utc2 = utc1 + interval;
        DateTime date2 = TimeZoneInfo.ConvertTimeFromUtc(utc2, pst);
        Console.WriteLine("{0:g} + {1:N1} hours = {2:g}",
                          date1, interval.TotalHours, date2);
    }
}

```

```
}
```

```
// The example displays the following output:
//      3/9/2013 10:30 AM + 48.0 hours = 3/11/2013 11:30 AM
```

For more information, see [Perform arithmetic operations with dates and times](#).

Use culture-sensitive names for date elements

Your app may need to display the name of the month or the day of the week. To do this, code such as the following is common.

```
C#
```

```
using System;

public class Example12
{
    public static void Main12()
    {
        DateTime midYear = new DateTime(2013, 7, 1);
        Console.WriteLine("{0:d} is a {1}.", midYear, GetDayName(midYear));
    }

    private static string GetDayName(DateTime date)
    {
        return date.DayOfWeek.ToString("G");
    }
}

// The example displays the following output:
//      7/1/2013 is a Monday.
```

However, this code always returns the names of the days of the week in English. Code that extracts the name of the month is often even more inflexible. It frequently assumes a twelve-month calendar with names of months in a specific language.

By using [custom date and time format strings](#) or the properties of the [DateTimeFormatInfo](#) object, it is easy to extract strings that reflect the names of days of the week or months in the user's culture, as the following example illustrates. It changes the current culture to French (France) and displays the name of the day of the week and the name of the month for July 1, 2013.

```
C#
```

```
using System;
using System.Globalization;
```

```

public class Example13
{
    public static void Main13()
    {
        // Set the current culture to French (France).
        CultureInfo.CurrentCulture = CultureInfo.CreateSpecificCulture("fr-
FR");

        DateTime midYear = new DateTime(2013, 7, 1);
        Console.WriteLine("{0:d} is a {1}.", midYear,
DateUtilities.GetDayName(midYear));
        Console.WriteLine("{0:d} is a {1}.", midYear,
DateUtilities.GetDayName((int)midYear.DayOfWeek));
        Console.WriteLine("{0:d} is in {1}.", midYear,
DateUtilities.GetMonthName(midYear));
        Console.WriteLine("{0:d} is in {1}.", midYear,
DateUtilities.GetMonthName(midYear.Month));
    }
}

public static class DateUtilities
{
    public static string GetDayName(int dayOfWeek)
    {
        if (dayOfWeek < 0 | dayOfWeek >
DateTimeFormatInfo.CurrentInfo.DayNames.Length)
            return String.Empty;
        else
            return DateTimeFormatInfo.CurrentInfo.DayNames[dayOfWeek];
    }

    public static string GetDayName(DateTime date)
    {
        return date.ToString("dddd");
    }

    public static string GetMonthName(int month)
    {
        if (month < 1 | month >
DateTimeFormatInfo.CurrentInfo.MonthNames.Length - 1)
            return String.Empty;
        else
            return DateTimeFormatInfo.CurrentInfo.MonthNames[month - 1];
    }

    public static string GetMonthName(DateTime date)
    {
        return date.ToString("MMMM");
    }
}

// The example displays the following output:
//      01/07/2013 is a lundi.
//      01/07/2013 is a lundi.

```

```
//      01/07/2013 is in juillet.  
//      01/07/2013 is in juillet.
```

Numeric values

The handling of numbers depends on whether they are displayed in the user interface or persisted. This section examines both usages.

① Note

In parsing and formatting operations, .NET recognizes only the Basic Latin characters 0 through 9 (U+0030 through U+0039) as numeric digits.

Display numeric values

Typically, when numbers are displayed in the user interface, you should use the formatting conventions of the user's culture, which is defined by the [CultureInfo.CurrentCulture](#) property and by the [NumberFormatInfo](#) object returned by the [CultureInfo.CurrentCulture.NumberFormat](#) property. The formatting conventions of the current culture are automatically used when you format a date in the following ways:

- Using the parameterless `ToString` method of any numeric type.
- Using the `ToString(String)` method of any numeric type, which includes a format string as an argument.
- Using [composite formatting](#) with numeric values.

The following example displays the average temperature per month in Paris, France. It first sets the current culture to French (France) before displaying the data, and then sets it to English (United States). In each case, the month names and temperatures are displayed in the format that is appropriate for that culture. Note that the two cultures use different decimal separators in the temperature value. Also note that the example uses the "MMMM" custom date and time format string to display the full month name, and that it allocates the appropriate amount of space for the month name in the result string by determining the length of the longest month name in the [DateTimeFormatInfo.MonthNames](#) array.

C#

```
using System;  
using System.Globalization;  
using System.Threading;
```

```

public class Example14
{
    public static void Main14()
    {
        DateTime dateForMonth = new DateTime(2013, 1, 1);
        double[] temperatures = { 3.4, 3.5, 7.6, 10.4, 14.5, 17.2,
                                  19.9, 18.2, 15.9, 11.3, 6.9, 5.3 };

        Thread.CurrentThread.CurrentCulture =
CultureInfo.CreateSpecificCulture("fr-FR");
        Console.WriteLine("Current Culture: {0}",
CultureInfo.CurrentCulture.DisplayName);
        // Build the format string dynamically so we allocate enough space
for the month name.
        string fmtString = "{0,-" + GetLongestMonthNameLength().ToString() +
":MMMM}" {1,4}";
        for (int ctr = 0; ctr < temperatures.Length; ctr++)
            Console.WriteLine(fmtString,
dateForMonth.AddMonths(ctr),
temperatures[ctr]);

        Console.WriteLine();

        Thread.CurrentThread.CurrentCulture =
CultureInfo.CreateSpecificCulture("en-US");
        Console.WriteLine("Current Culture: {0}",
CultureInfo.CurrentCulture.DisplayName);
        fmtString = "{0,-" + GetLongestMonthNameLength().ToString() +
":MMMM}" {1,4}";
        for (int ctr = 0; ctr < temperatures.Length; ctr++)
            Console.WriteLine(fmtString,
dateForMonth.AddMonths(ctr),
temperatures[ctr]);
    }

    private static int GetLongestMonthNameLength()
    {
        int length = 0;
        foreach (var nameOfMonth in
DateTimeFormatInfo.CurrentInfo.MonthNames)
            if (nameOfMonth.Length > length) length = nameOfMonth.Length;

        return length;
    }
}

// The example displays the following output:
// Current Culture: French (France)
//      janvier      3,4
//      février      3,5
//      mars         7,6
//      avril         10,4
//      mai          14,5
//      juin          17,2

```

```
//      juillet      19,9
//      août         18,2
//      septembre   15,9
//      octobre      11,3
//      novembre     6,9
//      décembre     5,3
//
//      Current Culture: English (United States)
//      January       3.4
//      February      3.5
//      March         7.6
//      April         10.4
//      May           14.5
//      June          17.2
//      July          19.9
//      August        18.2
//      September     15.9
//      October       11.3
//      November      6.9
//      December       5.3
```

Persist numeric values

You should never persist numeric data in a culture-specific format. This is a common programming error that results in either corrupted data or a run-time exception. The following example generates ten random floating-point numbers, and then serializes them as strings by using the formatting conventions of the English (United States) culture. When the data is retrieved and parsed by using the conventions of the English (United States) culture, it is successfully restored. However, when it is retrieved and parsed by using the conventions of the French (France) culture, none of the numbers can be parsed because the cultures use different decimal separators.

C#

```
using System;
using System.Globalization;
using System.IO;
using System.Threading;

public class Example15
{
    public static void Main15()
    {
        // Create ten random doubles.
        Thread.CurrentThread.CurrentCulture =
CultureInfo.CreateSpecificCulture("en-US");
        double[] numbers = GetRandomNumbers(10);
        DisplayRandomNumbers(numbers);
```

```

        // Persist the numbers as strings.
        StreamWriter sw = new StreamWriter("randoms.dat");
        for (int ctr = 0; ctr < numbers.Length; ctr++)
            sw.Write("{0:R}{1}", numbers[ctr], ctr < numbers.Length - 1 ?
"|" : "");
    }

    sw.Close();

    // Read the persisted data.
    StreamReader sr = new StreamReader("randoms.dat");
    string numericData = sr.ReadToEnd();
    sr.Close();
    string[] numberStrings = numericData.Split('|');

    // Restore and display the data using the conventions of the en-US
    culture.
    Console.WriteLine("Current Culture: {0}",
                      Thread.CurrentThread.CurrentCulture.DisplayName);
    foreach (var numberStr in numberStrings)
    {
        double restoredNumber;
        if (Double.TryParse(numberStr, out restoredNumber))
            Console.WriteLine(restoredNumber.ToString("R"));
        else
            Console.WriteLine("ERROR: Unable to parse '{0}'",
numberStr);
    }
    Console.WriteLine();

    // Restore and display the data using the conventions of the fr-FR
    culture.
    Thread.CurrentThread.CurrentCulture =
CultureInfo.CreateSpecificCulture("fr-FR");
    Console.WriteLine("Current Culture: {0}",
                      Thread.CurrentThread.CurrentCulture.DisplayName);
    foreach (var numberStr in numberStrings)
    {
        double restoredNumber;
        if (Double.TryParse(numberStr, out restoredNumber))
            Console.WriteLine(restoredNumber.ToString("R"));
        else
            Console.WriteLine("ERROR: Unable to parse '{0}'",
numberStr);
    }
}

private static double[] GetRandomNumbers(int n)
{
    Random rnd = new Random();
    double[] numbers = new double[n];
    for (int ctr = 0; ctr < n; ctr++)
        numbers[ctr] = rnd.NextDouble() * 1000;
    return numbers;
}

```

```

private static void DisplayRandomNumbers(double[] numbers)
{
    for (int ctr = 0; ctr < numbers.Length; ctr++)
        Console.WriteLine(numbers[ctr].ToString("R"));
    Console.WriteLine();
}
}

// The example displays output like the following:
//      487.0313743534644
//      674.12000879371533
//      498.72077885024288
//      42.3034229512808
//      970.57311049223563
//      531.33717716268131
//      587.82905693530529
//      562.25210175023039
//      600.7711019370571
//      299.46113717717174
//
//      Current Culture: English (United States)
//      487.0313743534644
//      674.12000879371533
//      498.72077885024288
//      42.3034229512808
//      970.57311049223563
//      531.33717716268131
//      587.82905693530529
//      562.25210175023039
//      600.7711019370571
//      299.46113717717174
//
//      Current Culture: French (France)
//      ERROR: Unable to parse '487.0313743534644'
//      ERROR: Unable to parse '674.12000879371533'
//      ERROR: Unable to parse '498.72077885024288'
//      ERROR: Unable to parse '42.3034229512808'
//      ERROR: Unable to parse '970.57311049223563'
//      ERROR: Unable to parse '531.33717716268131'
//      ERROR: Unable to parse '587.82905693530529'
//      ERROR: Unable to parse '562.25210175023039'
//      ERROR: Unable to parse '600.7711019370571'
//      ERROR: Unable to parse '299.46113717717174'

```

To avoid this problem, you can use one of these techniques:

- Save and parse the string representation of the number by using a custom format string that is the same regardless of the user's culture.
- Save the number as a string by using the formatting conventions of the invariant culture, which is returned by the [CultureInfo.InvariantCulture](#) property.

Serializing currency values is a special case. Because a currency value depends on the unit of currency in which it's expressed, it makes little sense to treat it as an independent numeric value. However, if you save a currency value as a formatted string that includes a currency symbol, it cannot be deserialized on a system whose default culture uses a different currency symbol, as the following example shows.

C#

```
using System;
using System.Globalization;
using System.IO;
using System.Threading;

public class Example1
{
    public static void Main()
    {
        // Display the currency value.
        Thread.CurrentThread.CurrentCulture =
CultureInfo.CreateSpecificCulture("en-US");
        Decimal value = 16039.47m;
        Console.WriteLine("Current Culture: {0}",
CultureInfo.CurrentCulture.DisplayName);
        Console.WriteLine("Currency Value: {0:C2}", value);

        // Persist the currency value as a string.
        StreamWriter sw = new StreamWriter("currency.dat");
        sw.Write(value.ToString("C2"));
        sw.Close();

        // Read the persisted data using the current culture.
        StreamReader sr = new StreamReader("currency.dat");
        string currencyData = sr.ReadToEnd();
        sr.Close();

        // Restore and display the data using the conventions of the current
culture.
        Decimal restoredValue;
        if (Decimal.TryParse(currencyData, out restoredValue))
            Console.WriteLine(restoredValue.ToString("C2"));
        else
            Console.WriteLine("ERROR: Unable to parse '{0}'", currencyData);
        Console.WriteLine();

        // Restore and display the data using the conventions of the en-GB
culture.
        Thread.CurrentThread.CurrentCulture =
CultureInfo.CreateSpecificCulture("en-GB");
        Console.WriteLine("Current Culture: {0}",
                Thread.CurrentThread.CurrentCulture.DisplayName);
        if (Decimal.TryParse(currencyData, NumberStyles.Currency, null, out
restoredValue))
            Console.WriteLine(restoredValue.ToString("C2"));
```

```

        else
            Console.WriteLine("ERROR: Unable to parse '{0}'", currencyData);
        Console.WriteLine();
    }
}

// The example displays output like the following:
//      Current Culture: English (United States)
//      Currency Value: $16,039.47
//      ERROR: Unable to parse '$16,039.47'
//
//      Current Culture: English (United Kingdom)
//      ERROR: Unable to parse '$16,039.47'

```

Instead, you should serialize the numeric value along with some cultural information, such as the name of the culture, so that the value and its currency symbol can be deserialized independently of the current culture. The following example does that by defining a `CurrencyValue` structure with two members: the `Decimal` value and the name of the culture to which the value belongs.

C#

```

using System;
using System.Globalization;
using System.Text.Json;
using System.Threading;

public class Example2
{
    public static void Main2()
    {
        // Display the currency value.
        Thread.CurrentThread.CurrentCulture =
CultureInfo.CreateSpecificCulture("en-US");
        Decimal value = 16039.47m;
        Console.WriteLine($"Current Culture:
{CultureInfo.CurrentCulture.DisplayName}");
        Console.WriteLine($"Currency Value: {value:C2}");

        // Serialize the currency data.
        CurrencyValue data = new()
        {
            Amount = value,
            CultureName = CultureInfo.CurrentCulture.Name
        };
        string serialized = JsonSerializer.Serialize(data);
        Console.WriteLine();

        // Change the current culture.
        CultureInfo.CurrentCulture = CultureInfo.CreateSpecificCulture("en-
GB");
        Console.WriteLine($"Current Culture:
{CultureInfo.CurrentCulture.DisplayName}");

```

```

    // Deserialize the data.
    CurrencyValue restoredData =
JsonSerializer.Deserialize<CurrencyValue>(serialized);

    // Display the round-tripped value.
    CultureInfo culture =
CultureInfo.CreateSpecificCulture(restoredData.CultureName);
    Console.WriteLine($"Currency Value:
{restoredData.Amount.ToString("C2", culture)}");
}
}

internal struct CurrencyValue
{
    public decimal Amount { get; set; }
    public string CultureName { get; set; }
}

// The example displays the following output:
//      Current Culture: English (United States)
//      Currency Value: $16,039.47
//
//      Current Culture: English (United Kingdom)
//      Currency Value: $16,039.47

```

Work with culture-specific settings

In .NET, the [CultureInfo](#) class represents a particular culture or region. Some of its properties return objects that provide specific information about some aspect of a culture:

- The [CultureInfo.CompareInfo](#) property returns a [CompareInfo](#) object that contains information about how the culture compares and orders strings.
- The [CultureInfo.DateTimeFormat](#) property returns a [DateTimeFormatInfo](#) object that provides culture-specific information used in formatting date and time data.
- The [CultureInfo.NumberFormat](#) property returns a [NumberFormatInfo](#) object that provides culture-specific information used in formatting numeric data.
- The [CultureInfo.TextInfo](#) property returns a [TextInfo](#) object that provides information about the culture's writing system.

In general, do not make any assumptions about the values of specific [CultureInfo](#) properties and their related objects. Instead, you should view culture-specific data as subject to change, for these reasons:

- Individual property values are subject to change and revision over time, as data is corrected, better data becomes available, or culture-specific conventions change.
- Individual property values may vary across versions of .NET or operating system versions.
- .NET supports replacement cultures. This makes it possible to define a new custom culture that either supplements existing standard cultures or completely replaces an existing standard culture.
- On Windows systems, the user can customize culture-specific settings by using the **Region and Language** app in Control Panel. When you instantiate a [CultureInfo](#) object, you can determine whether it reflects these user customizations by calling the [CultureInfo\(String, Boolean\)](#) constructor. Typically, for end-user apps, you should respect user preferences so that the user is presented with data in a format that they expect.

.NET globalization and ICU

Article • 08/29/2023

Before .NET 5, the .NET globalization APIs used different underlying libraries on different platforms. On Unix, the APIs used [International Components for Unicode \(ICU\)](#), and on Windows, they used [National Language Support \(NLS\)](#). This resulted in some behavioral differences in a handful of globalization APIs when running applications on different platforms. Behavior differences were evident in these areas:

- Cultures and culture data
- String casing
- String sorting and searching
- Sort keys
- String normalization
- Internationalized Domain Names (IDN) support
- Time zone display name on Linux

Starting with .NET 5, developers have more control over which underlying library is used, enabling applications to avoid differences across platforms.

ICU on Windows

Windows now incorporates a preinstalled [icu.dll](#) version as part of its features that's automatically employed for globalization tasks. This modification allows .NET to leverage this ICU library for its globalization support. In cases where the ICU library is unavailable or cannot be loaded, as is the case with older Windows versions, .NET 5 and subsequent versions revert to using the NLS-based implementation.

The following table shows which versions of .NET are capable of loading the ICU library across different Windows client and server versions:

[] Expand table

| .NET version | Windows version |
|------------------|---|
| .NET 5 or .NET 6 | Windows client 10 version 1903 or later |
| .NET 5 or .NET 6 | Windows Server 2022 or later |
| .NET 7 or later | Windows client 10 version 1703 or later |
| .NET 7 or later | Windows Server 2019 or later |

ⓘ Note

.NET 7 and later versions have the capability to load ICU on older Windows versions, in contrast to .NET 6 and .NET 5.

ⓘ Note

Even when using ICU, the `CurrentCulture`, `CurrentUICulture`, and `CurrentRegion` members still use Windows operating system APIs to honor user settings.

Behavioral differences

If you upgrade your app to target .NET 5 or later, you might see changes in your app even if you don't realize you're using globalization facilities. This section lists one of the behavioral changes you might see, but there are others too.

String.IndexOf

Consider the following code that calls `String.IndexOf(String)` to find the index of the null character `\0` in a string.

C#

```
const string greeting = "He\0llo";
Console.WriteLine(${greeting.IndexOf("\0")});
Console.WriteLine(${greeting.IndexOf("\0",
 StringComparison.CurrentCulture)});
Console.WriteLine(${greeting.IndexOf("\0", StringComparison.Ordinal)});
```

- In .NET Core 3.1 and earlier versions on Windows, the snippet prints `3` on each of the three lines.
- For .NET 5 and subsequent versions running on the Windows versions listed in the [ICU on Windows](#) section table, the snippet prints `0`, `0`, and `3` (for the ordinal search).

By default, `String.IndexOf(String)` performs a culture-aware linguistic search. ICU considers the null character `\0` to be a *zero-weight character*, and thus the character isn't found in the string when using a linguistic search on .NET 5 and later. However, NLS doesn't consider the null character `\0` to be a zero-weight character, and a linguistic

search on .NET Core 3.1 and earlier locates the character at position 3. An ordinal search finds the character at position 3 on all .NET versions.

You can run code analysis rules [CA1307: Specify StringComparison for clarity](#) and [CA1309: Use ordinal StringComparison](#) to find call sites in your code where the string comparison isn't specified or it is not ordinal.

For more information, see [Behavior changes when comparing strings on .NET 5+](#).

String.EndsWith

C#

```
const string foo = "abc";

Console.WriteLine(foo.EndsWith("\0"));
Console.WriteLine(foo.EndsWith("c"));
Console.WriteLine(foo.EndsWith("\0", StringComparison.CurrentCulture));
Console.WriteLine(foo.EndsWith("\0", StringComparison.Ordinal));
Console.WriteLine(foo.EndsWith('\0'));
```

ⓘ Important

In .NET 5+ running on Windows versions listed in the [ICU on Windows](#) table, the preceding snippet prints:

Output

```
True
True
True
False
False
```

To avoid this behavior, use the `char` parameter overload or `StringComparison.Ordinal`.

String.StartsWith

C#

```
const string foo = "abc";

Console.WriteLine(foo.StartsWith("\0"));
Console.WriteLine(foo.StartsWith("a"));
```

```
Console.WriteLine(foo.StartsWith("\0", StringComparison.CurrentCulture));
Console.WriteLine(foo.StartsWith("\0", StringComparison.Ordinal));
Console.WriteLine(foo.StartsWith('\0'));
```

ⓘ Important

In .NET 5+ running on Windows versions listed in the [ICU on Windows](#) table, the preceding snippet prints:

Output

```
True
True
True
False
False
```

To avoid this behavior, use the `char` parameter overload or `StringComparison.Ordinal`.

TimeZoneInfo.FindSystemTimeZoneById

ICU provides the flexibility to create `TimeZoneInfo` instances using [IANA](#) time zone IDs, even when the application is running on Windows. Similarly, you can create `TimeZoneInfo` instances with Windows time zone IDs, even when running on non-Windows platforms. However, it's important to note that this functionality isn't available when using [NLS mode](#) or [globalization invariant mode](#).

ICU dependent APIs

.NET introduced APIs that are dependent on ICU. These APIs can succeed only when using ICU. Here are some examples:

- [TryConvertIanaIdToWindowsId\(String, String\)](#)
- [TryConvertWindowsIdToIanaId](#)

On the Windows versions listed in the [ICU on Windows](#) section table, the mentioned APIs will consistently succeed. However, on older versions of Windows, these APIs will consistently fail. In such cases, you can enable the [app-local ICU](#) feature to ensure the success of these APIs. On non-Windows platforms, these APIs will always succeed regardless of the version.

In addition, it's crucial for apps to ensure that they're not running in [globalization invariant mode](#) or [NLS mode](#) to guarantee the success of these APIs.

Use NLS instead of ICU

Using ICU instead of NLS may result in behavioral differences with some globalization-related operations. To revert back to using NLS, a developer can opt out of the ICU implementation. Applications can enable NLS mode in any of the following ways:

- In the project file:

XML

```
<ItemGroup>
  <RuntimeHostConfigurationOption Include="System.Globalization.UseNls"
    Value="true" />
</ItemGroup>
```

- In the `runtimeconfig.json` file:

JSON

```
{
  "runtimeOptions": {
    "configProperties": {
      "System.Globalization.UseNls": true
    }
  }
}
```

- By setting the environment variable `DOTNET_SYSTEM_GLOBALIZATION_USENLS` to the value `true` or `1`.

ⓘ Note

A value set in the project or in the `runtimeconfig.json` file takes precedence over the environment variable.

For more information, see [Runtime config settings](#).

Determine if your app is using ICU

The following code snippet can help you determine if your app is running with ICU libraries (and not NLS).

C#

```
public static bool ICUMode()
{
    SortVersion sortVersion =
CultureInfo.InvariantCulture.CompareInfo.Version;
    byte[] bytes = sortVersion.SortId.ToByteArray();
    int version = bytes[3] << 24 | bytes[2] << 16 | bytes[1] << 8 |
bytes[0];
    return version != 0 && version == sortVersion.FullVersion;
}
```

To determine the version of .NET, use [RuntimeInformation.FrameworkDescription](#).

App-local ICU

Each release of ICU may bring with it bug fixes as well as updated Common Locale Data Repository (CLDR) data that describes the world's languages. Moving between versions of ICU can subtly impact app behavior when it comes to globalization-related operations. To help application developers ensure consistency across all deployments, .NET 5 and later versions enable apps on both Windows and Unix to carry and use their own copy of ICU.

Applications can opt-in to an app-local ICU implementation mode in one of the following ways:

- In the project file, set the appropriate `RuntimeHostConfigurationOption` value:

XML

```
<ItemGroup>
    <RuntimeHostConfigurationOption
        Include="System.Globalization.AppLocalIcu" Value="<suffix>:<version> or
<version>" />
</ItemGroup>
```

- Or in the `runtimeconfig.json` file, set the appropriate

`runtimeOptions.configProperties` value:

JSON

```
{
    "runtimeOptions": {
```

```
        "configProperties": {
            "System.Globalization.AppLocalIcu": "<suffix>:<version> or
<version>"
        }
    }
}
```

- Or by setting the environment variable `DOTNET_SYSTEM_GLOBALIZATION_APPLOCALICU` to the value `<suffix>:<version>` or `<version>`.

`<suffix>`: Optional suffix of fewer than 36 characters in length, following the public ICU packaging conventions. When building a custom ICU, you can customize it to produce the lib names and exported symbol names to contain a suffix, for example, `libicuucmyapp`, where `myapp` is the suffix.

`<version>`: A valid ICU version, for example, 67.1. This version is used to load the binaries and to get the exported symbols.

When either of these options is set, you can add a [Microsoft.ICU.ICU4C.Runtime](#)  `PackageReference` to your project that corresponds to the configured `version` and that's all that is needed.

Alternatively, to load ICU when the app-local switch is set, .NET uses the [NativeLibrary.TryLoad](#) method, which probes multiple paths. The method first tries to find the library in the `NATIVE_DLL_SEARCH_DIRECTORIES` property, which is created by the dotnet host based on the `deps.json` file for the app. For more information, see [Default probing](#).

For self-contained apps, no special action is required by the user, other than making sure ICU is in the app directory (for self-contained apps, the working directory defaults to `NATIVE_DLL_SEARCH_DIRECTORIES`).

If you're consuming ICU via a NuGet package, this works in framework-dependent applications. NuGet resolves the native assets and includes them in the `deps.json` file and in the output directory for the application under the `runtimes` directory. .NET loads it from there.

For framework-dependent apps (not self-contained) where ICU is consumed from a local build, you must take additional steps. The .NET SDK doesn't yet have a feature for "loose" native binaries to be incorporated into `deps.json` (see [this SDK issue](#) ). Instead, you can enable this by adding additional information into the application's project file. For example:

XML

```

<ItemGroup>
  <IcuAssemblies Include="icu\*.so*" />
  <RuntimeTargetsCopyLocalItems Include="@{IcuAssemblies}" AssetType="native" CopyLocal="true"
    DestinationSubDirectory="runtimes/linux-x64/native/"
    DestinationSubPath"%(FileName)%(Extension)"
    RuntimeIdentifier="linux-x64"
    NuGetPackageId="System.Private.Runtime.UnicodeData" />
</ItemGroup>

```

This must be done for all the ICU binaries for the supported runtimes. Also, the `NuGetPackageId` metadata in the `RuntimeTargetsCopyLocalItems` item group needs to match a NuGet package that the project actually references.

macOS behavior

macOS has a different behavior for resolving dependent dynamic libraries from the load commands specified in the `Mach-O` file than the Linux loader. In the Linux loader, .NET can try `libcudata`, `libicuuc`, and `libicui18n` (in that order) to satisfy ICU dependency graph. However, on macOS, this doesn't work. When building ICU on macOS, you, by default, get a dynamic library with these load commands in `libicuuc`. The following snippet shows an example.

```

sh

~/ % otool -L /Users/santifdezr/repos/icu-build/icu/install/lib/libicuuc.67.1.dylib
/Users/santifdezr/repos/icu-build/icu/install/lib/libicuuc.67.1.dylib:
  libicuuc.67.dylib (compatibility version 67.0.0, current version 67.1.0)
  libicudata.67.dylib (compatibility version 67.0.0, current version 67.1.0)
  /usr/lib/libSystem.B.dylib (compatibility version 1.0.0, current version
  1281.100.1)
  /usr/lib/libc++.1.dylib (compatibility version 1.0.0, current version
  902.1.0)

```

These commands just reference the name of the dependent libraries for the other components of ICU. The loader performs the search following the `dlopen` conventions, which involves having these libraries in the system directories or setting the `LD_LIBRARY_PATH` env vars, or having ICU at the app-level directory. If you can't set `LD_LIBRARY_PATH` or ensure that ICU binaries are at the app-level directory, you will need to do some extra work.

There are some directives for the loader, like `@loader_path`, which tell the loader to search for that dependency in the same directory as the binary with that load command.

There are two ways to achieve this:

- `install_name_tool -change`

Run the following commands:

Bash

```
install_name_tool -change "libcudata.67.dylib"
"@loader_path/libicudata.67.dylib" /path/to/libicuuc.67.1.dylib
install_name_tool -change "libcudata.67.dylib"
"@loader_path/libicudata.67.dylib" /path/to/libicui18n.67.1.dylib
install_name_tool -change "libicuuc.67.dylib"
"@loader_path/libicuuc.67.dylib" /path/to/libicui18n.67.1.dylib
```

- Patch ICU to produce the install names with `@loader_path`

Before running autoconf (`./runConfigureICU`), change [these lines ↗](#) to:

```
LD SONAME = -Wl,-compatibility_version -Wl,$(SO_TARGET_VERSION_MAJOR) -
Wl,-current_version -Wl,$(SO_TARGET_VERSION) -install_name
@loader_path/${notdir $(MIDDLE_SO_TARGET)}
```

ICU on WebAssembly

A version of ICU is available that's specifically for WebAssembly workloads. This version provides globalization compatibility with desktop profiles. To reduce the ICU data file size from 24 MB to 1.4 MB (or ~0.3 MB if compressed with Brotli), this workload has a handful of limitations.

The following APIs are not supported:

- [CultureInfo.EnglishName](#)
- [CultureInfo.NativeName](#)
- [DateTimeFormatInfo.NativeCalendarName](#)
- [RegionInfo.NativeName](#)

The following APIs are supported with limitations:

- [String.Normalize\(NormalizationForm\)](#) and [String.IsNormalized\(NormalizationForm\)](#) don't support the rarely used [FormKC](#) and [FormKD](#) forms.
- [RegionInfo.CurrencyNativeName](#) returns the same value as [RegionInfo.CurrencyEnglishName](#).

In addition, fewer locales are supported. The supported list can be found in the [dotnet/icu repo ↗](#).

Perform culture-insensitive string operations

Article • 03/18/2023

Culture-sensitive string operations are advantageous if you're creating applications designed to display results to users on a per-culture basis. By default, culture-sensitive methods obtain the culture to use from the [CurrentCulture](#) property for the current thread.

Sometimes, culture-sensitive string operations are not the desired behavior. Using culture-sensitive operations when results should be independent of culture can cause application code to fail on cultures with custom case mappings and sorting rules. For an example, see the [String Comparisons that Use the Current Culture](#) section in [Best Practices for Using Strings](#).

Whether string operations should be culture-sensitive or culture-insensitive depends on how your application uses the results. String operations that display results to the user should typically be culture-sensitive. For example, if an application displays a sorted list of localized strings in a list box, the application should perform a culture-sensitive sort.

Results of string operations that are used internally should typically be culture-insensitive. In general, if the application is working with file names, persistence formats, or symbolic information that is not displayed to the user, results of string operations should not vary by culture. For example, if an application compares a string to determine whether it is a recognized XML tag, the comparison should not be culture-sensitive. In addition, if a security decision is based on the result of a string comparison or case change operation, the operation should be culture-insensitive to ensure that the result is not affected by the value of [CurrentCulture](#).

Most .NET methods that *by default* perform culture-sensitive string operations also provide an overload that allows you to guarantee culture-insensitive results. These overloads that take a [CultureInfo](#) argument allow you to eliminate cultural variations in case mappings and sorting rules. For culture-insensitive string operations, specify the culture as [CultureInfo.InvariantCulture](#).

In this section

The articles in this section demonstrate how to perform culture-insensitive string operations using .NET methods that are culture-sensitive by default.

Performing culture-insensitive string comparisons

Describes how to use the [String.Compare](#) and [String.CompareTo](#) methods to perform culture-insensitive string comparisons.

Performing culture-insensitive case changes

Describes how to use the [String.ToUpper](#), [String.ToLower](#), [Char.ToUpper](#), and [Char.ToLower](#) methods to perform culture-insensitive case changes.

Performing culture-insensitive string operations in collections

Describes how to use the [CaseInsensitiveComparer](#), [CaseInsensitiveHashCodeProvider](#) class, [SortedList](#), [ArrayList.Sort](#) and [CollectionsUtil.CreateCaseInsensitiveHashtable](#) to perform culture-insensitive operations in collections.

Performing culture-insensitive string operations in arrays

Describes how to use the [Array.Sort](#) and [Array.BinarySearch](#) methods to perform culture-insensitive operations in arrays.

Perform culture-insensitive string comparisons

Article • 03/18/2023

By default, the [String.Compare](#) method performs culture-sensitive and case-sensitive comparisons. This method also includes several overloads that provide a `culture` parameter that lets you specify the culture to use, and a `comparisonType` parameter that lets you specify the comparison rules to use. Calling these methods instead of the default overload removes any ambiguity about the rules used in a particular method call, and makes it clear whether a particular comparison is culture-sensitive or culture-insensitive.

ⓘ Note

Both overloads of the [String.CompareTo](#) method perform culture-sensitive and case-sensitive comparisons; you cannot use this method to perform culture-insensitive comparisons. For code clarity, we recommend that you use the [String.Compare](#) method instead.

For culture-sensitive operations, specify the [StringComparison.CurrentCulture](#) or [StringComparison.CurrentCultureIgnoreCase](#) enumeration value as the `comparisonType` parameter. If you want to perform a culture-sensitive comparison using a designated culture other than the current culture, specify the [CultureInfo](#) object that represents that culture as the `culture` parameter.

The culture-insensitive string comparisons supported by the [String.Compare](#) method are either linguistic (based on the sorting conventions of the invariant culture) or non-linguistic (based on the ordinal value of the characters in the string). Most culture-insensitive string comparisons are non-linguistic. For these comparisons, specify the [StringComparison.Ordinal](#) or [StringComparison.OrdinalIgnoreCase](#) enumeration value as the `comparisonType` parameter. For example, if a security decision (such as a user name or password comparison) is based on the result of a string comparison, the operation should be culture-insensitive and non-linguistic to ensure that the result is not affected by the conventions of a particular culture or language.

Use culture-insensitive linguistic string comparison if you want to handle linguistically relevant strings from multiple cultures in a consistent way. For example, if your application displays words that use multiple character sets in a list box, you might want to display words in the same order regardless of the current culture. For culture-

insensitive linguistic comparisons, .NET defines an invariant culture that is based on the linguistic conventions of English. To perform a culture-insensitive linguistic comparison, specify [StringComparison.InvariantCulture](#) or [StringComparison.InvariantCultureIgnoreCase](#) as the `comparisonType` parameter.

The following example performs two culture-insensitive, non-linguistic string comparisons. The first is case-sensitive, but the second is not.

C#

```
using System;

public class CompareSample
{
    public static void Main()
    {
        string string1 = "file";
        string string2 = "FILE";
        int compareResult = 0;

        compareResult = String.Compare(string1, string2,
                                       StringComparison.Ordinal);
        Console.WriteLine("{0} comparison of '{1}' and '{2}': {3}",
                          StringComparison.Ordinal, string1, string2,
                          compareResult);

        compareResult = String.Compare(string1, string2,
                                       StringComparison.OrdinalIgnoreCase);
        Console.WriteLine("{0} comparison of '{1}' and '{2}': {3}",
                          StringComparison.OrdinalIgnoreCase, string1,
                          string2,
                          compareResult);
    }
}

// The example displays the following output:
//   Ordinal comparison of 'file' and 'FILE': 32
//   OrdinalIgnoreCase comparison of 'file' and 'FILE': 0
```

You can download the [Sorting Weight Tables](#), a set of text files that contain information on the character weights used in sorting and comparison operations for Windows operating systems, and the [Default Unicode Collation Element Table](#), the sort weight table for Linux and macOS.

Perform culture-insensitive case changes

Article • 03/13/2023

The `String.ToUpper`, `String.ToLower`, `Char.ToUpper`, and `Char.ToLower` methods provide overloads that do not accept any parameters. By default, these overloads without parameters perform case changes based on the value of the `CultureInfo.CurrentCulture`. This produces case-sensitive results that can vary by culture. To make it clear whether you want case changes to be culture-sensitive or culture-insensitive, you should use the overloads of these methods that require you to explicitly specify a `culture` parameter. For culture-sensitive case changes, specify `CultureInfo.CurrentCulture` for the `culture` parameter. For culture-insensitive case changes, specify `CultureInfo.InvariantCulture` for the `culture` parameter.

Often, strings are converted to a standard case to enable easier lookup later. When strings are used in this way, you should specify `CultureInfo.InvariantCulture` for the `culture` parameter, because the value of `Thread.CurrentCulture` can potentially change between the time that the case is changed and the time that the lookup occurs.

If a security decision is based on a case change operation, the operation should be culture-insensitive to ensure that the result is not affected by the value of `CultureInfo.CurrentCulture`. See the "String Comparisons that Use the Current Culture" section of the [Best Practices for Using Strings](#) article for an example that demonstrates how culture-sensitive string operations can produce inconsistent results.

String.ToUpper and String.ToLower

For code clarity, it's recommended that you always use overloads of the `String.ToUpper` and `String.ToLower` methods that let you specify a culture explicitly. For example, the following code performs an identifier lookup. The `key.ToLower` operation is culture-sensitive by default, but this behavior is not clear from reading the code.

Example

C#

```
static object LookupKey(string key)
{
```

```
        return internalHashtable[key.ToLower()];
    }
```

If you want the `key.ToLower` operation to be culture-insensitive, change the preceding example as follows to explicitly use `CultureInfo.InvariantCulture` when changing the case.

C#

```
static object LookupKey(string key)
{
    return internalHashtable[key.ToLower(CultureInfo.InvariantCulture)];
}
```

Char.ToUpper and Char.ToLower

Although the `Char.ToUpper` and `Char.ToLower` methods have the same characteristics as the `String.ToUpper` and `String.ToLower` methods, the only cultures that are affected are Turkish (Türkiye) and Azerbaijani (Latin, Azerbaijan). These are the only two cultures with single-character casing differences. For more details about this unique case mapping, see the "Casing" section in the [String](#) class documentation. For code clarity and to ensure consistent results, it's recommended that you always use the overloads of these methods that accept a `CultureInfo` parameter.

Perform culture-insensitive string operations in collections

Article • 03/18/2023

There are classes and members in the [System.Collections](#) namespace that provide culture-sensitive behavior by default. The parameterless constructors for the [CaseInsensitiveComparer](#) and [CaseInsensitiveHashCodeProvider](#) classes initialize a new instance using the [Thread.CurrentCulture](#) property. All overloads of the [CollectionsUtil.CreateCaseInsensitiveHashtable](#) method create a new instance of the [Hashtable](#) class using the [Thread.CurrentCulture](#) property by default. Overloads of the [ArrayList.Sort](#) method perform culture-sensitive sorts by default using [Thread.CurrentCulture](#). Sorting and lookup in a [SortedList](#) can be affected by [Thread.CurrentCulture](#) when strings are used as the keys. Follow the usage recommendations provided in this section to obtain culture-insensitive results from these classes and methods in the [collections](#) namespace.

ⓘ Note

Passing [CultureInfo.InvariantCulture](#) to a comparison method does perform a culture-insensitive comparison. However, it does not cause a non-linguistic comparison, for example, for file paths, registry keys, and environment variables. Neither does it support security decisions based on the comparison result. For a non-linguistic comparison or support for result-based security decisions, the application should use a comparison method that accepts a [StringComparison](#) value. The application should then pass [StringComparison](#).

Use the [CaseInsensitiveComparer](#) and [CaseInsensitiveHashCodeProvider](#) classes

The parameterless constructors for [CaseInsensitiveHashCodeProvider](#) and [CaseInsensitiveComparer](#) initialize a new instance of the class using the [Thread.CurrentCulture](#), resulting in culture-sensitive behavior. The following code example demonstrates the constructor for a [Hashtable](#) that is culture-sensitive because it uses the parameterless constructors for [CaseInsensitiveHashCodeProvider](#) and [CaseInsensitiveComparer](#).

C#

```
internalHashtable = new Hashtable(CaseInsensitiveHashCodeProvider.Default,
CaseInsensitiveComparer.Default);
```

If you want to create a culture-insensitive `Hashtable` using the `CaseInsensitiveComparer` and `CaseInsensitiveHashCodeProvider` classes, initialize new instances of these classes using the constructors that accept a `culture` parameter. For the `culture` parameter, specify `CultureInfo.InvariantCulture`. The following code example demonstrates the constructor for a culture-insensitive `Hashtable`.

C#

```
internalHashtable = new Hashtable(new CaseInsensitiveHashCodeProvider(
    CultureInfo.InvariantCulture),
    new CaseInsensitiveComparer(CultureInfo.InvariantCulture));
```

Use the `CollectionsUtil.CreateCaseInsensitiveHashTable` method

The `CollectionsUtil.CreateCaseInsensitiveHashTable` method is a useful shortcut for creating a new instance of the `Hashtable` class that ignores the case of strings. However, all overloads of the `CollectionsUtil.CreateCaseInsensitiveHashTable` method are culture-sensitive because they use the `Thread.CurrentCulture` property. You cannot create a culture-insensitive `Hashtable` using this method. To create a culture-insensitive `Hashtable`, use the `Hashtable` constructor that accepts a `culture` parameter. For the `culture` parameter, specify `CultureInfo.InvariantCulture`. The following code example demonstrates the constructor for a culture-insensitive `Hashtable`.

C#

```
internalHashtable = new Hashtable(new CaseInsensitiveHashCodeProvider(
    CultureInfo.InvariantCulture),
    new CaseInsensitiveComparer(CultureInfo.InvariantCulture));
```

Use the `SortedList` class

A `SortedList` represents a collection of key-and-value pairs that are sorted by the keys and are accessible by key and by index. When you use a `SortedList` where strings are

the keys, the sorting and lookup can be affected by the `Thread.CurrentCulture` property. To obtain culture-insensitive behavior from a `SortedList`, create a `SortedList` using one of the constructors that accepts a `comparer` parameter. The `comparer` parameter specifies the `IComparer` implementation to use when comparing keys. For the parameter, specify a custom comparer class that uses `CultureInfo.InvariantCulture` to compare keys. The following example illustrates a custom culture-insensitive comparer class that you can specify as the `comparer` parameter to a `SortedList` constructor.

C#

```
using System;
using System.Collections;
using System.Globalization;

internal class InvariantComparer : IComparer
{
    private CompareInfo _compareInfo;
    internal static readonly InvariantComparer Default = new
        InvariantComparer();

    internal InvariantComparer()
    {
        _compareInfo = CultureInfo.InvariantCulture.CompareInfo;
    }

    public int Compare(Object a, Object b)
    {
        if (a is string sa && b is string sb)
            return _compareInfo.Compare(sa, sb);
        else
            return Comparer.Default.Compare(a,b);
    }
}
```

In general, if you use a `SortedList` on strings without specifying a custom invariant comparer, a change to `Thread.CurrentCulture` after the list has been populated can invalidate the list.

Use the `ArrayList.Sort` method

Overloads of the `ArrayList.Sort` method perform culture-sensitive sorts by default using the `Thread.CurrentCulture` property. Results can vary by culture due to different sort orders. To eliminate culture-sensitive behavior, use the overloads of this method that accept an `IComparer` implementation. For the `comparer` parameter, specify a custom

invariant comparer class that uses `CultureInfo.InvariantCulture`. An example of a custom invariant comparer class is provided in the [Using the SortedList Class](#) topic.

Perform culture-insensitive string operations in arrays

Article • 03/18/2023

Overloads of the [Array.Sort](#) and [Array.BinarySearch](#) methods perform culture-sensitive sorts by default using the [Thread.CurrentCulture](#) property. Culture-sensitive results returned by these methods can vary by culture due to differences in sort orders. To eliminate culture-sensitive behavior, use one of the overloads of this method that accepts a `comparer` parameter. The `comparer` parameter specifies the [IComparer](#) implementation to use when comparing elements in the array. For the parameter, specify a custom invariant comparer class that uses [CultureInfo.InvariantCulture](#). An example of a custom invariant comparer class is provided in the "Using the SortedList Class" subtopic of the [Perform culture-insensitive string operations in collections](#) topic.

ⓘ Note

Passing [CultureInfo.InvariantCulture](#) to a comparison method does perform a culture-insensitive comparison. However, it does not cause a non-linguistic comparison, for example, for file paths, registry keys, and environment variables. Neither does it support security decisions based on the comparison result. For a non-linguistic comparison or support for result-based security decisions, the application should use a comparison method that accepts a [StringComparison](#) value. The application should then pass [Ordinal](#).

Best practices for developing world-ready applications

Article • 03/18/2023

This section describes the best practices to follow when developing world-ready applications.

Globalization best practices

1. Make your application Unicode internally.
2. Use the culture-aware classes provided by the [System.Globalization](#) namespace to manipulate and format data.
 - For sorting, use the [SortKey](#) class and the [CompareInfo](#) class.
 - For string comparisons, use the [CompareInfo](#) class.
 - For date and time formatting, use the [DateTimeFormatInfo](#) class.
 - For numeric formatting, use the [NumberFormatInfo](#) class.
 - For Gregorian and non-Gregorian calendars, use the [Calendar](#) class or one of the specific calendar implementations.
3. Use the culture property settings provided by the [System.Globalization.CultureInfo](#) class in the appropriate situations. Use the [CultureInfo.CurrentCulture](#) property for formatting tasks, such as date and time or numeric formatting. Use the [CultureInfo.CurrentUICulture](#) property to retrieve resources. Note that the `CurrentCulture` and `CurrentUICulture` properties can be set per thread.
4. Enable your application to read and write data to and from a variety of encodings by using the encoding classes in the [System.Text](#) namespace. Do not assume ASCII data. Assume that international characters will be supplied anywhere a user can enter text. For example, the application should accept international characters in server names, directories, file names, user names, and URLs.
5. When using the [UTF8Encoding](#) class, for security reasons, use the error detection feature offered by this class. To turn on the error detection feature, create an instance of the class using the constructor that takes a `throwOnInvalidBytes` parameter and set the value of this parameter to `true`.
6. Whenever possible, handle strings as entire strings instead of as a series of individual characters. This is especially important when sorting or searching for

substrings. This will prevent problems associated with parsing combined characters. You can also work with units of text rather than single characters by using the [System.Globalization.StringInfo](#) class.

7. Display text using the classes provided by the [System.Drawing](#) namespace.
8. For consistency across operating systems, do not allow user settings to override [CultureInfo](#). Use the `cultureInfo` constructor that accepts a `useUserOverride` parameter and set it to `false`.
9. Test your application functionality on international operating system versions, using international data.
10. If a security decision is based on the result of a string comparison or case change operation, use a culture-insensitive string operation. This practice ensures that the result is not affected by the value of `cultureInfo.CurrentCulture`. See the "[String Comparisons that Use the Current Culture](#)" section of [Best Practices for Using Strings](#) for an example that demonstrates how culture-sensitive string comparisons can produce inconsistent results.

Localization best practices

1. Move all localizable resources to separate resource-only DLLs. Localizable resources include user interface elements, such as strings, error messages, dialog boxes, menus, and embedded object resources.
2. Do not hardcode strings or user interface resources.
3. Do not put non-localizable resources into the resource-only DLLs. This confuses translators.
4. Do not use composite strings that are built at run time from concatenated phrases. Composite strings are difficult to localize because they often assume an English grammatical order that does not apply to all languages.
5. Avoid ambiguous constructs such as "Empty Folder" where the strings can be translated differently depending on the grammatical roles of the string components. For example, "empty" can be either a verb or an adjective, which can lead to different translations in languages such as Italian or French.
6. Avoid using images and icons that contain text in your application. They are expensive to localize.

7. Allow plenty of room for the length of strings to expand in the user interface. In some languages, phrases can require 50-75 percent more space than they need in other languages.
8. Use the [System.Resources.ResourceManager](#) class to retrieve resources based on culture.
9. Use [Visual Studio](#) to create Windows Forms dialog boxes so they can be localized using the [Windows Forms Resource Editor \(Winres.exe\)](#). Do not code Windows Forms dialog boxes by hand.
10. Arrange for professional localization (translation).
11. For a complete description of creating and localizing resources, see [Resources in .NET apps](#).

Globalization best practices for ASP.NET applications

Tip

The following best practices are for ASP.NET Framework apps. For ASP.NET Core apps, see [Globalization and localization in ASP.NET Core](#).

1. Explicitly set the [CurrentUICulture](#) and [CurrentCulture](#) properties in your application. Do not rely on defaults.
2. Note that ASP.NET applications are managed applications and therefore can use the same classes as other managed applications for retrieving, displaying, and manipulating information based on culture.
3. Be aware that you can specify the following three types of encodings in ASP.NET:
 - `requestEncoding` specifies the encoding received from the client's browser.
 - `responseEncoding` specifies the encoding to send to the client browser. In most situations, this encoding should be the same as that specified for `requestEncoding`.
 - `fileEncoding` specifies the default encoding for `.aspx`, `.asmx`, and `.asax` file parsing.
4. Specify the values for the `requestEncoding`, `responseEncoding`, `fileEncoding`, `culture`, and `uiCulture` attributes in the following three places in an ASP.NET

application:

- In the globalization section of a `Web.config` file. This file is external to the ASP.NET application. For more information, see [`<globalization>` element](#).
- In a page directive. Note that, when an application is in a page, the file has already been read. Therefore, it is too late to specify `fileEncoding` and `requestEncoding`. Only `uiCulture`, `culture`, and `responseEncoding` can be specified in a page directive.
- Programmatically in application code. This setting can vary per request. As with a page directive, by the time the application's code is reached, it is too late to specify `fileEncoding` and `requestEncoding`. Only `uiCulture`, `culture`, and `responseEncoding` can be specified in the application code.

5. Note that the `uiCulture` value can be set to the browser accept language.

Localizability review

Article • 03/18/2023

The localizability review is an intermediate step in the development of a world-ready application. It verifies that a globalized application is ready for localization and identifies any code or any aspects of the user interface that require special handling. This step also helps ensure that the localization process will not introduce any functional defects into your application. When all the issues raised by the localizability review have been addressed, your application is ready for localization. If the localizability review is thorough, you should not have to modify any source code during the localization process.

The localizability review consists of the following three checks:

- ✓ Are the globalization recommendations implemented?
- ✓ Are culture-sensitive features handled correctly?
- ✓ Have you tested your application with international data?

Implement globalization recommendations

If you have designed and developed your application with localization in mind, and if you have followed the recommendations discussed in the [Globalization](#) article, the localizability review will largely be a quality assurance pass. Otherwise, during this stage you should review and implement the recommendations for [globalization](#) and fix the errors in source code that prevent localization.

Handle culture-sensitive features

.NET does not provide programmatic support in a number of areas that vary widely by culture. In most cases, you have to write custom code to handle feature areas like the following:

- Addresses
- Telephone numbers
- Paper sizes
- Units of measure used for lengths, weights, area, volume, and temperatures

Although .NET does not offer built-in support for converting between units of measure, you can use the `RegionInfo.IsMetric` property to determine whether a particular country or region uses the metric system, as the following example illustrates.

C#

```
using System;
using System.Globalization;

public class Example
{
    public static void Main()
    {
        string[] cultureNames = { "en-US", "en-GB", "fr-FR",
                                  "ne-NP", "es-BO", "ig-NG" };
        foreach (var cultureName in cultureNames) {
            RegionInfo region = new RegionInfo(cultureName);
            Console.WriteLine("{0} {1} the metric system.",
region.EnglishName,
                           region.IsMetric ? "uses" : "does not use");
        }
    }
}
// The example displays the following output:
//      United States does not use the metric system.
//      United Kingdom uses the metric system.
//      France uses the metric system.
//      Nepal uses the metric system.
//      Bolivia uses the metric system.
//      Nigeria uses the metric system.
```

Test your application

Before you localize your application, you should test it by using international data on international versions of the operating system. Although most of the user interface will not be localized at this point, you will be able to detect problems such as the following:

- Serialized data that does not deserialize correctly across operating system versions.
- Numeric data that does not reflect the conventions of the current culture. For example, numbers may be displayed with inaccurate group separators, decimal separators, or currency symbols.
- Date and time data that does not reflect the conventions of the current culture. For example, numbers that represent the month and day may appear in the wrong

order, date separators may be incorrect, or time zone information may be incorrect.

- Resources that cannot be found because you have not identified a default culture for your application.
- Strings that are displayed in an unusual order for the specific culture.
- String comparisons or comparisons for equality that return unexpected results.

If you've followed the globalization recommendations when developing your application, handled culture-sensitive features correctly, and identified and addressed the localization issues that arose during testing, you can proceed to the next step, [Localization](#).

Localization in .NET

Article • 12/19/2023

Localization is the process of translating an application's resources into localized versions for each culture that the application will support. You should proceed to the localization step only after completing the [Localizability review](#) step to verify that the globalized application is ready for localization.

An application that is ready for localization is separated into two conceptual blocks: a block that contains all user interface elements and a block that contains executable code. The user interface block contains only localizable user-interface elements such as strings, error messages, dialog boxes, menus, embedded object resources, and so on for the neutral culture. The code block contains only the application code to be used by all supported cultures. The common language runtime supports a satellite assembly resource model that separates an application's executable code from its resources. For more information about implementing this model, see [Resources in .NET](#).

For each localized version of your application, add a new satellite assembly that contains the localized user interface block translated into the appropriate language for the target culture. The code block for all cultures should remain the same. The combination of a localized version of the user interface block with the code block produces a localized version of your application.

In this article, you will learn how to use the [IStringLocalizer<T>](#) and [IStringLocalizerFactory](#) implementations. All of the example source code in this article relies on the [Microsoft.Extensions.Localization](#) ↗ and [Microsoft.Extensions.Hosting](#) ↗ NuGet packages. For more information on hosting, see [.NET Generic Host](#).

Resource files

The primary mechanism for isolating localizable strings is with **resource files**. A resource file is an XML file with the `.resx` file extension. Resource files are translated prior to the execution of the consuming application — in other words, they represent translated content at rest. A resource file name most commonly contains a locale identifier, and takes on the following form:

`<FullTypeName><.Locale>.resx`

Where:

- The `<FullTypeName>` represents localizable resources for a specific type.

- The optional `<.Locale>` represents the locale of the resource file contents.

Specifying locales

The locale should define the language, at a bare minimum, but it can also define the culture (regional language), and even the country or region. These segments are commonly delimited by the `-` character. With the added specificity of a culture, the "culture fallback" rules are applied where best matches are prioritized. The locale should map to a well-known language tag. For more information, see [CultureInfo.Name](#).

Culture fallback scenarios

Imagine that your localized app supports various Serbian locales, and has the following resource files for its `MessageService`:

[\[+\] Expand table](#)

| File | Regional language | Country Code |
|---|-------------------------------|--------------|
| <code>MessageService.sr-Cyrl-RS.resx</code> | (Cyrillic, Serbia) | RS |
| <code>MessageService.sr-Cyrl.resx</code> | Cyrillic | |
| <code>MessageService.sr-Latn-BA.resx</code> | (Latin, Bosnia & Herzegovina) | BA |
| <code>MessageService.sr-Latn-ME.resx</code> | (Latin, Montenegro) | ME |
| <code>MessageService.sr-Latn-RS.resx</code> | (Latin, Serbia) | RS |
| <code>MessageService.sr-Latn.resx</code> | Latin | |
| <code>MessageService.sr.resx</code> | [†] Latin | |
| <code>MessageService.resx</code> | | |

[†] The default regional language for the language.

When your app is running with the `CultureInfo.CurrentCulture` set to a culture of `"sr-Cyrl-RS"` localization attempts to resolve files in the following order:

1. `MessageService.sr-Cyrl-RS.resx`
2. `MessageService.sr-Cyrl.resx`
3. `MessageService.sr.resx`
4. `MessageService.resx`

However, if your app was running with the `CultureInfo.CurrentCulture` set to a culture of `"sr-Latn-BA"` localization attempts to resolve files in the following order:

1. `MessageService.sr-Latn-BA.resx`
2. `MessageService.sr-Latn.resx`
3. `MessageService.sr.resx`
4. `MessageService.resx`

The "culture fallback" rule will ignore locales when there are no corresponding matches, meaning resource file number four is selected if it's unable to find a match. If the culture was set to `"fr-FR"`, localization would end up falling to the `MessageService.resx` file which can be problematic. For more information, see [The resource fallback process](#).

Resource lookup

Resource files are automatically resolved as part of a lookup routine. If your project file name is different than the root namespace of your project, the assembly name might differ. This can prevent resource lookup from being otherwise successful. To address this mismatch, use the `RootNamespaceAttribute` to provide a hint to the localization services. When provided, it is used during resource lookup.

The example project is named `example.csproj`, which creates an `example.dll` and `example.exe` — however, the `Localization.Example` namespace is used. Apply an `assembly` level attribute to correct this mismatch:

```
C#  
[assembly: RootNamespace("Localization.Example")]
```

Register localization services

To register localization services, call one of the `AddLocalization` extension methods during the configuration of services. This will enable dependency injection (DI) of the following types:

- `Microsoft.Extensions.Localization.IStringLocalizer<T>`
- `Microsoft.Extensions.Localization.IStringLocalizerFactory`

Configure localization options

The `AddLocalization(IServiceCollection, Action<LocalizationOptions>)` overload accepts a `setupAction` parameter of type `Action<LocalizationOptions>`. This allows you to configure localization options.

C#

```
HostApplicationBuilder builder = Host.CreateApplicationBuilder(args);

builder.Services.AddLocalization(options =>
{
    options.ResourcesPath = "Resources";
});

// Omitted for brevity.
```

Resource files can live anywhere in a project, but there are common practices in place that have proven to be successful. More often than not, the path of least resistance is followed. The preceding C# code:

- Creates the default host app builder.
- Calls `AddLocalization` on the service collection, specifying `LocalizationOptions.ResourcesPath` as `"Resources"`.

This would cause the localization services to look in the `Resources` directory for resource files.

Use `IStringLocalizer<T>` and `IStringLocalizerFactory`

After you've [registered](#) (and optionally [configured](#)) the localization services, you can use the following types with DI:

- `IStringLocalizer<T>`
- `IStringLocalizerFactory`

To create a message service that is capable of returning localized strings, consider the following `MessageService`:

C#

```
using System.Diagnostics.CodeAnalysis;
using Microsoft.Extensions.Localization;

namespace Localization.Example;
```

```

public sealed class MessageService(IStringLocalizer<MessageService>
localizer)
{
    [return: NotNullIfNotNull(nameof(localizer))]
    public string? GetGreetingMessage()
    {
        LocalizedString localizedString = localizer["GreetingMessage"];

        return localizedString;
    }
}

```

In the preceding C# code:

- A `IStringLocalizer<MessageService>` `localizer` field is declared.
- The primary constructor defines an `IStringLocalizer<MessageService>` parameter and captures it as a `localizer` argument.
- The `GetGreetingMessage` method invokes the `IStringLocalizer.Item[String]` passing `"GreetingMessage"` as an argument.

The `IStringLocalizer` also supports parameterized string resources, consider the following `ParameterizedMessageService`:

C#

```

using System.Diagnostics.CodeAnalysis;
using Microsoft.Extensions.Localization;

namespace Localization.Example;

public class ParameterizedMessageService(IStringLocalizerFactory factory)
{
    private readonly IStringLocalizer _localizer =
        factory.Create(typeof(ParameterizedMessageService));

    [return: NotNullIfNotNull(nameof(_localizer))]
    public string? GetFormattedMessage(DateTime dateTime, double
dinnerPrice)
    {
        LocalizedString localizedString = _localizer["DinnerPriceFormat",
dateTime, dinnerPrice];

        return localizedString;
    }
}

```

In the preceding C# code:

- A `IStringLocalizer _localizer` field is declared.

- The primary constructor takes an `IStringLocalizerFactory` parameter, which is used to create an `IStringLocalizer` from the `ParameterizedMessageService` type, and assigns it to the `_localizer` field.
- The `GetFormattedMessage` method invokes `IStringLocalizer.Item[String, Object[]]`, passing `"DinnerPriceFormat"`, a `dateTime` object, and `dinnerPrice` as arguments.

ⓘ Important

The `IStringLocalizerFactory` isn't required. Instead, it is preferred for consuming services to require the `IStringLocalizer<T>`.

Both `IStringLocalizer.Item[]` indexers return a `LocalizedString`, which have `implicit conversions` to `string?`.

Put it all together

To exemplify an app using both message services, along with localization and resource files, consider the following `Program.cs` file:

C#

```
using System.Globalization;
using Localization.Example;
using Microsoft.Extensions.DependencyInjection;
using Microsoft.Extensions.Hosting;
using Microsoft.Extensions.Localization;
using Microsoft.Extensions.Logging;
using static System.Console;
using static System.Text.Encoding;

[assembly: RootNamespace("Localization.Example")]

OutputEncoding = Unicode;

if (args is { Length: 1 })
{
    CultureInfo.CurrentCulture =
        CultureInfo.CurrentUICulture =
            CultureInfo.GetCultureInfo(args[0]);
}

HostApplicationBuilder builder = Host.CreateApplicationBuilder(args);

builder.Services.AddLocalization();
builder.Services.AddTransient<MessageService>();
builder.Services.AddTransient<ParameterizedMessageService>();
builder.Logging.SetMinimumLevel(LogLevel.Warning);
```

```

using IHost host = builder.Build();

IServiceProvider services = host.Services;

ILogger logger =
    services.GetRequiredService<ILoggerFactory>()
        .CreateLogger("Localization.Example");

MessageService messageService =
    services.GetRequiredService<MessageService>();
logger.LogWarning(
    "{Msg}",
    messageService.GetGreetingMessage());

ParameterizedMessageService parameterizedMessageService =
    services.GetRequiredService<ParameterizedMessageService>();
logger.LogWarning(
    "{Msg}",
    parameterizedMessageService.GetFormattedMessage(
        DateTime.Today.AddDays(-3), 37.63));

await host.RunAsync();

```

In the preceding C# code:

- The [RootNamespaceAttribute](#) sets "Localization.Example" as the root namespace.
- The [Console.OutputEncoding](#) is assigned to [Encoding.Unicode](#).
- When a single argument is passed to `args`, the [CultureInfo.CurrentCulture](#) and [CultureInfo.CurrentUICulture](#) are assigned the result of [CultureInfo.GetCultureInfo\(String\)](#) given the `arg[0]`.
- The [Host](#) is created with [defaults](#).
- The localization services, `MessageService`, and `ParameterizedMessageService` are registered to the `IServiceCollection` for DI.
- To remove noise, logging is configured to ignore any log level lower than a warning.
- The `MessageService` is resolved from the `IServiceProvider` instance and its resulting message is logged.
- The `ParameterizedMessageService` is resolved from the `IServiceProvider` instance and its resulting formatted message is logged.

Each of the `*MessageService` classes defines a set of `.resx` files, each with a single entry. Here is the example content for the `MessageService` resource files, starting with `MessageService.resx`:

XML

```
<?xml version="1.0" encoding="utf-8"?>
<root>
  <data name="GreetingMessage" xml:space="preserve">
    <value>Hi friends, the ".NET" developer community is excited to see you here!</value>
  </data>
</root>
```

MessageService.sr-Cyrl-RS.resx:

XML

```
<?xml version="1.0" encoding="utf-8"?>
<root>
  <data name="GreetingMessage" xml:space="preserve">
    <value>Здраво пријатељи, ".NET" девелопер заједница је узбуђена што вас види овде!</value>
  </data>
</root>
```

MessageService.sr-Latn.resx:

XML

```
<?xml version="1.0" encoding="utf-8"?>
<root>
  <data name="GreetingMessage" xml:space="preserve">
    <value>Zdravo prijatelji, ".NET" developer zajednica je uzbudena sto vas vidi ovde!</value>
  </data>
</root>
```

Here is the example content for the `ParameterizedMessageService` resource files, starting with `ParameterizedMessageService.resx`:

XML

```
<?xml version="1.0" encoding="utf-8"?>
<root>
  <data name="DinnerPriceFormat" xml:space="preserve">
    <value>On {0:D} my dinner cost {1:C}.</value>
  </data>
</root>
```

ParameterizedMessageService.sr-Cyrl-RS.resx:

XML

```
<?xml version="1.0" encoding="utf-8"?>
<root>
    <data name="DinnerPriceFormat" xml:space="preserve">
        <value>У {0:D} моја вечера је коштала {1:C}.</value>
    </data>
</root>
```

ParameterizedMessageService.sr-Latn.resx:

XML

```
<?xml version="1.0" encoding="utf-8"?>
<root>
    <data name="DinnerPriceFormat" xml:space="preserve">
        <value>U {0:D} moja večera je koštala {1:C}.</value>
    </data>
</root>
```

Tip

All of the resource file XML comments, schema, and `<resheader>` elements are intentionally omitted for brevity.

Example runs

The following example runs show the various localized outputs, given targeted locales.

Consider "sr-Latn":

.NET CLI

```
dotnet run --project .\example\example.csproj sr-Latn

warn: Localization.Example[0]
      Zdravo prijatelji, ".NET" developer zajednica je uzbudena što vas vidi
ovde!
warn: Localization.Example[0]
      U utorak, 03. avgust 2021. moja večera je koštala 37,63 ₾.
```

When omitting an argument to the .NET CLI to run the project, the default system culture is used — in this case "en-US":

.NET CLI

```
dotnet run --project .\example\example.csproj

warn: Localization.Example[0]
      Hi friends, the ".NET" developer community is excited to see you here!
warn: Localization.Example[0]
      On Tuesday, August 3, 2021 my dinner cost $37.63.
```

When passing "sr-Cryl-RS", the correct corresponding resource files are found and the localization applied:

```
.NET CLI

dotnet run --project .\example\example.csproj sr-Cryl-RS

warn: Localization.Example[0]
      Здраво пријатељи, ".NET" девелопер заједница је узбуђена што вас види
овде!
warn: Localization.Example[0]
      У уторак, 03. август 2021. моја вечера је коштала 38 RSD.
```

The sample application does not provide resource files for "fr-CA", but when called with that culture, the non-localized resource files are used.

⚠ Warning

Since the culture is found but the correct resource files are not, when formatting is applied you end up with partial localization:

```
.NET CLI

dotnet run --project .\example\example.csproj fr-CA

warn: Localization.Example[0]
      Hi friends, the ".NET" developer community is excited to see you
here!
warn: Localization.Example[0]
      On mardi 3 août 2021 my dinner cost 37,63 $.
```

CompareInfo class

Article • 12/30/2023

This article provides supplementary remarks to the reference documentation for this API.

Conventions for comparing and sorting data vary from culture to culture. For example, sort order may be based on phonetics or on the visual representation of characters. In East Asian languages, characters are sorted by the stroke and radical of ideographs. Sorting also depends on the order languages and cultures use for the alphabet. For example, the Danish language has an "Æ" character that it sorts after "Z" in the alphabet. In addition, comparisons may be case-sensitive or case-insensitive, and casing rules may also differ by culture. The [CompareInfo](#) class is responsible for maintaining this culture-sensitive string comparison data and for performing culture-sensitive string operations.

Typically, you do not have to instantiate a [CompareInfo](#) object directly, because one is used implicitly by all non-ordinal string comparison operations, including calls to the [String.Compare](#) method. However, if you do want to retrieve a [CompareInfo](#) object, you can do it in one of these ways:

- By retrieving the value of the [CultureInfo.CompareInfo](#) property for a particular culture.
- By calling the static [GetCompareInfo](#) method with a culture name. This allows for late-bound access to a [CompareInfo](#) object.

Ignored search values

Character sets include ignorable characters, which are characters that are not considered when performing a linguistic or culture-sensitive comparison. Comparison methods such as [IndexOf](#) and [LastIndexOf](#) do not consider such characters when they perform a culture-sensitive comparison. Ignorable characters include:

- [String.Empty](#). Culture-sensitive comparison methods will always find an empty string at the beginning (index zero) of the string being searched.
- A character or string consisting of characters with code points that are not considered in the operation because of comparison options. In particular, the [CompareOptions.IgnoreNonSpace](#) and [CompareOptions.IgnoreSymbols](#) options produce searches in which symbols and nonspacing combining characters are ignored.

- A string with code points that have no linguistic significance. For example, a soft hyphen (U+00AD) is always ignored in a culture-sensitive string comparison.

Security considerations

If a security decision depends on a string comparison or a case change, you should use the [InvariantCulture](#) property to ensure that the behavior is consistent, regardless of the culture settings of the operating system.

Note

When possible, you should use string comparison methods that have a parameter of type [CompareOptions](#) to specify the kind of comparison expected. As a general rule, use linguistic options (using the current culture) for comparing strings displayed in the user interface and specify [Ordinal](#) or [OrdinalIgnoreCase](#) for security comparisons.

CompareOptions enum

Article • 12/30/2023

This article provides supplementary remarks to the reference documentation for this API.

The [CompareOptions](#) options denote case sensitivity or necessity to ignore types of characters.

.NET uses three distinct ways of sorting: word sort, string sort, and ordinal sort. Word sort performs a culture-sensitive comparison of strings. Certain nonalphanumeric characters might have special weights assigned to them. For example, the hyphen ("–") might have a very small weight assigned to it so that "coop" and "co-op" appear next to each other in a sorted list. String sort is similar to word sort, except that there are no special cases. Therefore, all nonalphanumeric symbols come before all alphanumeric characters. Ordinal sort compares strings based on the Unicode values of each element of the string. For a downloadable set of text files that contain information on the character weights used in sorting and comparison operations for Windows operating systems, see [Sorting Weight Tables](#). For the sort weight table for Linux and macOS, see the [Default Unicode Collation Element Table](#). The specific version of the sort weight table on Linux and macOS depends on the version of the [International Components for Unicode](#) libraries installed on the system. For information on ICU versions and the Unicode versions that they implement, see [Downloading ICU](#).

The `StringSort` value can only be used with [CompareInfo.Compare](#) and [CompareInfo.GetSortKey](#). [ArgumentException](#) is thrown if the `StringSort` value is used with [CompareInfo.IsPrefix](#), [CompareInfo.IsSuffix](#), [CompareInfo.IndexOf](#), or [CompareInfo.LastIndexOf](#).

ⓘ Note

When possible, you should use string comparison methods that accept a [CompareOptions](#) value to specify the kind of comparison expected. As a general rule, user-facing comparisons are best served by the use of linguistic options (using the current culture), while security comparisons should specify `ordinal` or `OrdinalIgnoreCase`.

Culture-sensitive sorts

Note

.NET Core running on Linux and macOS systems only: The collation behavior for the C and Posix cultures is always case-sensitive because these cultures do not use the expected Unicode collation order. We recommend that you use a culture other than C or Posix for performing culture-sensitive, case-insensitive sorting operations.

CultureAndRegionInfoBuilder class

Article • 01/10/2024

This article provides supplementary remarks to the reference documentation for this API.

ⓘ Note

The [CultureAndRegionInfoBuilder](#) class is useful only for Windows operating systems. The generated *.nlp* files aren't supported on non-Windows operating systems. Also, even on Windows, the generated *.nlp* files are supported only on .NET Framework (or in .NET Core when using [NLS globalization mode](#)).

The [CultureInfo](#) class holds culture-specific information, such as the associated language, sublanguage, country/region, calendar, and cultural conventions. This class also provides culture-specific instances of the [DateTimeFormatInfo](#), [NumberFormatInfo](#), [CompareInfo](#), and [TextInfo](#) classes, which are required for culture-specific operations such as casing, formatting and parsing dates and numbers, and comparing strings.

By default, .NET supports [CultureInfo](#) objects that represent a predefined set of cultures. For a list of these cultures available on Windows systems, see the [Language tag](#) column in the [list of language/region names supported by Windows](#). Culture names follow the standard defined by [BCP 47](#). The [CultureAndRegionInfoBuilder](#) class enables you to create a custom culture that is completely new or that overrides a predefined culture. When a custom culture is installed and registered on a particular computer, it becomes indistinguishable from predefined [CultureInfo](#) objects, and can be instantiated and used just like those objects.

ⓘ Important

The [CultureAndRegionInfoBuilder](#) class is found in an assembly named *sysglobl.dll*. To successfully compile code that uses this type, you must add a reference to *sysglobl.dll*.

A custom culture can be registered on a computer only by a user who has administrative rights on that computer. Consequently, apps typically do not create and install custom cultures. Instead, you can use the [CultureAndRegionInfoBuilder](#) class to create a special-purpose tool that an administrator can use to create, install, and register a custom culture. After the custom culture is registered on a computer, you can use the

`CultureInfo` class in your app to create instances of the custom culture just as you would for a predefined culture.

If you parse date and time strings generated for a custom culture, you should use the `DateTime.ParseExact` or `DateTime.TryParseExact` method instead of the `DateTime.Parse` or `DateTime.TryParse` method to improve the probability that the parse operation will succeed. A date and time string for a custom culture can be complicated and therefore difficult to parse. The `Parse` and `TryParse` methods try to parse a string with several implicit parse patterns, all of which might fail. The `TryParseExact` method, in contrast, requires the application to explicitly designate one or more exact parse patterns that are likely to succeed.

Define and create a custom culture

You use the `CultureAndRegionInfoBuilder` class to define and name a custom culture. The custom culture can be an entirely new culture, a new culture that is based on an existing culture (that is, a supplemental culture), or a culture that replaces an existing .NET culture. In each case, the basic steps are the same:

1. Instantiate a `CultureAndRegionInfoBuilder` object by calling its `CultureAndRegionInfoBuilder(String, CultureAndRegionModifiers)` constructor. To replace an existing culture, pass that culture's name and the `CultureAndRegionModifiers.Replacement` enumeration value to the constructor. To create a new culture or a supplemental culture, pass a unique culture name and either the `CultureAndRegionModifiers.Neutral` or `CultureAndRegionModifiers.None` enumeration value.

Note

If you use the `CultureAndRegionModifiers.Replacement` enumeration value to instantiate a `CultureAndRegionInfoBuilder` object, the `CultureAndRegionInfoBuilder` object's properties are automatically populated with values from the `CultureInfo` object to be replaced.

2. If you're creating a new or supplemental culture:

- Populate the `CultureAndRegionInfoBuilder` object's properties by calling the `LoadDataFromCultureInfo` method and passing a `CultureInfo` object whose property values are similar to your new object.
- Populate the `CultureAndRegionInfoBuilder` object's regional properties by calling the `LoadDataFromRegionInfo` method and passing a `RegionInfo`

object that represents the region of your custom culture.

3. Modify the properties of the [CultureAndRegionInfoBuilder](#) object as necessary.
4. If you are planning to register the custom culture in a separate routine, call the [Save](#) method. This generates an XML file that you can load and register in a separate custom culture installation routine.

Register a custom culture

If you are developing a registration application for a custom culture that is separate from the application that creates the culture, you call the [CreateFromLdml](#) method to load the XML file that contains the custom culture's definition and instantiate the [CultureAndRegionInfoBuilder](#) object. To handle the registration, call the [Register](#) method. For the registration to succeed, the application that registers the custom culture must be running with administrative privileges on the target system; otherwise, the call to [Register](#) throws an [UnauthorizedAccessException](#) exception.

Warning

Culture data can differ between systems. If you're using the [CultureAndRegionInfoBuilder](#) class to create a custom culture that is uniform across multiple systems and you are creating your custom culture by loading data from existing [CultureInfo](#) and [RegionInfo](#) objects and customizing it, you should develop two different utilities. The first creates the custom culture and saves it to an XML file. The second uses the [CreateFromLdml](#) method to load the custom culture from an XML file and register it on the target computer.

The registration process performs the following tasks:

- Creates an *.nlp* file that contains the information that's defined in the [CultureAndRegionInfoBuilder](#) object.
- Stores the *.nlp* file in the %windir%\Globalization system directory on the target computer. This enables the custom culture's settings to persist between sessions. (The [CultureAndRegionInfoBuilder](#) method requires administrative privileges because the *.nlp* file is stored in a system directory.)
- Prepares .NET to search the %windir%\Globalization system directory instead of an internal cache the next time there's a request to create your new custom culture.

When a custom culture is successfully registered, it's indistinguishable from the cultures that are predefined by .NET. The custom culture is available until a call to the

[CultureAndRegionInfoBuilder](#) method removes the *.nlp* file from the local computer.

Instantiate a custom culture

You can create an instance of the custom culture in one of the following ways:

- By invoking the [CultureInfo.CultureInfo](#) constructor with the culture name.
- By calling the [CultureInfo.CreateSpecificCulture](#) method with the culture name.
- By calling the [CultureInfo.GetCultureInfo](#) method with the culture name.

In addition, the array of [CultureInfo](#) objects that is returned by the [CultureInfo.GetCultures](#) method includes the custom culture.

CultureInfo class

Article • 12/30/2023

This article provides supplementary remarks to the reference documentation for this API.

The [CultureInfo](#) class provides culture-specific information, such as the language, sublanguage, country/region, calendar, and conventions associated with a particular culture. This class also provides access to culture-specific instances of the [DateTimeFormatInfo](#), [NumberFormatInfo](#), [CompareInfo](#), and [TextInfo](#) objects. These objects contain the information required for culture-specific operations, such as casing, formatting dates and numbers, and comparing strings. The [CultureInfo](#) class is used either directly or indirectly by classes that format, parse, or manipulate culture-specific data, such as [String](#), [DateTime](#), [DateTimeOffset](#), and the numeric types.

Culture names and identifiers

The [CultureInfo](#) class specifies a unique name for each culture, based on RFC 4646. The name is a combination of an ISO 639 two-letter or three-letter lowercase culture code associated with a language and an ISO 3166 two-letter uppercase subculture code associated with a country or region. In addition, for apps that target .NET Framework 4 or later and are running under Windows 10 or later, culture names that correspond to valid BCP-47 language tags are supported.

ⓘ Note

When a culture name is passed to a class constructor or a method such as [CreateSpecificCulture](#) or [CultureInfo](#), its case is not significant.

The format for the culture name based on RFC 4646 is `Languagecode2 - country/regioncode2`, where `Languagecode2` is the two-letter language code and `country/regioncode2` is the two-letter subculture code. Examples include `ja-JP` for Japanese (Japan) and `en-US` for English (United States). In cases where a two-letter language code is not available, a three-letter code as defined in ISO 639-3 is used.

Some culture names also specify an ISO 15924 script. For example, `Cyr` specifies the Cyrillic script and `Latn` specifies the Latin script. A culture name that includes a script uses the pattern `Languagecode2 - scripttag - country/regioncode2`. An example of this type of culture name is `uz-Cyr1-UZ` for Uzbek (Cyrillic, Uzbekistan). On Windows

operating systems before Windows Vista, a culture name that includes a script uses the pattern `Languagecode2 - country/regioncode2 - scripttag`, for example, `uz-UZ-Cyr1` for Uzbek (Cyrillic, Uzbekistan).

A neutral culture is specified by only the two-letter, lowercase language code. For example, `fr` specifies the neutral culture for French, and `de` specifies the neutral culture for German.

ⓘ Note

There are two culture names that contradict this rule. The cultures Chinese (Simplified), named `zh-Hans`, and Chinese (Traditional), named `zh-Hant`, are neutral cultures. The culture names represent the current standard and should be used unless you have a reason for using the older names `zh-CHS` and `zh-CHT`.

A culture identifier is a standard international numeric abbreviation and has the components necessary to uniquely identify one of the installed cultures. Your application can use predefined culture identifiers or define custom identifiers.

Certain predefined culture names and identifiers are used by this and other classes in the [System.Globalization](#) namespace. For detailed culture information for Windows systems, see the **Language tag** column in the [list of language/region names supported by Windows](#). Culture names follow the standard defined by [BCP 47](#).

The culture names and identifiers represent only a subset of cultures that can be found on a particular computer. Windows versions or service packs can change the available cultures. Applications can add custom cultures using the [CultureAndRegionInfoBuilder](#) class. Users can add their own custom cultures using the [Microsoft Locale Builder](#) tool. Microsoft Locale Builder is written in managed code using the [CultureAndRegionInfoBuilder](#) class.

Several distinct names are closely associated with a culture, notably the names associated with the following class members:

- [CultureInfo.ToString](#)
- [CultureInfo.Name](#)
- [CompareInfo.Name](#)

Invariant, neutral, and specific cultures

The cultures are generally grouped into three sets: invariant cultures, neutral cultures, and specific cultures.

An invariant culture is culture-insensitive. Your application specifies the invariant culture by name using an empty string ("") or by its identifier. [InvariantCulture](#) defines an instance of the invariant culture. It is associated with the English language but not with any country/region. It is used in almost any method in the [Globalization](#) namespace that requires a culture.

A neutral culture is a culture that is associated with a language but not with a country/region. A specific culture is a culture that is associated with a language and a country/region. For example, `fr` is the neutral name for the French culture, and `fr-FR` is the name of the specific French (France) culture. Note that Chinese (Simplified) and Chinese (Traditional) are also considered neutral cultures.

Creating an instance of a [CompareInfo](#) class for a neutral culture is not recommended because the data it contains is arbitrary. To display and sort data, specify both the language and region. Additionally, the [Name](#) property of a [CompareInfo](#) object created for a neutral culture returns only the country and does not include the region.

The defined cultures have a hierarchy in which the parent of a specific culture is a neutral culture and the parent of a neutral culture is the invariant culture. The [Parent](#) property contains the neutral culture associated with a specific culture. Custom cultures should define the [Parent](#) property in conformance with this pattern.

If the resources for a specific culture are not available in the operating system, the resources for the associated neutral culture are used. If the resources for the neutral culture are not available, the resources embedded in the main assembly are used. For more information on the resource fallback process, see [Packaging and Deploying Resources](#).

The list of locales in the Windows API is slightly different from the list of cultures supported by .NET. If interoperability with Windows is required, for example, through the p/invoke mechanism, the application should use a specific culture that's defined for the operating system. Use of the specific culture ensures consistency with the equivalent Windows locale, which is identified with a locale identifier that is the same as [LCID](#).

A [DateTimeFormatInfo](#) or a [NumberFormatInfo](#) can be created only for the invariant culture or for specific cultures, not for neutral cultures.

If [DateTimeFormatInfo.Calendar](#) is the [TaiwanCalendar](#) but the [Thread.CurrentCulture](#) is not set to `zh-TW`, then [DateTimeFormatInfo.NativeCalendarName](#),

`DateTimeFormatInfo.GetEraName`, and `DateTimeFormatInfo.GetAbbreviatedEraName` return an empty string ("").

Custom cultures

On Windows, you can create custom locales. For more information, see [Custom locales](#).

CultureInfo and cultural data

.NET derives its cultural data from one of a variety of sources, depending on implementation, platform, and version:

- In all versions of .NET (Core) running on Unix platforms or Windows 10 and later versions, cultural data is provided by the [International Components for Unicode \(ICU\) Library](#). The specific version of the ICU Library depends on the individual operating system.
- In all versions of .NET (Core) running on Windows 9 and earlier versions, cultural data is provided by the Windows operating system.
- In .NET Framework 4 and later versions, cultural data is provided by the Windows operating system.
- In .NET Framework 3.5 and earlier versions, cultural data is provided by both the Windows operating system and .NET Framework.

Because of this, a culture available on a particular .NET implementation, platform, or version may not be available on a different .NET implementation, platform, or version.

Some `CultureInfo` objects differ depending on the underlying platform. In particular, `zh-CN`, or Chinese (Simplified, China) and `zh-TW`, or Chinese (Traditional, Taiwan), are available cultures on Windows systems, but they are aliased cultures on Unix systems. "zh-CN" is an alias for the "zh-Hans-CN" culture, and "zh-TW" is an alias for the "zh-Hant-TW" culture. Aliased cultures are not returned by calls to the `GetCultures` method and may have different property values, including different `Parent` cultures, than their Windows counterparts. For the `zh-CN` and `zh-TW` cultures, these differences include the following:

- On Windows systems, the parent culture of the "zh-CN" culture is "zh-Hans", and the parent culture of the "zh-TW" culture is "zh-Hant". The parent culture of both these cultures is "zh". On Unix systems, the parents of both cultures are "zh". This means that, if you don't provide culture-specific resources for the "zh-CN" or "zh-TW" cultures but do provide resources for the neutral "zh-Hans" or "zh-Hant" culture, your application will load the resources for the neutral culture on Windows

but not on Unix. On Unix systems, you must explicitly set the thread's [CurrentUICulture](#) to either "zh-Hans" or "zh-Hant".

- On Windows systems, calling [CultureInfo.Equals](#) on an instance that represents the "zh-CN" culture and passing it a "zh-Hans-CN" instance returns `true`. On Unix systems, the method call returns `false`. This behavior also applies to calling [Equals](#) on a "zh-TW" [CultureInfo](#) instance and passing it a "zh-Hant-Tw" instance.

Dynamic culture data

Except for the invariant culture, culture data is dynamic. This is true even for the predefined cultures. For example, countries or regions adopt new currencies, change their spellings of words, or change their preferred calendar, and culture definitions change to track this. Custom cultures are subject to change without notice, and any specific culture might be overridden by a custom replacement culture. Also, as discussed below, an individual user can override cultural preferences. Applications should always obtain culture data at run time.

⊗ Caution

When saving data, your application should use the invariant culture, a binary format, or a specific culture-independent format. Data saved according to the current values associated with a particular culture, other than the invariant culture, might become unreadable or might change in meaning if that culture changes.

The current culture and current UI culture

Every thread in a .NET application has a current culture and a current UI culture. The current culture determines the formatting conventions for dates, times, numbers, and currency values, the sort order of text, casing conventions, and the ways in which strings are compared. The current UI culture is used to retrieve culture-specific resources at run time.

ⓘ Note

For information on how the current and current UI culture is determined on a per-thread basis, see the [Culture and threads](#) section. For information on how the current and current UI culture is determined on threads executing in a new application domain, and on threads that cross application domain boundaries, see the [Culture and application domains](#) section. For information on how the current

and current UI culture is determined on threads performing task-based asynchronous operations, see the [Culture and task-based asynchronous operations](#) section.

For more detailed information on the current culture, see the [CultureInfo.CurrentCulture](#) property. For more detailed information on the current UI culture, see the [CultureInfo.CurrentUICulture](#) property topic.

Retrieve the current and current UI cultures

You can get a [CultureInfo](#) object that represents the current culture in either of two ways:

- By retrieving the value of the [CultureInfo.CurrentCulture](#) property.
- By retrieving the value of the [Thread.CurrentThread.CurrentCulture](#) property.

The following example retrieves both property values, compares them to show that they are equal, and displays the name of the current culture.

C#

```
using System;
using System.Globalization;
using System.Threading;

public class CurrentCultureEx
{
    public static void Main()
    {
        CultureInfo culture1 = CultureInfo.CurrentCulture;
        CultureInfo culture2 = Thread.CurrentThread.CurrentCulture;
        Console.WriteLine("The current culture is {0}", culture1.Name);
        Console.WriteLine("The two CultureInfo objects are equal: {0}",
                          culture1 == culture2);
    }
}

// The example displays output like the following:
//      The current culture is en-US
//      The two CultureInfo objects are equal: True
```

You can get a [CultureInfo](#) object that represents the current UI culture in either of two ways:

- By retrieving the value of the [CultureInfo.CurrentUICulture](#) property.
- By retrieving the value of the [Thread.CurrentThread.CurrentUICulture](#) property.

The following example retrieves both property values, compares them to show that they are equal, and displays the name of the current UI culture.

```
C#  
  
using System;  
using System.Globalization;  
using System.Threading;  
  
public class CurrentUIEx  
{  
    public static void Main()  
    {  
        CultureInfo uiCulture1 = CultureInfo.CurrentCulture;  
        CultureInfo uiCulture2 = Thread.CurrentThread.CurrentCulture;  
        Console.WriteLine("The current UI culture is {0}", uiCulture1.Name);  
        Console.WriteLine("The two CultureInfo objects are equal: {0}",  
                          uiCulture1 == uiCulture2);  
    }  
}  
// The example displays output like the following:  
//     The current UI culture is en-US  
//     The two CultureInfo objects are equal: True
```

Set the current and current UI cultures

To change the culture and UI culture of a thread, do the following:

1. Instantiate a [CultureInfo](#) object that represents that culture by calling a [CultureInfo](#) class constructor and passing it the name of the culture. The [CultureInfo\(String\)](#) constructor instantiates a [CultureInfo](#) object that reflects user overrides if the new culture is the same as the current Windows culture. The [CultureInfo\(String, Boolean\)](#) constructor allows you to specify whether the newly instantiated [CultureInfo](#) object reflects user overrides if the new culture is the same as the current Windows culture.
2. Assign the [CultureInfo](#) object to the [CultureInfo.CurrentCulture](#) or [CultureInfo.CurrentUICulture](#) property on .NET Core and .NET Framework 4.6 and later versions. (On .NET Framework 4.5.2 and earlier versions, you can assign the [CultureInfo](#) object to the [Thread.CurrentCulture](#) or [Thread.CurrentUICulture](#) property.)

The following example retrieves the current culture. If it is anything other than the French (France) culture, it changes the current culture to French (France). Otherwise, it changes the current culture to French (Luxembourg).

C#

```
using System;
using System.Globalization;

public class ChangeEx1
{
    public static void Main()
    {
        CultureInfo current = CultureInfo.CurrentCulture;
        Console.WriteLine("The current culture is {0}", current.Name);
        CultureInfo newCulture;
        if (current.Name.Equals("fr-FR"))
            newCulture = new CultureInfo("fr-LU");
        else
            newCulture = new CultureInfo("fr-FR");

        CultureInfo.CurrentCulture = newCulture;
        Console.WriteLine("The current culture is now {0}",
                          CultureInfo.CurrentCulture.Name);
    }
}

// The example displays output like the following:
//      The current culture is en-US
//      The current culture is now fr-FR
```

The following example retrieves the current culture. If it is anything other the Slovenian (Slovenia) culture, it changes the current culture to Slovenian (Slovenia). Otherwise, it changes the current culture to Croatian (Croatia).

C#

```
using System;
using System.Globalization;

public class ChangeUICultureEx
{
    public static void Main()
    {
        CultureInfo current = CultureInfo.CurrentCulture;
        Console.WriteLine("The current UI culture is {0}", current.Name);
        CultureInfo newUICulture;
        if (current.Name.Equals("sl-SI"))
            newUICulture = new CultureInfo("hr-HR");
        else
            newUICulture = new CultureInfo("sl-SI");

        CultureInfo.CurrentCulture = newUICulture;
        Console.WriteLine("The current UI culture is now {0}",
                          CultureInfo.CurrentCulture.Name);
    }
}
```

```
// The example displays output like the following:  
//      The current UI culture is en-US  
//      The current UI culture is now sl-SI
```

Get all cultures

You can retrieve an array of specific categories of cultures or of all the cultures available on the local computer by calling the [GetCultures](#) method. For example, you can retrieve custom cultures, specific cultures, or neutral cultures either alone or in combination.

The following example calls the [GetCultures](#) method twice, first with the [System.Globalization.CultureTypes](#) enumeration member to retrieve all custom cultures, and then with the [System.Globalization.CultureTypes](#) enumeration member to retrieve all replacement cultures.

C#

```
using System;  
using System.Globalization;  
  
public class GetCulturesEx  
{  
    public static void Main()  
    {  
        // Get all custom cultures.  
        CultureInfo[] custom =  
CultureInfo.GetCultures(CultureTypes.UserCustomCulture);  
        if (custom.Length == 0)  
        {  
            Console.WriteLine("There are no user-defined custom cultures.");  
        }  
        else  
        {  
            Console.WriteLine("Custom cultures:");  
            foreach (var culture in custom)  
                Console.WriteLine("    {0} -- {1}", culture.Name,  
culture.DisplayName);  
        }  
        Console.WriteLine();  
  
        // Get all replacement cultures.  
        CultureInfo[] replacements =  
CultureInfo.GetCultures(CultureTypes.ReplacementCultures);  
        if (replacements.Length == 0)  
        {  
            Console.WriteLine("There are no replacement cultures.");  
        }  
        else  
        {  
            Console.WriteLine("Replacement cultures:");  
        }  
    }  
}
```

```

        foreach (var culture in replacements)
            Console.WriteLine("  {0} -- {1}", culture.Name,
culture.DisplayName);
    }
    Console.WriteLine();
}
// The example displays output like the following:
//   Custom cultures:
//     x-en-US-sample -- English (United States)
//     fj-FJ -- Boumaa Fijian (Viti)
//
// There are no replacement cultures.

```

Culture and threads

When a new application thread is started, its current culture and current UI culture are defined by the current system culture, and not by the current thread culture. The following example illustrates the difference. It sets the current culture and current UI culture of an application thread to the French (France) culture (fr-FR). If the current culture is already fr-FR, the example sets it to the English (United States) culture (en-US). It displays three random numbers as currency values and then creates a new thread, which, in turn, displays three more random numbers as currency values. But as the output from the example shows, the currency values displayed by the new thread do not reflect the formatting conventions of the French (France) culture, unlike the output from the main application thread.

C#

```

using System;
using System.Globalization;
using System.Threading;

public class DefaultThreadEx
{
    static Random rnd = new Random();

    public static void Main()
    {
        if (Thread.CurrentThread.CurrentCulture.Name != "fr-FR")
        {
            // If current culture is not fr-FR, set culture to fr-FR.
            Thread.CurrentThread.CurrentCulture =
CultureInfo.CreateSpecificCulture("fr-FR");
            Thread.CurrentThread.CurrentUICulture =
CultureInfo.CreateSpecificCulture("fr-FR");
        }
        else

```

```

    {
        // Set culture to en-US.
        Thread.CurrentThread.CurrentCulture =
CultureInfo.CreateSpecificCulture("en-US");
        Thread.CurrentThread.CurrentUICulture =
CultureInfo.CreateSpecificCulture("en-US");
    }
    ThreadProc();

    Thread worker = new Thread(ThreadProc);
    worker.Name = "WorkerThread";
    worker.Start();
}

private static void DisplayThreadInfo()
{
    Console.WriteLine("\nCurrent Thread Name: '{0}'",
                      Thread.CurrentThread.Name);
    Console.WriteLine("Current Thread Culture/UI Culture: {0}/{1}",
                      Thread.CurrentThread.CurrentCulture.Name,
                      Thread.CurrentThread.CurrentUICulture.Name);
}

private static void DisplayValues()
{
    // Create new thread and display three random numbers.
    Console.WriteLine("Some currency values:");
    for (int ctr = 0; ctr <= 3; ctr++)
        Console.WriteLine("    {0:C2}", rnd.NextDouble() * 10);
}

private static void ThreadProc()
{
    DisplayThreadInfo();
    DisplayValues();
}
}

// The example displays output similar to the following:
//      Current Thread Name: ''
//      Current Thread Culture/UI Culture: fr-FR/fr-FR
//      Some currency values:
//          8,11 €
//          1,48 €
//          8,99 €
//          9,04 €
//
//      Current Thread Name: 'WorkerThread'
//      Current Thread Culture/UI Culture: en-US/en-US
//      Some currency values:
//          $6.72
//          $6.35
//          $2.90
//          $7.72

```

You can set the culture and UI culture of all threads in an application domain by assigning a [CultureInfo](#) object that represents that culture to the [DefaultThreadCurrentCulture](#) and [DefaultThreadCurrentUICulture](#) properties. The following example uses these properties to ensure that all threads in the default application domain share the same culture.

C#

```
using System;
using System.Globalization;
using System.Threading;

public class SetThreadsEx
{
    static Random rnd = new Random();

    public static void Main()
    {
        if (Thread.CurrentThread.CurrentCulture.Name != "fr-FR")
        {
            // If current culture is not fr-FR, set culture to fr-FR.
            CultureInfo.DefaultThreadCurrentCulture =
CultureInfo.CreateSpecificCulture("fr-FR");
            CultureInfo.DefaultThreadCurrentUICulture =
CultureInfo.CreateSpecificCulture("fr-FR");
        }
        else
        {
            // Set culture to en-US.
            CultureInfo.DefaultThreadCurrentCulture =
CultureInfo.CreateSpecificCulture("en-US");
            CultureInfo.DefaultThreadCurrentUICulture =
CultureInfo.CreateSpecificCulture("en-US");
        }
        ThreadProc();
    }

    Thread worker = new Thread(SetThreadsEx.ThreadProc);
    worker.Name = "WorkerThread";
    worker.Start();
}

private static void DisplayThreadInfo()
{
    Console.WriteLine("\nCurrent Thread Name: '{0}'",
                    Thread.CurrentThread.Name);
    Console.WriteLine("Current Thread Culture/UI Culture: {0}/{1}",
                    Thread.CurrentThread.CurrentCulture.Name,
                    Thread.CurrentThread.CurrentUICulture.Name);
}

private static void DisplayValues()
{
    // Create new thread and display three random numbers.
}
```

```

        Console.WriteLine("Some currency values:");
        for (int ctr = 0; ctr <= 3; ctr++)
            Console.WriteLine("    {0:C2}", rnd.NextDouble() * 10);
    }

    private static void ThreadProc()
    {
        DisplayThreadInfo();
        DisplayValues();
    }
}

// The example displays output similar to the following:
//      Current Thread Name: ''
//      Current Thread Culture/UI Culture: fr-FR/fr-FR
//      Some currency values:
//          6,83 €
//          3,47 €
//          6,07 €
//          1,70 €
//
//      Current Thread Name: 'WorkerThread'
//      Current Thread Culture/UI Culture: fr-FR/fr-FR
//      Some currency values:
//          9,54 €
//          9,50 €
//          0,58 €
//          6,91 €

```

Warning

Although the [DefaultThreadCurrentCulture](#) and [DefaultThreadCurrentUICulture](#) properties are static members, they define the default culture and default UI culture only for the application domain that is current at the time these property values are set. For more information, see the next section, [Culture and application domains](#).

When you assign values to the [DefaultThreadCurrentCulture](#) and [DefaultThreadCurrentUICulture](#) properties, the culture and UI culture of the threads in the application domain also change if they have not explicitly been assigned a culture. However, these threads reflect the new culture settings only while they execute in the current application domain. If these threads execute in another application domain, their culture becomes the default culture defined for that application domain. As a result, we recommend that you always set the culture of the main application thread, and not rely on the [DefaultThreadCurrentCulture](#) and [DefaultThreadCurrentUICulture](#) properties to change it.

Culture and application domains

`DefaultThreadCurrentCulture` and `DefaultThreadCurrentUICulture` are static properties that explicitly define a default culture only for the application domain that is current when the property value is set or retrieved. The following example sets the default culture and default UI culture in the default application domain to French (France), and then uses the `AppDomainSetup` class and the `AppDomainInitializer` delegate to set the default culture and UI culture in a new application domain to Russian (Russia). A single thread then executes two methods in each application domain. Note that the thread's culture and UI culture are not explicitly set; they are derived from the default culture and UI culture of the application domain in which the thread is executing. Note also that the `DefaultThreadCurrentCulture` and `DefaultThreadCurrentUICulture` properties return the default `CultureInfo` values of the application domain that is current when the method call is made.

C#

```
using System;
using System.Globalization;

public class Example
{
    public static void Main()
    {
        // Set the default culture and display the current date in the
        current application domain.
        Info info1 = new Info();
        SetAppDomainCultures("fr-FR");

        // Create a second application domain.
        AppDomainSetup setup = new AppDomainSetup();
        setup.AppDomainInitializer = SetAppDomainCultures;
        setup.AppDomainInitializerArguments = new string[] { "ru-RU" };
        AppDomain domain = AppDomain.CreateDomain("Domain2", null, setup);
        // Create an Info object in the new application domain.
        Info info2 =
(Info)domain.CreateInstanceAndUnwrap(typeof(Example).Assembly.FullName,
                                         "Info");

        // Execute methods in the two application domains.
        info2.DisplayDate();
        info2.DisplayCultures();

        info1.DisplayDate();
        info1.DisplayCultures();
    }

    public static void SetAppDomainCultures(string[] names)
    {
        SetAppDomainCultures(names[0]);
    }
}
```

```

public static void SetAppDomainCultures(string name)
{
    try
    {
        CultureInfo.DefaultThreadCurrentCulture =
CultureInfo.CreateSpecificCulture(name);
        CultureInfo.DefaultThreadCurrentUICulture =
CultureInfo.CreateSpecificCulture(name);
    }
    // If an exception occurs, we'll just fall back to the system
default.
    catch (CultureNotFoundException)
    {
        return;
    }
    catch (ArgumentException)
    {
        return;
    }
}
}

public class Info : MarshalByRefObject
{
    public void DisplayDate()
    {
        Console.WriteLine("Today is {0:D}", DateTime.Now);
    }

    public void DisplayCultures()
    {
        Console.WriteLine("Application domain is {0}",
AppDomain.CurrentDomain.Id);
        Console.WriteLine("Default Culture: {0}",
CultureInfo.DefaultThreadCurrentCulture);
        Console.WriteLine("Default UI Culture: {0}",
CultureInfo.DefaultThreadCurrentUICulture);
    }
}
// The example displays the following output:
//      Today is 14 октября 2011 г.
//      Application domain is 2
//      Default Culture: ru-RU
//      Default UI Culture: ru-RU
//      Today is vendredi 14 octobre 2011
//      Application domain is 1
//      Default Culture: fr-FR
//      Default UI Culture: fr-FR

```

For more information about cultures and application domains, see the "Application Domains and Threads" section in the [Application Domains](#) topic.

Culture and task-based asynchronous operations

The [task-based asynchronous programming pattern](#) uses `Task` and `Task<TResult>` objects to asynchronously execute delegates on thread pool threads. The specific thread on which a particular task runs is not known in advance, but is determined only at runtime.

For apps that target .NET Framework 4.6 or a later version, culture is part of an asynchronous operation's context. In other words, asynchronous operations by default inherit the values of the `CurrentCulture` and `CurrentUICulture` properties of the thread from which they are launched. If the current culture or current UI culture differs from the system culture, the current culture crosses thread boundaries and becomes the current culture of the thread pool thread that is executing an asynchronous operation.

The following example provides a simple illustration. The example defines a `Func<TResult>` delegate, `formatDelegate`, that returns some numbers formatted as currency values. The example changes the current system culture to either French (France) or, if French (France) is already the current culture, English (United States). It then:

- Invokes the delegate directly so that it runs synchronously on the main app thread.
- Creates a task that executes the delegate asynchronously on a thread pool thread.
- Creates a task that executes the delegate synchronously on the main app thread by calling the `Task.RunSynchronously` method.

As the output from the example shows, when the current culture is changed to French (France), the current culture of the thread from which tasks are invoked asynchronously becomes the current culture for that asynchronous operation.

C#

```
using System;
using System.Globalization;
using System.Threading;
using System.Threading.Tasks;

public class AsyncCultureEx1
{
    public static void Main()
    {
        decimal[] values = { 163025412.32m, 18905365.59m };
        string formatString = "C2";

        string FormatDelegate()
```

```

    {
        string output = $"Formatting using the
{CultureInfo.CurrentCulture.Name} " +
            "culture on thread {Thread.CurrentThread.ManagedThreadId}.\n";
        foreach (decimal value in values)
            output += $"{value.ToString(formatString)}    ";

        output += Environment.NewLine;
        return output;
    }

    Console.WriteLine($"The example is running on thread
{Thread.CurrentThread.ManagedThreadId}");
    // Make the current culture different from the system culture.
    Console.WriteLine($"The current culture is
{CultureInfo.CurrentCulture.Name}");
    if (CultureInfo.CurrentCulture.Name == "fr-FR")
        Thread.CurrentThread.CurrentCulture = new CultureInfo("en-US");
    else
        Thread.CurrentThread.CurrentCulture = new CultureInfo("fr-FR");

    Console.WriteLine($"Changed the current culture to
{CultureInfo.CurrentCulture.Name}.\n");

    // Execute the delegate synchronously.
    Console.WriteLine("Executing the delegate synchronously:");
    Console.WriteLine(FormatDelegate());

    // Call an async delegate to format the values using one format
string.
    Console.WriteLine("Executing a task asynchronously:");
    var t1 = Task.Run(FormatDelegate);
    Console.WriteLine(t1.Result);

    Console.WriteLine("Executing a task synchronously:");
    var t2 = new Task<string>(FormatDelegate);
    t2.RunSynchronously();
    Console.WriteLine(t2.Result);
}
}

// The example displays the following output:
//      The example is running on thread 1
//      The current culture is en-US
//      Changed the current culture to fr-FR.

//
//      Executing the delegate synchronously:
//      Formatting using the fr-FR culture on thread 1.
//      163 025 412,32 €  18 905 365,59 €

//
//      Executing a task asynchronously:
//      Formatting using the fr-FR culture on thread 3.
//      163 025 412,32 €  18 905 365,59 €

//
//      Executing a task synchronously:

```

```
//      Formatting using the fr-FR culture on thread 1.  
//      163 025 412,32 €    18 905 365,59 €
```

For apps that target versions of .NET Framework from .NET Framework 4.5 and later but prior to .NET Framework 4.6, you can use the [DefaultThreadCurrentCulture](#) and [DefaultThreadCurrentUICulture](#) properties to ensure that the culture of the calling thread is used in asynchronous tasks that execute on thread pool threads. The following example is identical to the previous example, except that it uses the [DefaultThreadCurrentCulture](#) property to ensure that thread pool threads have the same culture as the main app thread.

C#

```
using System;  
using System.Globalization;  
using System.Threading;  
using System.Threading.Tasks;  
  
public class AsyncCultureEx3  
{  
    public static void Main()  
    {  
        decimal[] values = { 163025412.32m, 18905365.59m };  
        string formatString = "C2";  
        Func<String> formatDelegate = () =>  
        {  
            string output = String.Format("Formatting using the {0} culture  
on thread {1}.\n",  
                CultureInfo.CurrentCulture.Name,  
                Thread.CurrentThread.ManagedThreadId);  
            foreach (var value in values)  
                output += String.Format("{0}    ",  
                    value.ToString(formatString));  
  
            output += Environment.NewLine;  
            return output;  
        };  
  
        Console.WriteLine("The example is running on thread {0}",  
            Thread.CurrentThread.ManagedThreadId);  
        // Make the current culture different from the system culture.  
        Console.WriteLine("The current culture is {0}",  
            CultureInfo.CurrentCulture.Name);  
        if (CultureInfo.CurrentCulture.Name == "fr-FR")  
            Thread.CurrentThread.CurrentCulture = new CultureInfo("en-US");  
        else  
            Thread.CurrentThread.CurrentCulture = new CultureInfo("fr-FR");  
  
        Console.WriteLine("Changed the current culture to {0}.\n",
```

```

        CultureInfo.CurrentCulture.Name);
CultureInfo.DefaultThreadCurrentCulture =
CultureInfo.CurrentCulture;

    // Execute the delegate synchronously.
Console.WriteLine("Executing the delegate synchronously:");
Console.WriteLine(formatDelegate());

    // Call an async delegate to format the values using one format
string.
Console.WriteLine("Executing a task asynchronously:");
var t1 = Task.Run(formatDelegate);
Console.WriteLine(t1.Result);

Console.WriteLine("Executing a task synchronously:");
var t2 = new Task<String>(formatDelegate);
t2.RunSynchronously();
Console.WriteLine(t2.Result);
}

}

// The example displays the following output:
//   The example is running on thread 1
//   The current culture is en-US
//   Changed the current culture to fr-FR.
//
//   Executing the delegate synchronously:
//   Formatting using the fr-FR culture on thread 1.
//   163 025 412,32 €   18 905 365,59 €

//
//   Executing a task asynchronously:
//   Formatting using the fr-FR culture on thread 3.
//   163 025 412,32 €   18 905 365,59 €

//
//   Executing a task synchronously:
//   Formatting using the fr-FR culture on thread 1.
//   163 025 412,32 €   18 905 365,59 €

```

`DefaultThreadCurrentCulture` and `DefaultThreadCurrentUICulture` are per-app domain properties; that is, they establish a default culture for all threads not explicitly assigned a culture in a specific application domain. However, for apps that target .NET Framework 4.6 or later, the culture of the calling thread remains part of an asynchronous task's context even if the task crosses app domain boundaries.

CultureInfo object serialization

When a `CultureInfo` object is serialized, all that is actually stored is `Name` and `UseUserOverride`. It is successfully deserialized only in an environment where that `Name` has the same meaning. The following three examples show why this is not always the case:

- If the `CultureTypes` property value is `CultureTypes.InstalledWin32Cultures`, and if that culture was first introduced in a particular version of the Windows operating system, it is not possible to deserialize it on an earlier version of Windows. For example, if a culture was introduced in Windows 10, it cannot be deserialized on Windows 8.
- If the `CultureTypes` value is `CultureTypes.UserCustomCulture`, and the computer on which it is serialized does not have this user custom culture installed, it is not possible to deserialize it.
- If the `CultureTypes` value is `CultureTypes.ReplacementCultures`, and the computer on which it is serialized does not have this replacement culture, it serializes to the same name, but not all of the same characteristics. For example, if `en-US` is a replacement culture on computer A, but not on computer B, and if a `CultureInfo` object referring to this culture is serialized on computer A and serialized on computer B, then none of the custom characteristics of the culture are transmitted. The culture serializes successfully, but with a different meaning.

Control Panel overrides

The user might choose to override some of the values associated with the current culture of Windows through the regional and language options portion of Control Panel. For example, the user might choose to display the date in a different format or to use a currency other than the default for the culture. In general, your applications should honor these user overrides.

If `UseUserOverride` is `true` and the specified culture matches the current culture of Windows, the `CultureInfo` uses those overrides, including user settings for the properties of the `DateTimeFormatInfo` instance returned by the `DateTimeFormat` property, and the properties of the `NumberFormatInfo` instance returned by the `NumberFormat` property. If the user settings are incompatible with the culture associated with the `CultureInfo`, for example, if the selected calendar is not one of the `OptionalCalendars`, the results of the methods and the values of the properties are undefined.

Alternate sort orders

Some cultures support more than one sort order. For example:

- The Spanish (Spain) culture has two sort orders: the default international sort order, and the traditional sort order. When you instantiate a `CultureInfo` object with the `es-ES` culture name, the international sort order is used. When you

instantiate a [CultureInfo](#) object with the `es-ES-tradnl` culture name, the traditional sort order is used.

- The `zh-CN` (Chinese (Simplified, PRC)) culture supports two sort orders: by pronunciation (the default) and by stroke count. When you instantiate a [CultureInfo](#) object with the `zh-CN` culture name, the default sort order is used. When you instantiate a [CultureInfo](#) object with a local identifier of `0x00020804`, strings are sorted by stroke count.

The following table lists the cultures that support alternate sort orders and the identifiers for the default and alternate sort orders.

[\[+\] Expand table](#)

| Culture name | Culture | Default sort name and identifier | Alternate sort name and identifier |
|--------------|-------------------------|---|---|
| es-ES | Spanish (Spain) | International: <code>0x00000C0A</code> | Traditional: <code>0x0000040A</code> |
| zh-TW | Chinese (Taiwan) | Stroke Count: <code>0x00000404</code> | Bopomofo: <code>0x00030404</code> |
| zh-CN | Chinese (PRC) | Pronunciation: <code>0x00000804</code> | Stroke Count: <code>0x00020804</code> |
| zh-HK | Chinese (Hong Kong SAR) | Stroke Count: <code>0x00000c04</code> | Stroke Count: <code>0x00020c04</code> |
| zh-SG | Chinese (Singapore) | Pronunciation: <code>0x00001004</code> | Stroke Count: <code>0x00021004</code> |
| zh-MO | Chinese (Macao SAR) | Pronunciation: <code>0x00001404</code> | Stroke Count: <code>0x00021404</code> |
| ja-JP | Japanese (Japan) | Default: <code>0x00000411</code> | Unicode: <code>0x00010411</code> |
| ko-KR | Korean (Korea) | Default: <code>0x00000412</code> | Korean Xwansung - Unicode: <code>0x00010412</code> |
| de-DE | German (Germany) | Dictionary: <code>0x00000407</code> | Phone Book Sort DIN: <code>0x00010407</code> |
| hu-HU | Hungarian (Hungary) | Default: <code>0x0000040e</code> | Technical Sort: <code>0x0001040e</code> |
| ka-GE | Georgian (Georgia) | Traditional: <code>0x00000437</code> | Modern Sort: <code>0x00010437</code> |

The current culture and UWP apps

In Universal Windows Platform (UWP) apps, the [CurrentCulture](#) and [CurrentUICulture](#) properties are read-write, just as they are in .NET Framework and .NET Core apps. However, UWP apps recognize a single culture. The [CurrentCulture](#) and [CurrentUICulture](#) properties map to the first value in the [Windows.ApplicationModel.Resources.Core.ResourceManager.DefaultContext.Languages](#) collection.

In .NET apps, the current culture is a per-thread setting, and the [CurrentCulture](#) and [CurrentUICulture](#) properties reflect the culture and UI culture of the current thread only.

In UWP apps, the current culture maps to the [Windows.ApplicationModel.Resources.Core.ResourceManager.DefaultContext.Languages](#) collection, which is a global setting. Setting the [CurrentCulture](#) or [CurrentUICulture](#) property changes the culture of the entire app; culture cannot be set on a per-thread basis.

DateTimeFormatInfo class

Article • 12/30/2023

This article provides supplementary remarks to the reference documentation for this API.

The properties of the [DateTimeFormatInfo](#) class contain culture-specific information for formatting or parsing date and time values such as the following:

- The patterns used to format date values.
- The patterns used to format time values.
- The names of the days of the week.
- The names of the months of the year.
- The A.M. and P.M. designators used in time values.
- The calendar in which dates are expressed.

Instantiate a DateTimeFormatInfo object

A [DateTimeFormatInfo](#) object can represent the formatting conventions of the invariant culture, a specific culture, a neutral culture, or the current culture. This section discusses how to instantiate each type of [DateTimeFormatInfo](#) object.

Instantiate a DateTimeFormatInfo object for the invariant culture

The invariant culture represents a culture that is culture-insensitive. It is based on the English language, but not on any specific English-speaking country/region. Although the data of specific cultures can be dynamic and can change to reflect new cultural conventions or user preferences, the data of the invariant culture does not change. You can instantiate a [DateTimeFormatInfo](#) object that represents the formatting conventions of the invariant culture in the following ways:

- By retrieving the value of the [InvariantInfo](#) property. The returned [DateTimeFormatInfo](#) object is read-only.
- By calling the parameterless [DateTimeFormatInfo](#) constructor. The returned [DateTimeFormatInfo](#) object is read/write.
- By retrieving the value of the [DateTimeFormat](#) property from the [CultureInfo](#) object that is returned by the [CultureInfo.InvariantCulture](#) property. The returned [DateTimeFormatInfo](#) object is read-only.

The following example uses each of these methods to instantiate a [DateTimeFormatInfo](#) object that represents the invariant culture. It then indicates whether the object is read-only.

C#

```
System.Globalization.DateTimeFormatInfo dtfi;

dtfi = System.Globalization.DateTimeFormatInfo.InvariantInfo;
Console.WriteLine(dtfi.IsReadOnly);

dtfi = new System.Globalization.DateTimeFormatInfo();
Console.WriteLine(dtfi.IsReadOnly);

dtfi = System.Globalization.CultureInfo.InvariantCulture.DateTimeFormat;
Console.WriteLine(dtfi.IsReadOnly);
// The example displays the following output:
//      True
//      False
//      True
```

Instantiate a [DateTimeFormatInfo](#) object for a specific culture

A specific culture represents a language that is spoken in a particular country/region. For example, en-US is a specific culture that represents the English language spoken in the United States, and en-CA is a specific culture that represents the English language spoken in Canada. You can instantiate a [DateTimeFormatInfo](#) object that represents the formatting conventions of a specific culture in the following ways:

- By calling the [CultureInfo.GetCultureInfo\(String\)](#) method and retrieving the value of the returned [CultureInfo](#) object's [CultureInfo.DateTimeFormat](#) property. The returned [DateTimeFormatInfo](#) object is read-only.
- By passing the static [GetInstance](#) method a [CultureInfo](#) object that represents the culture whose [DateTimeFormatInfo](#) object you want to retrieve. The returned [DateTimeFormatInfo](#) object is read/write.
- By calling the static [CultureInfo.CreateSpecificCulture](#) method and retrieving the value of the returned [CultureInfo](#) object's [CultureInfo.DateTimeFormat](#) property. The returned [DateTimeFormatInfo](#) object is read/write.
- By calling the [CultureInfo.CultureInfo](#) class constructor and retrieving the value of the returned [CultureInfo](#) object's [CultureInfo.DateTimeFormat](#) property. The returned [DateTimeFormatInfo](#) object is read/write.

The following example illustrates each of these ways to instantiate a [DateTimeFormatInfo](#) object and indicates whether the resulting object is read-only.

C#

```
System.Globalization.CultureInfo ci = null;
System.Globalization.DateTimeFormatInfo dtfi = null;

// Instantiate a culture using CreateSpecificCulture.
ci = System.Globalization.CultureInfo.CreateSpecificCulture("en-US");
dtfi = ci.DateTimeFormat;
Console.WriteLine("{0} from CreateSpecificCulture: {1}", ci.Name,
dtfi.IsReadOnly);

// Instantiate a culture using the CultureInfo constructor.
ci = new System.Globalization.CultureInfo("en-CA");
dtfi = ci.DateTimeFormat;
Console.WriteLine("{0} from CultureInfo constructor: {1}", ci.Name,
dtfi.IsReadOnly);

// Retrieve a culture by calling the GetCultureInfo method.
ci = System.Globalization.CultureInfo.GetCultureInfo("en-AU");
dtfi = ci.DateTimeFormat;
Console.WriteLine("{0} from GetCultureInfo: {1}", ci.Name, dtfi.IsReadOnly);

// Instantiate a DateTimeFormatInfo object by calling
DateTimeFormatInfo.GetInstance.
ci = System.Globalization.CultureInfo.CreateSpecificCulture("en-GB");
dtfi = System.Globalization.DateTimeFormatInfo.GetInstance(ci);
Console.WriteLine("{0} from GetInstance: {1}", ci.Name, dtfi.IsReadOnly);

// The example displays the following output:
//      en-US from CreateSpecificCulture: False
//      en-CA from CultureInfo constructor: False
//      en-AU from GetCultureInfo: True
//      en-GB from GetInstance: False
```

Instantiate a [DateTimeFormatInfo](#) object for a neutral culture

A neutral culture represents a culture or language that is independent of a country/region; it is typically the parent of one or more specific cultures. For example, Fr is a neutral culture for the French language and the parent of the fr-FR culture. You can instantiate a [DateTimeFormatInfo](#) object that represents the formatting conventions of a neutral culture in the same ways that you create a [DateTimeFormatInfo](#) object that represents the formatting conventions of a specific culture. In addition, you can retrieve a neutral culture's [DateTimeFormatInfo](#) object by retrieving a neutral culture from a specific culture's [CultureInfo.Parent](#) property and retrieving the [DateTimeFormatInfo](#)

object returned by its [CultureInfo.DateTimeFormat](#) property. Unless the parent culture represents the invariant culture, the returned [DateTimeFormatInfo](#) object is read/write. The following example illustrates these ways of instantiating a [DateTimeFormatInfo](#) object that represents a neutral culture.

C#

```
System.Globalization.CultureInfo specific, neutral;
System.Globalization.DateTimeFormatInfo dtfi;

// Instantiate a culture by creating a specific culture and using its Parent
// property.
specific = System.Globalization.CultureInfo.GetCultureInfo("fr-FR");
neutral = specific.Parent;
dtfi = neutral.DateTimeFormat;
Console.WriteLine("{0} from Parent property: {1}", neutral.Name,
dtfi.IsReadOnly);

dtfi = System.Globalization.CultureInfo.GetCultureInfo("fr-
FR").Parent.DateTimeFormat;
Console.WriteLine("{0} from Parent property: {1}", neutral.Name,
dtfi.IsReadOnly);

// Instantiate a neutral culture using the CultureInfo constructor.
neutral = new System.Globalization.CultureInfo("fr");
dtfi = neutral.DateTimeFormat;
Console.WriteLine("{0} from CultureInfo constructor: {1}", neutral.Name,
dtfi.IsReadOnly);

// Instantiate a culture using CreateSpecificCulture.
neutral = System.Globalization.CultureInfo.CreateSpecificCulture("fr");
dtfi = neutral.DateTimeFormat;
Console.WriteLine("{0} from CreateSpecificCulture: {1}", neutral.Name,
dtfi.IsReadOnly);

// Retrieve a culture by calling the GetCultureInfo method.
neutral = System.Globalization.CultureInfo.GetCultureInfo("fr");
dtfi = neutral.DateTimeFormat;
Console.WriteLine("{0} from GetCultureInfo: {1}", neutral.Name,
dtfi.IsReadOnly);

// Instantiate a DateTimeFormatInfo object by calling GetInstance.
neutral = System.Globalization.CultureInfo.CreateSpecificCulture("fr");
dtfi = System.Globalization.DateTimeFormatInfo.GetInstance(neutral);
Console.WriteLine("{0} from GetInstance: {1}", neutral.Name,
dtfi.IsReadOnly);

// The example displays the following output:
//      fr from Parent property: False
//      fr from Parent property: False
//      fr from CultureInfo constructor: False
//      fr-FR from CreateSpecificCulture: False
```

```
//      fr from GetCultureInfo: True
//      fr-FR from GetInstance: False
```

However, a neutral culture lacks culture-specific formatting information, because it is independent of a specific country/region. Instead of populating the [DateTimeFormatInfo](#) object with generic values, .NET returns a [DateTimeFormatInfo](#) object that reflects the formatting conventions of a specific culture that is a child of the neutral culture. For example, the [DateTimeFormatInfo](#) object for the neutral en culture reflects the formatting conventions of the en-US culture, and the [DateTimeFormatInfo](#) object for the fr culture reflects the formatting conventions of the fr-FR culture.

You can use code like the following to determine which specific culture's formatting conventions a neutral culture represents. The example uses reflection to compare the [DateTimeFormatInfo](#) properties of a neutral culture with the properties of a specific child culture. It considers two calendars to be equivalent if they are the same calendar type and, for Gregorian calendars, if their [GregorianCalendar.CalendarType](#) properties have identical values.

C#

```
using System;
using System.Collections;
using System.Collections.Generic;
using System.Globalization;
using System.Reflection;

public class InstantiateEx6
{
    public static void Main()
    {
        // Get all the neutral cultures
        List<String> names = new List<String>();
        Array.ForEach(CultureInfo.GetCultures(CultureTypes.NeutralCultures),
                     culture => names.Add(culture.Name));
        names.Sort();
        foreach (var name in names)
        {
            // Ignore the invariant culture.
            if (name == "") continue;

            ListSimilarChildCultures(name);
        }
    }

    private static void ListSimilarChildCultures(String name)
    {
        // Create the neutral DateTimeFormatInfo object.
        DateTimeFormatInfo dtfi =
            CultureInfo.GetCultureInfo(name).DateTimeFormat;
```

```

    // Retrieve all specific cultures of the neutral culture.
    CultureInfo[] cultures =
Array.FindAll(CultureInfo.GetCultures(CultureTypes.SpecificCultures),
                culture => culture.Name.StartsWith(name +
"--", StringComparison.OrdinalIgnoreCase));
    // Create an array of DateTimeFormatInfo properties
    PropertyInfo[] properties =
typeof(DateTimeFormatInfo).GetProperties(BindingFlags.Instance |
BindingFlags.Public);
    bool hasOneMatch = false;

    foreach (var ci in cultures)
    {
        bool match = true;
        // Get the DateTimeFormatInfo for a specific culture.
        DateTimeFormatInfo specificDtfi = ci.DateTimeFormat;
        // Compare the property values of the two.
        foreach (var prop in properties)
        {
            // We're not interested in the value of IsReadOnly.
            if (prop.Name == "IsReadOnly") continue;

            // For arrays, iterate the individual elements to see if
they are the same.
            if (prop.PropertyType.IsArray)
            {
                IList nList = (IList)prop.GetValue(dtfi, null);
                IList sList = (IList)prop.GetValue(specificDtfi, null);
                if (nList.Count != sList.Count)
                {
                    match = false;
                    Console.WriteLine("  Different n in {2} array for
{0} and {1}", name, ci.Name, prop.Name);
                    break;
                }

                for (int ctr = 0; ctr < nList.Count; ctr++)
                {
                    if (!nList[ctr].Equals(sList[ctr]))
                    {
                        match = false;
                        Console.WriteLine("  {0} value different for
{1} and {2}", prop.Name, name, ci.Name);
                        break;
                    }
                }

                if (!match) break;
            }
            // Get non-array values.
            else
            {
                Object specificValue = prop.GetValue(specificDtfi);
                Object neutralValue = prop.GetValue(dtfi);

```

```

        // Handle comparison of Calendar objects.
        if (prop.Name == "Calendar")
        {
            // The cultures have a different calendar type.
            if (specificValue.ToString() !=
neutralValue.ToString())
            {
                Console.WriteLine("  Different calendar types
for {0} and {1}", name, ci.Name);
                match = false;
                break;
            }

            if (specificValue is GregorianCalendar)
            {
                if
(((GregorianCalendar)specificValue).CalendarType !=
((GregorianCalendar)neutralValue).CalendarType)
                {
                    Console.WriteLine("  Different Gregorian
calendar types for {0} and {1}", name, ci.Name);
                    match = false;
                    break;
                }
            }
            else if (!specificValue.Equals(neutralValue))
            {
                match = false;
                Console.WriteLine("  Different {0} values for {1}
and {2}", prop.Name, name, ci.Name);
                break;
            }
        }
        if (match)
        {
            Console.WriteLine("DateTimeFormatInfo object for '{0}'
matches '{1}'",
                               name, ci.Name);
            hasOneMatch = true;
        }
    }
    if (!hasOneMatch)
        Console.WriteLine("DateTimeFormatInfo object for '{0}' --> No
Match", name);

    Console.WriteLine();
}
}

```

Instantiate a `DateTimeFormatInfo` object for the current culture

You can instantiate a `DateTimeFormatInfo` object that represents the formatting conventions of the current culture in the following ways:

- By retrieving the value of the `CurrentInfo` property. The returned `DateTimeFormatInfo` object is read-only.
- By retrieving the value of the `DateFormat` property from the `CultureInfo` object that is returned by the `CultureInfo.CurrentCulture` property. The returned `DateTimeFormatInfo` object is read-only.
- By calling the `GetInstance` method with a `CultureInfo` object that represents the current culture. The returned `DateTimeFormatInfo` object is read-only.

The following example uses each of these methods to instantiate a `DateTimeFormatInfo` object that represents the formatting conventions of the current culture. It then indicates whether the object is read-only.

C#

```
DateTimeFormatInfo dtfi;

dtfi = DateTimeFormatInfo.CurrentInfo;
Console.WriteLine(dtfi.IsReadOnly);

dtfi = CultureInfo.CurrentCulture.DateTimeFormat;
Console.WriteLine(dtfi.IsReadOnly);

dtfi = DateTimeFormatInfo.GetInstance(CultureInfo.CurrentCulture);
Console.WriteLine(dtfi.IsReadOnly);
// The example displays the following output:
//    True
//    True
//    True
```

You can create a writable `DateTimeFormatInfo` object that represents the conventions of the current culture in one of these ways:

- By retrieving a `DateTimeFormatInfo` object in any of the three previous ways and calling the `Clone` method on the returned `DateTimeFormatInfo` object. This creates a copy of the original `DateTimeFormatInfo` object, except that its `IsReadOnly` property is `false`.

- By calling the [CultureInfo.CreateSpecificCulture](#) method to create a [CultureInfo](#) object that represents the current culture, and then using its [CultureInfo.DateTimeFormat](#) property to retrieve the [DateTimeFormatInfo](#) object.

The following example illustrates each way of instantiating a read/write [DateTimeFormatInfo](#) object and displays the value of its [IsReadOnly](#) property.

C#

```
using System;
using System.Globalization;

public class InstantiateEx1
{
    public static void Main()
    {
        DateTimeFormatInfo current1 = DateTimeFormatInfo.CurrentInfo;
        current1 = (DateTimeFormatInfo)current1.Clone();
        Console.WriteLine(current1.IsReadOnly);

        CultureInfo culture2 =
CultureInfo.CreateSpecificCulture(CultureInfo.CurrentCulture.Name);
        DateTimeFormatInfo current2 = culture2.DateTimeFormat;
        Console.WriteLine(current2.IsReadOnly);
    }
}

// The example displays the following output:
//      False
//      False
```

In Windows, the user can override some of the [DateTimeFormatInfo](#) property values used in formatting and parsing operations through the [Region and Language](#) application in Control Panel. For example, a user whose culture is English (United States) might choose to display long time values using a 24-hour clock (in the format HH:mm:ss) instead of the default 12-hour clock (in the format h:mm:ss tt). The [DateTimeFormatInfo](#) objects retrieved in the ways discussed previously all reflect these user overrides. If this is undesirable, you can create a [NumberFormatInfo](#) object that does not reflect user overrides (and is also read/write instead of read-only) by calling the [CultureInfo.CultureInfo\(String, Boolean\)](#) constructor and supplying a value of `false` for the `useUserOverride` argument. The following example illustrates this for a system whose current culture is English (United States) and whose long time pattern has been changed from the default of h:mm:ss tt to HH:mm:ss.

C#

```
using System;
using System.Globalization;
```

```

public class InstantiateEx3
{
    public static void Main()
    {
        CultureInfo culture;
        DateTimeFormatInfo dtfi;

        culture = CultureInfo.CurrentCulture;
        dtfi = culture.DateTimeFormat;
        Console.WriteLine("Culture Name: {0}", culture.Name);
        Console.WriteLine("User Overrides: {0}",
culture.UseUserOverride);
        Console.WriteLine("Long Time Pattern: {0}\n",
culture.DateTimeFormat.LongTimePattern);

        culture = new CultureInfo(CultureInfo.CurrentCulture.Name, false);
        Console.WriteLine("Culture Name: {0}", culture.Name);
        Console.WriteLine("User Overrides: {0}",
culture.UseUserOverride);
        Console.WriteLine("Long Time Pattern: {0}\n",
culture.DateTimeFormat.LongTimePattern);
    }
}
// The example displays the following output:
//      Culture Name: en-US
//      User Overrides: True
//      Long Time Pattern: HH:mm:ss
//
//      Culture Name: en-US
//      User Overrides: False
//      Long Time Pattern: h:mm:ss tt

```

DateDateTimeFormatInfo and dynamic data

The culture-specific data for formatting date and time values provided by the [DateTimeFormatInfo](#) class is dynamic, just like cultural data provided by the [CultureInfo](#) class. You should not make any assumptions about the stability of values for [DateTimeFormatInfo](#) objects that are associated with particular [CultureInfo](#) objects. Only the data provided by the invariant culture and its associated [DateTimeFormatInfo](#) object is stable. Other data can change between application sessions or even while your application is running. There are four major sources of change:

- System updates. Cultural preferences such as the preferred calendar or customary date and time formats change over time. When this happens, Windows Update includes changes to the [DateTimeFormatInfo](#) property value for a particular culture.

- Replacement cultures. The [CultureAndRegionInfoBuilder](#) class can be used to replace the data of an existing culture.
- Cascading changes to property values. A number of culture-related properties can change at run time, which, in turn, causes [DateTimeFormatInfo](#) data to change. For example, the current culture can be changed either programmatically or through user action. When this happens, the [DateTimeFormatInfo](#) object returned by the [CurrentInfo](#) property changes to an object associated with the current culture. Similarly, a culture's calendar can change, which can result in changes to numerous [DateTimeFormatInfo](#) property values.
- User preferences. Users of your application might choose to override some of the values associated with the current system culture through the regional and language options in Control Panel. For example, users might choose to display the date in a different format. If the [CultureInfo.UseUserOverride](#) property is set to `true`, the properties of the [DateTimeFormatInfo](#) object is also retrieved from the user settings. If the user settings are incompatible with the culture associated with the [CultureInfo](#) object (for example, if the selected calendar is not one of the calendars indicated by the [OptionalCalendars](#) property), the results of the methods and the values of the properties are undefined.

To minimize the possibility of inconsistent data, all user-overridable properties of a [DateTimeFormatInfo](#) object are initialized when the object is created. There is still a possibility of inconsistency, because neither object creation nor the user override process is atomic and the relevant values can change during object creation. However, this situation should be extremely rare.

You can control whether user overrides are reflected in [DateTimeFormatInfo](#) objects that represent the same culture as the system culture. The following table lists the ways in which a [DateTimeFormatInfo](#) object can be retrieved and indicates whether the resulting object reflects user overrides.

[+] Expand table

| Source of CultureInfo and DateTimeFormatInfo object | Reflects user overrides |
|---|-------------------------|
| <code>CultureInfo.CurrentCulture.DateTimeFormat</code> property | Yes |
| <code>DateTimeFormatInfo.CurrentInfo</code> property | Yes |
| <code>CultureInfo.CreateSpecificCulture</code> method | Yes |
| <code>CultureInfo.GetCultureInfo</code> method | No |

| Source of CultureInfo and DateTimeFormatInfo object | Reflects user overrides |
|--|--|
| CultureInfo.CultureInfo(String) constructor | Yes |
| CultureInfo.CultureInfo(String, Boolean) constructor | Depends on value of <code>useUserOverride</code> parameter |

Unless there is a compelling reason to do otherwise, you should respect user overrides when you use the [DateTimeFormatInfo](#) object in client applications to format and parse user input or to display data. For server applications or unattended applications, you should not. However, if you are using the [DateTimeFormatInfo](#) object either explicitly or implicitly to persist date and time data in string form, you should either use a [DateTimeFormatInfo](#) object that reflects the formatting conventions of the invariant culture, or you should specify a custom date and time format string that you use regardless of culture.

Format dates and times

A [DateTimeFormatInfo](#) object is used implicitly or explicitly in all date and time formatting operations. These include calls to the following methods:

- All date and time formatting methods, such as [DateTime.ToString\(\)](#) and [DateTimeOffset.ToString\(String\)](#).
- The major composite formatting method, which is [String.Format](#).
- Other composite formatting methods, such as [Console.WriteLine\(String, Object\[\]\)](#) and [StringBuilder.AppendFormat\(String, Object\[\]\)](#).

All date and time formatting operations make use of an [IFormatProvider](#) implementation. The [IFormatProvider](#) interface includes a single method, [IFormatProvider.GetFormat\(Type\)](#). This callback method is passed a [Type](#) object that represents the type needed to provide formatting information. The method returns either an instance of that type or `null` if it cannot provide an instance of the type. .NET includes two [IFormatProvider](#) implementations for formatting dates and times:

- The [CultureInfo](#) class, which represents a specific culture (or a specific language in a specific country/region). In a date and time formatting operation, the [CultureInfo.GetFormat](#) method returns the [DateTimeFormatInfo](#) object associated with its [CultureInfo.DateTimeFormat](#) property.
- The [DateTimeFormatInfo](#) class, which provides information about the formatting conventions of its associated culture. The [DateTimeFormatInfo.GetFormat](#) method returns an instance of itself.

If an [IFormatProvider](#) implementation is not provided to a formatting method explicitly, the [CultureInfo](#) object returned by the [CultureInfo.CurrentCulture](#) property that represents the current culture is used.

The following example illustrates the relationship between the [IFormatProvider](#) interface and the [DateTimeFormatInfo](#) class in formatting operations. It defines a custom [IFormatProvider](#) implementation whose [GetFormat](#) method displays the type of the object requested by the formatting operation. If it is requesting a [DateTimeFormatInfo](#) object, the method provides the [DateTimeFormatInfo](#) object for the current culture. As the output from the example shows, the [Decimal.ToString\(IFormatProvider\)](#) method requests a [DateTimeFormatInfo](#) object to provide formatting information, whereas the [String.Format\(IFormatProvider, String, Object\[\]\)](#) method requests [NumberFormatInfo](#) and [DateTimeFormatInfo](#) objects as well as an [ICustomFormatter](#) implementation.

C#

```
using System;
using System.Globalization;

public class CurrentCultureFormatProvider : IFormatProvider
{
    public Object GetFormat(Type formatType)
    {
        Console.WriteLine("Requesting an object of type {0}",
                          formatType.Name);
        if (formatType == typeof(NumberFormatInfo))
            return NumberFormatInfo.CurrentInfo;
        else if (formatType == typeof(DateTimeFormatInfo))
            return DateTimeFormatInfo.CurrentInfo;
        else
            return null;
    }
}

public class FormatProviderEx1
{
    public static void Main()
    {
        DateTime dateValue = new DateTime(2013, 5, 28, 13, 30, 0);
        string value = dateValue.ToString("F", new
CurrentCultureFormatProvider());
        Console.WriteLine(value);
        Console.WriteLine();
        string composite = String.Format(new CurrentCultureFormatProvider(),
                                         "Date: {0:d}    Amount: {1:C}
Description: {2}",
                                         dateValue, 1264.03m, "Service
Charge");
        Console.WriteLine(composite);
        Console.WriteLine();
    }
}
```

```
        }
    }
// The example displays output like the following:
//      Requesting an object of type DateTimeFormatInfo
//      Tuesday, May 28, 2013 1:30:00 PM
//
//      Requesting an object of type ICustomFormatter
//      Requesting an object of type DateTimeFormatInfo
//      Requesting an object of type NumberFormatInfo
//      Date: 5/28/2013  Amount: $1,264.03  Description: Service Charge
```

Format strings and DateTimeFormatInfo properties

The [DateTimeFormatInfo](#) object includes three kinds of properties that are used in formatting operations with date and time values:

- Calendar-related properties. Properties such as [AbbreviatedDayNames](#), [AbbreviatedMonthNames](#), [DayNames](#), and [MonthNames](#), are associated with the calendar used by the culture, which is defined by the [Calendar](#) property. These properties are used for long date and time formats.
- Properties that produce a standards-defined result string. The [RFC1123Pattern](#), [SortableDateTimePattern](#), and [UniversalSortableDateTimePattern](#) properties contain custom format strings that produce result strings defined by international standards. These properties are read-only and cannot be modified.
- Properties that define culture-sensitive result strings. Some properties, such as [FullDateTimePattern](#) and [ShortDatePattern](#), contain [custom format strings](#) that specify the format of the result string. Others, such as [AMDesignator](#), [DateSeparator](#), [PMDesignator](#), and [TimeSeparator](#), define culture-sensitive symbols or substrings that can be included in a result string.

The [standard date and time format strings](#), such as "d", "D", "f", and "F", are aliases that correspond to particular [DateTimeFormatInfo](#) format pattern properties. Most of the [custom date and time format strings](#) are related to strings or substrings that a formatting operation inserts into the result stream. The following table lists the standard and custom date and time format specifiers and their associated [DateTimeFormatInfo](#) properties. For details about how to use these format specifiers, see [Standard Date and Time Format Strings](#) and [Custom Date and Time Format Strings](#). Note that each standard format string corresponds to a [DateTimeFormatInfo](#) property whose value is a custom date and time format string. The individual specifiers in this custom format string in turn correspond to other [DateTimeFormatInfo](#) properties. The table lists only

the [DateTimeFormatInfo](#) properties for which the standard format strings are aliases, and does not list properties that may be accessed by custom format strings assigned to those aliased properties. In addition, the table lists only custom format specifiers that correspond to [DateTimeFormatInfo](#) properties.

[+] Expand table

| Format specifier | Associated properties |
|---|--|
| "d" (short date; standard format string) | ShortDatePattern , to define the overall format of the result string. |
| "D" (long date; standard format string) | LongDatePattern , to define the overall format of the result string. |
| "f" (full date / short time; standard format string) | LongDatePattern , to define the format of the date component of the result string. ShortTimePattern , to define the format of the time component of the result string. |
| "F" (full date / long time; standard format string) | LongDatePattern , to define the format of the date component of the result string. LongTimePattern , to define the format of the time component of the result string. |
| "g" (general date / short time; standard format string) | ShortDatePattern , to define the format of the date component of the result string. ShortTimePattern , to define the format of the time component of the result string. |
| "G" (general date / long time; standard format string) | ShortDatePattern , to define the format of the date component of the result string. LongTimePattern , to define the format of the time component of the result string. |
| "M", "m" (month/day; standard format string) | MonthDayPattern , to define the overall format of the result string. |
| "O", "o" (round-trip date/time; standard format string) | None. |
| "R", "r" (RFC1123; standard format string) | RFC1123Pattern , to define a result string that conforms to the RFC 1123 standard. The property is read-only. |

| Format specifier | Associated properties |
|---|--|
| "s" (sortable date/time; standard format string) | SortableDateTimePattern , to define a result string that conforms to the ISO 8601 standard. The property is read-only. |
| "t" (short time; standard format string) | ShortTimePattern , to define the overall format of the result string. |
| "T" (long time; standard format string) | LongTimePattern , to define the overall format of the result string. |
| "u" (universal sortable date/time; standard format string) | UniversalSortableDateTimePattern , to define a result string that conforms to the ISO 8601 standard for coordinated universal time. The property is read-only. |
| "U" (universal full date/time; standard format string) | FullDateTimePattern , to define the overall format of the result string. |
| "Y", "y" (year month; standard format string) | YearMonthPattern , to define the overall format of the result string. |
| "ddd" (custom format specifier) | AbbreviatedDayNames , to include the abbreviated name of the day of the week in the result string. |
| "g", "gg" (custom format specifier) | Calls the GetEraName method to insert the era name in the result string. |
| "MMM" (custom format specifier) | AbbreviatedMonthNames , to include the abbreviated month name in the result string. |
| "MMMM" (custom format specifier) | MonthNames or MonthGenitiveNames , to include the full month name in the result string. |
| "t" (custom format specifier) | AMDesignator or PMDesignator , to include the first character of the AM/PM designator in the result string. |
| "tt" (custom format specifier) | AMDesignator or PMDesignator , to include the full AM/PM designator in the result string. |
| TimeSeparator , to include the time separator in the result string. | |
| "/" (custom format specifier) | DateSeparator , to include the date separator in the result string. |

Modify **DateTimeFormatInfo** properties

You can change the result string produced by date and time format strings by modifying the associated properties of a writable [DateTimeFormatInfo](#) object. To determine if a

[DateTimeFormatInfo](#) object is writable, use the [IsReadOnly](#) property. To customize a [DateTimeFormatInfo](#) object in this way:

1. Create a read/write copy of a [DateTimeFormatInfo](#) object whose formatting conventions you want to modify.
2. Modify the property or properties that are used to produce the desired result string. (For information about how formatting methods use [DateTimeFormatInfo](#) properties to define result strings, see the previous section, [Format strings and DateTimeFormatInfo properties](#).)
3. Use the custom [DateTimeFormatInfo](#) object you created as the [IFormatProvider](#) argument in calls to formatting methods.

There are two other ways to change the format of a result string:

- You can use the [CultureAndRegionInfoBuilder](#) class to define either a custom culture (a culture that has a unique name and that supplements existing cultures) or a replacement culture (one that is used instead of a specific culture). You can save and access this culture programmatically as you would any [CultureInfo](#) object supported by .NET.
- If the result string is not culture-sensitive and doesn't follow a predefined format, you can use a custom date and time format string. For example, if you are serializing date and time data in the format YYYYMMDDHHmmss, you can generate the result string by passing the custom format string to the [DateTime.ToString\(String\)](#) method, and you can convert the result string back to a [DateTime](#) value by calling the [DateTime.ParseExact](#) method.

Change the short date pattern

The following example changes the format of a result string produced by the "d" (short date) standard format string. It changes the associated [ShortDatePattern](#) property for the en-US or English (United States) culture from its default of "M/d/yyyy" to "yyyy"- "MM"- "dd" and uses the "d" standard format string to display the date both before and after the [ShortDatePattern](#) property is changed.

C#

```
using System;
using System.Globalization;

public class Example1
{
    public static void Main()
```

```

{
    DateTime dateValue = new DateTime(2013, 8, 18);
    CultureInfo enUS = CultureInfo.CreateSpecificCulture("en-US");
    DateTimeFormatInfo dtfi = enUS.DateTimeFormat;

    Console.WriteLine("Before modifying DateTimeFormatInfo object: ");
    Console.WriteLine("{0}: {1}\n", dtfi.ShortDatePattern,
                      dateValue.ToString("d", enUS));

    // Modify the short date pattern.
    dtfi.ShortDatePattern = "yyyy-MM-dd";
    Console.WriteLine("After modifying DateTimeFormatInfo object: ");
    Console.WriteLine("{0}: {1}", dtfi.ShortDatePattern,
                      dateValue.ToString("d", enUS));
}

// The example displays the following output:
//      Before modifying DateTimeFormatInfo object:
//      M/d/yyyy: 8/18/2013
//
//      After modifying DateTimeFormatInfo object:
//      yyyy-MM-dd: 2013-08-18

```

Change the date separator character

The following example changes the date separator character in a [DateTimeFormatInfo](#) object that represents the formatting conventions of the fr-FR culture. The example uses the "g" standard format string to display the date both before and after the [DateSeparator](#) property is changed.

C#

```

using System;
using System.Globalization;

public class Example3
{
    public static void Main()
    {
        DateTime dateValue = new DateTime(2013, 08, 28);
        CultureInfo frFR = CultureInfo.CreateSpecificCulture("fr-FR");
        DateTimeFormatInfo dtfi = frFR.DateTimeFormat;

        Console.WriteLine("Before modifying DateSeparator property: {0}",
                          dateValue.ToString("g", frFR));

        // Modify the date separator.
        dtfi.DateSeparator = "-";
        Console.WriteLine("After modifying the DateSeparator property: {0}",
                          dateValue.ToString("g", frFR));
    }
}

```

```
}
```

```
// The example displays the following output:
```

```
//      Before modifying DateSeparator property: 28/08/2013 00:00
```

```
//      After modifying the DateSeparator property: 28-08-2013 00:00
```

Change day name abbreviations and the long date pattern

In some cases, the long date pattern, which typically displays the full day and month name along with the number of the day of the month and the year, may be too long. The following example shortens the long date pattern for the en-US culture to return a one-character or two-character day name abbreviation followed by the day number, the month name abbreviation, and the year. It does this by assigning shorter day name abbreviations to the [AbbreviatedDayNames](#) array, and by modifying the custom format string assigned to the [LongDatePattern](#) property. This affects the result strings returned by the "D" and "f" standard format strings.

C#

```
using System;
using System.Globalization;

public class Example2
{
    public static void Main()
    {
        DateTime value = new DateTime(2013, 7, 9);
        CultureInfo enUS = CultureInfo.CreateSpecificCulture("en-US");
        DateTimeFormatInfo dtfi = enUS.DateTimeFormat;
        String[] formats = { "D", "F", "f" };

        // Display date before modifying properties.
        foreach (var fmt in formats)
            Console.WriteLine("{0}: {1}", fmt, value.ToString(fmt, dtfi));

        Console.WriteLine();

        // We don't want to change the FullDateTimePattern, so we need to
        // save it.
        String originalFullDateTimePattern = dtfi.FullDateTimePattern;

        // Modify day name abbreviations and long date pattern.
        dtfi.AbbreviatedDayNames = new String[] { "Su", "M", "Tu", "W",
        "Th", "F", "Sa" };
        dtfi.LongDatePattern = "ddd dd-MMM-yyyy";
        dtfi.FullDateTimePattern = originalFullDateTimePattern;
        foreach (var fmt in formats)
            Console.WriteLine("{0}: {1}", fmt, value.ToString(fmt, dtfi));
    }
}
```

```
}

// The example displays the following output:
//      D: Tuesday, July 9, 2013
//      F: Tuesday, July 9, 2013 12:00:00 AM
//      f: Tuesday, July 9, 2013 12:00 AM
//
//      D: Tu 09-Jul-2013
//      F: Tuesday, July 9, 2013 12:00:00 AM
//      f: Tu 09-Jul-2013 12:00 AM
```

Ordinarily, the change to the [LongDatePattern](#) property also affects the [FullDateTimePattern](#) property, which in turn defines the result string returned by the "F" standard format string. To preserve the original full date and time pattern, the example reassigns the original custom format string assigned to the [FullDateTimePattern](#) property after the [LongDatePattern](#) property is modified.

Change from a 12-hour clock to a 24-hour clock

For many cultures in .NET, the time is expressed by using a 12-hour clock and an AM/PM designator. The following example defines a [ReplaceWith24HourClock](#) method that replaces any time format that uses a 12-hour clock with a format that uses a 24-hour clock.

C#

```
using System;
using System.Globalization;
using System.Text.RegularExpressions;

public class Example5
{
    public static void Main()
    {
        CultureInfo enUS = CultureInfo.CreateSpecificCulture("en-US");
        DateTimeFormatInfo dtfi = enUS.DateTimeFormat;

        Console.WriteLine("Original Property Values:");
        Console.WriteLine("ShortTimePattern: " + dtfi.ShortTimePattern);
        Console.WriteLine("LongTimePattern: " + dtfi.LongTimePattern);
        Console.WriteLine("FullDateTimePattern: " +
dtfi.FullDateTimePattern);
        Console.WriteLine();

        dtfi.LongTimePattern = ReplaceWith24HourClock(dtfi.LongTimePattern);
        dtfi.ShortTimePattern =
ReplaceWith24HourClock(dtfi.ShortTimePattern);

        Console.WriteLine("Modified Property Values:");
        Console.WriteLine("ShortTimePattern: " + dtfi.ShortTimePattern);
```

```

        Console.WriteLine("LongTimePattern: " + dtfi.LongTimePattern);
        Console.WriteLine("FullDateTimePattern: " +
dtfi.FullDateTimePattern);
    }

    private static string ReplaceWith24HourClock(string fmt)
{
    string pattern = @"^(<openAMPM>\s*t+\s*)? " +
                    @"(?(openAMPM) h+(<nonHours>[^ht]+)$ " +
                    @"| \s*h+(<nonHours>[^ht]+)\s*t+)";
    return Regex.Replace(fmt, pattern, "HH${nonHours}",
                         RegexOptions.IgnorePatternWhitespace);
}
}

// The example displays the following output:
//     Original Property Values:
//     ShortTimePattern: h:mm tt
//     LongTimePattern: h:mm:ss tt
//     FullDateTimePattern: dddd, MMMM dd, yyyy h:mm:ss tt
//
//     Modified Property Values:
//     ShortTimePattern: HH:mm
//     LongTimePattern: HH:mm:ss
//     FullDateTimePattern: dddd, MMMM dd, yyyy HH:mm:ss

```

The example uses a regular expression to modify the format string. The regular expression pattern `@"^(?<openAMPM>\s*t+\s*)? (?(openAMPM) h+(<nonHours>[^ht]+)$ | \s*h+(<nonHours>[^ht]+)\s*t+)"` is defined as follows:

[\[\] Expand table](#)

| Pattern | Description |
|--|---|
| <code>^</code> | Begin the match at the beginning of the string. |
| <code>(?<openAMPM>\s*t+\s*)?</code> | Match zero or one occurrence of zero or more white-space characters, followed by the letter "t" one or more times, followed by zero or more white-space characters. This capturing group is named <code>openAMPM</code> . |
| <code>(?(openAMPM) h+(<nonHours>[^ht]+)\$</code> | If the <code>openAMPM</code> group has a match, match the letter "h" one or more times, followed by one or more characters that are neither "h" nor "t". The match ends at the end of the string. All characters captured after "h" are included in a capturing group named <code>nonHours</code> . |
| <code>&#124; \s*h+(<nonHours>[^ht]+)\s*t+</code> | If the <code>openAMPM</code> group does not have a match, match the letter "h" one or more times, followed by one or more characters that are neither "h" nor "t", followed by zero or more white-space characters. Finally, match one or more occurrences of the letter "t". All characters captured after "h" and before the white-spaces and "t" are included in a capturing group named <code>nonHours</code> . |

The `nonHours` capturing group contains the minute and possibly the second component of a custom date and time format string, along with any time separator symbols. The replacement pattern `HH${nonHours}` prepends the substring "HH" to these elements.

Display and change the era in a date

The following example adds the "g" custom format specifier to the [LongDatePattern](#) property of an object that represents the formatting conventions of the en-US culture. This addition affects the following three standard format strings:

- The "D" (long date) standard format string, which maps directly to the [LongDatePattern](#) property.
- The "f" (full date / short time) standard format string, which produces a result string that concatenates the substrings produced by the [LongDatePattern](#) and [ShortTimePattern](#) properties.
- The "F" (full date / long time) standard format string, which maps directly to the [FullDateTimePattern](#) property. Because we have not explicitly set this property value, it is generated dynamically by concatenating the [LongDatePattern](#) and [LongTimePattern](#) properties.

The example also shows how to change the era name for a culture whose calendar has a single era. In this case, the en-US culture uses the Gregorian calendar, which is represented by a [GregorianCalendar](#) object. The [GregorianCalendar](#) class supports a single era, which it names A.D. (Anno Domini). The example changes the era name to C.E. (Common Era) by replacing the "g" custom format specifier in the format string assigned to the [FullDateTimePattern](#) property with a literal string. The use of a literal string is necessary, because the era name is typically returned by the [GetEraName](#) method from private data in the culture tables supplied by either .NET or the operating system.

C#

```
using System;
using System.Globalization;

public class Example4
{
    public static void Main()
    {
        DateTime dateValue = new DateTime(2013, 5, 18, 13, 30, 0);
        String[] formats = { "D", "f", "F" };

        CultureInfo enUS = CultureInfo.CreateSpecificCulture("en-US");
```

```

        DateTimeFormatInfo dtfi = enUS.DateTimeFormat;
        String originalLongDatePattern = dtfi.LongDatePattern;

        // Display the default form of three long date formats.
        foreach (var fmt in formats)
            Console.WriteLine(dateValue.ToString(fmt, dtfi));

        Console.WriteLine();

        // Modify the long date pattern.
        dtfi.LongDatePattern = originalLongDatePattern + " g";
        foreach (var fmt in formats)
            Console.WriteLine(dateValue.ToString(fmt, dtfi));

        Console.WriteLine();

        // Change A.D. to C.E. (for Common Era)
        dtfi.LongDatePattern = originalLongDatePattern + @" 'C.E.'";
        foreach (var fmt in formats)
            Console.WriteLine(dateValue.ToString(fmt, dtfi));
    }
}

// The example displays the following output:
//      Saturday, May 18, 2013
//      Saturday, May 18, 2013 1:30 PM
//      Saturday, May 18, 2013 1:30:00 PM
//
//      Saturday, May 18, 2013 A.D.
//      Saturday, May 18, 2013 A.D. 1:30 PM
//      Saturday, May 18, 2013 A.D. 1:30:00 PM
//
//      Saturday, May 18, 2013 C.E.
//      Saturday, May 18, 2013 C.E. 1:30 PM
//      Saturday, May 18, 2013 C.E. 1:30:00 PM

```

Parse date and time strings

Parsing involves converting the string representation of a date and time to a [DateTime](#) or [DateTimeOffset](#) value. Both of these types include the `Parse`, `TryParse`, `ParseExact`, and `TryParseExact` methods to support parsing operations. The `Parse` and `TryParse` methods convert a string that can have a variety of formats, whereas `ParseExact` and `TryParseExact` require that the string have a defined format or formats. If the parsing operation fails, `Parse` and `ParseExact` throw an exception, whereas `TryParse` and `TryParseExact` return `false`.

The parsing methods implicitly or explicitly use a [DateTimeStyles](#) enumeration value to determine which style elements (such as leading, trailing, or inner white space) can be present in the string to be parsed, and how to interpret the parsed string or any missing

elements. If you don't provide a `DateTimeStyles` value when you call the `Parse` or `TryParse` method, the default is `DateTimeStyles.AllowWhiteSpaces`, which is a composite style that includes the `DateTimeStyles.AllowLeadingWhite`, `DateTimeStyles.AllowTrailingWhite`, and `DateTimeStyles.AllowInnerWhite` flags. For the `ParseExact` and `TryParseExact` methods, the default is `DateTimeStyles.None`; the input string must correspond precisely to a particular custom date and time format string.

The parsing methods also implicitly or explicitly use a `DateTimeFormatInfo` object that defines the specific symbols and patterns that can occur in the string to be parsed. If you don't provide a `DateTimeFormatInfo` object, the `DateTimeFormatInfo` object for the current culture is used by default. For more information about parsing date and time strings, see the individual parsing methods, such as `DateTime.Parse`, `DateTime.TryParse`, `DateTimeOffset.ParseExact`, and `DateTimeOffset.TryParseExact`.

The following example illustrates the culture-sensitive nature of parsing date and time strings. It tries to parse two date strings by using the conventions of the en-US, en-GB, fr-FR, and fi-FI cultures. The date that is interpreted as 8/18/2014 in the en-US culture throws a `FormatException` exception in the other three cultures because 18 is interpreted as the month number. 1/2/2015 is parsed as the second day of the first month in the en-US culture, but as the first day of the second month in the remaining cultures.

C#

```
using System;
using System.Globalization;

public class ParseEx1
{
    public static void Main()
    {
        string[] dateStrings = { "08/18/2014", "01/02/2015" };
        string[] cultureNames = { "en-US", "en-GB", "fr-FR", "fi-FI" };

        foreach (var cultureName in cultureNames)
        {
            CultureInfo culture =
CultureInfo.CreateSpecificCulture(cultureName);
            Console.WriteLine("Parsing strings using the {0} culture.",
                           culture.Name);
            foreach (var dateStr in dateStrings)
            {
                try
                {
                    Console.WriteLine(String.Format(culture,
                      "'{0}' --> {1:D}", dateStr,
                      DateTime.Parse(dateStr, culture)));
                }
            }
        }
    }
}
```

```

        catch (FormatException)
    {
        Console.WriteLine("  Unable to parse '{0}'", dateStr);
    }
}
}

// The example displays the following output:
//   Parsing strings using the en-US culture.
//     '08/18/2014' --> Monday, August 18, 2014
//     '01/02/2015' --> Friday, January 02, 2015
//   Parsing strings using the en-GB culture.
//     Unable to parse '08/18/2014'
//     '01/02/2015' --> 01 February 2015
//   Parsing strings using the fr-FR culture.
//     Unable to parse '08/18/2014'
//     '01/02/2015' --> dimanche 1 février 2015
//   Parsing strings using the fi-FI culture.
//     Unable to parse '08/18/2014'
//     '01/02/2015' --> 1. helmikuuta 2015

```

Date and time strings are typically parsed for two reasons:

- To convert user input into a date and time value.
- To round-trip a date and time value; that is, to deserialize a date and time value that was previously serialized as a string.

The following sections discuss these two operations in greater detail.

Parse user strings

When you parse date and time strings input by the user, you should always instantiate a [DateTimeFormatInfo](#) object that reflects the user's cultural settings, including any customizations the user may have made. Otherwise, the date and time object may have incorrect values. For information about how to instantiate a [DateTimeFormatInfo](#) object that reflects user cultural customizations, see the [DateTimeFormatInfo and dynamic data](#) section.

The following example illustrates the difference between a parsing operation that reflects user cultural settings and one that does not. In this case, the default system culture is en-US, but the user has used Control Panel, **Region and Language** to change the short date pattern from its default of "M/d/yyyy" to "yy/MM/dd". When the user enters a string that reflects user settings, and the string is parsed by a [DateTimeFormatInfo](#) object that also reflects user settings (overrides), the parsing operation returns a correct result. However, when the string is parsed by a [DateTimeFormatInfo](#) object that reflects standard en-US cultural settings, the parsing

method throws a `FormatException` exception because it interprets 14 as the number of the month, not the last two digits of the year.

```
C#  
  
using System;  
using System.Globalization;  
  
public class ParseEx2  
{  
    public static void Main()  
    {  
        string inputDate = "14/05/10";  
  
        CultureInfo[] cultures = { CultureInfo.GetCultureInfo("en-US"),  
                                   CultureInfo.CreateSpecificCulture("en-US")};  
  
        foreach (var culture in cultures)  
        {  
            try  
            {  
                Console.WriteLine("{0} culture reflects user overrides:  
{1}",  
                                  culture.Name, culture.UseUserOverride);  
                DateTime occasion = DateTime.Parse(inputDate, culture);  
                Console.WriteLine("'{0}' --> {1}", inputDate,  
                               occasion.ToString("D",  
CultureInfo.InvariantCulture));  
            }  
            catch (FormatException)  
            {  
                Console.WriteLine("Unable to parse '{0}'", inputDate);  
            }  
            Console.WriteLine();  
        }  
    }  
}  
// The example displays the following output:  
//      en-US culture reflects user overrides: False  
//      Unable to parse '14/05/10'  
//  
//      en-US culture reflects user overrides: True  
//      '14/05/10' --> Saturday, 10 May 2014
```

Serialize and deserialize date and time data

Serialized date and time data are expected to round-trip; that is, all serialized and deserialized values should be identical. If a date and time value represents a single moment in time, the deserialized value should represent the same moment in time

regardless of the culture or time zone of the system on which it was restored. To round-trip date and time data successfully, you must use the conventions of the invariant culture, which is returned by the [InvariantInfo](#) property, to generate and parse the data. The formatting and parsing operations should never reflect the conventions of the default culture. If you use default cultural settings, the portability of the data is strictly limited; it can be successfully serialized only on a thread whose cultural-specific settings are identical to those of the thread on which it was serialized. In some cases, this means that the data cannot even be successfully serialized and deserialized on the same system.

If the time component of a date and time value is significant, it should also be converted to UTC and serialized by using the "o" or "r" [standard format string](#). The time data can then be restored by calling a parsing method and passing it the appropriate format string along with the invariant culture as the `provider` argument.

The following example illustrates the process of round-tripping a date and time value. It serializes a date and time on a system that observes U.S. Pacific time and whose current culture is en-US.

C#

```
using System;
using System.Globalization;
using System.IO;

public class SerializeEx1
{
    public static void Main()
    {
        StreamWriter sw = new StreamWriter(@".\DateData.dat");
        // Define a date and time to serialize.
        DateTime originalDate = new DateTime(2014, 08, 18, 08, 16, 35);
        // Display information on the date and time.
        Console.WriteLine("Date to serialize: {0:F}", originalDate);
        Console.WriteLine("Current Culture: {0}",
                          CultureInfo.CurrentCulture.Name);
        Console.WriteLine("Time Zone: {0}",
                          TimeZoneInfo.Local.DisplayName);
        // Convert the date value to UTC.
        DateTime utcDate = originalDate.ToUniversalTime();
        // Serialize the UTC value.
        sw.Write(utcDate.ToString("o", DateTimeFormatInfo.InvariantInfo));
        sw.Close();
    }
}
// The example displays the following output:
//      Date to serialize: Monday, August 18, 2014 8:16:35 AM
```

```
//      Current Culture: en-US
//      Time Zone:          (UTC-08:00) Pacific Time (US & Canada)
```

It deserializes the data on a system in the Brussels, Copenhagen, Madrid and Paris time zone and whose current culture is fr-FR. The restored date is nine hours later than the original date, which reflects the time zone adjustment from eight hours behind UTC to one hour ahead of UTC. Both the original date and the restored date represent the same moment in time.

C#

```
using System;
using System.Globalization;
using System.IO;

public class SerializeEx2
{
    public static void Main()
    {
        // Open the file and retrieve the date string.
        StreamReader sr = new StreamReader(@".\DateData.dat");
        String dateValue = sr.ReadToEnd();

        // Parse the date.
        DateTime parsedDate = DateTime.ParseExact(dateValue, "o",
                                                    DateTimeFormatInfo.InvariantInfo);
        // Convert it to local time.
        DateTime restoredDate = parsedDate.ToLocalTime();
        // Display information on the date and time.
        Console.WriteLine("Deserialized date: {0:F}", restoredDate);
        Console.WriteLine("Current Culture:  {0}",
                          CultureInfo.CurrentCulture.Name);
        Console.WriteLine("Time Zone:       {0}",
                          TimeZoneInfo.Local.DisplayName);
    }
}

// The example displays the following output:
//      Deserialized date: lundi 18 août 2014 17:16:35
//      Current Culture:   fr-FR
//      Time Zone:         (UTC+01:00) Brussels, Copenhagen, Madrid, Paris
```

NumberFormatInfo class

Article • 12/30/2023

This article provides supplementary remarks to the reference documentation for this API.

The [NumberFormatInfo](#) class contains culture-specific information that is used when you format and parse numeric values. This information includes the currency symbol, the decimal symbol, the group separator symbol, and the symbols for positive and negative signs.

Instantiate a NumberFormatInfo object

You can instantiate a [NumberFormatInfo](#) object that represents the formatting conventions of the current culture, the invariant culture, a specific culture, or a neutral culture.

Instantiate a NumberFormatInfo object for the current culture

You can instantiate a [NumberFormatInfo](#) object for the current culture in any of the following ways. In each case, the returned [NumberFormatInfo](#) object is read-only.

- By retrieving a [CultureInfo](#) object that represents the current culture from the [CultureInfo.CurrentCulture](#) property, and retrieving the [CultureInfo](#) object from its [CultureInfo.NumberFormat](#) property.
- By retrieving the [NumberFormatInfo](#) object returned by the `static` (`Shared` in Visual Basic) [CurrentInfo](#) property.
- By calling the [GetInstance](#) method with a [CultureInfo](#) object that represents the current culture.

The following example uses these three ways to create [NumberFormatInfo](#) objects that represent the formatting conventions of the current culture. It also retrieves the value of the [IsReadOnly](#) property to illustrate that each object is read-only.

C#

```
using System;
using System.Globalization;
```

```

public class InstantiateEx1
{
    public static void Main()
    {
        NumberFormatInfo current1 = CultureInfo.CurrentCulture.NumberFormat;
        Console.WriteLine(current1.IsReadOnly);

        NumberFormatInfo current2 = NumberFormatInfo.CurrentInfo;
        Console.WriteLine(current2.IsReadOnly);

        NumberFormatInfo current3 =
NumberFormatInfo.GetInstance(CultureInfo.CurrentCulture);
        Console.WriteLine(current3.IsReadOnly);
    }
}

// The example displays the following output:
//      True
//      True
//      True

```

You can create a writable [NumberFormatInfo](#) object that represents the conventions of the current culture in any of the following ways:

- By retrieving a [NumberFormatInfo](#) object in any of the ways illustrated in the previous code example, and calling the [Clone](#) method on the returned [NumberFormatInfo](#) object. This creates a copy of the original [NumberFormatInfo](#) object, except that its [IsReadOnly](#) property is `false`.
- By calling the [CultureInfo.CreateSpecificCulture](#) method to create a [CultureInfo](#) object that represents the current culture, and then using its [CultureInfo.NumberFormat](#) property to retrieve the [NumberFormatInfo](#) object.

The following example illustrates these two ways of instantiating a [NumberFormatInfo](#) object, and displays the value of its [IsReadOnly](#) property to illustrate that the object is not read-only.

C#

```

using System;
using System.Globalization;

public class InstantiateEx2
{
    public static void Main()
    {
        NumberFormatInfo current1 = NumberFormatInfo.CurrentInfo;
        current1 = (NumberFormatInfo)current1.Clone();
        Console.WriteLine(current1.IsReadOnly);

        CultureInfo culture2 =

```

```

CultureInfo.CreateSpecificCulture(CultureInfo.CurrentCulture.Name);
    NumberFormatInfo current2 = culture2.NumberFormat;
    Console.WriteLine(current2.IsReadOnly);
}
}
// The example displays the following output:
//      False
//      False

```

Note that the Windows operating system allows the user to override some of the [NumberFormatInfo](#) property values used in numeric formatting and parsing operations through the **Region and Language** item in Control Panel. For example, a user whose culture is English (United States) might choose to display currency values as 1.1 USD instead of the default of \$1.1. The [NumberFormatInfo](#) objects retrieved in the ways discussed previously all reflect these user overrides. If this is undesirable, you can create a [NumberFormatInfo](#) object that does not reflect user overrides (and that is also read/write rather than read-only) by calling the [CultureInfo.CultureInfo\(String, Boolean\)](#) constructor and supplying a value of `false` for the `useUserOverride` argument. The following example provides an illustration for a system whose current culture is English (United States) and whose currency symbol has been changed from the default of \$ to USD.

C#

```

using System;
using System.Globalization;

public class InstantiateEx3
{
    public static void Main()
    {
        CultureInfo culture;
        NumberFormatInfo nfi;

        culture = CultureInfo.CurrentCulture;
        nfi = culture.NumberFormat;
        Console.WriteLine("Culture Name: {0}", culture.Name);
        Console.WriteLine("User Overrides: {0}", culture.UseUserOverride);
        Console.WriteLine("Currency Symbol: {0}\n",
culture.NumberFormat.CurrencySymbol);

        culture = new CultureInfo(CultureInfo.CurrentCulture.Name, false);
        Console.WriteLine("Culture Name: {0}", culture.Name);
        Console.WriteLine("User Overrides: {0}", culture.UseUserOverride);
        Console.WriteLine("Currency Symbol: {0}",
culture.NumberFormat.CurrencySymbol);
    }
}
// The example displays the following output:

```

```
//      Culture Name:    en-US
//      User Overrides:  True
//      Currency Symbol: USD
//
//      Culture Name:    en-US
//      User Overrides:  False
//      Currency Symbol: $
```

If the [CultureInfo.UseUserOverride](#) property is set to `true`, the properties [CultureInfo.DateTimeFormat](#), [CultureInfo.NumberFormat](#), and [CultureInfo.TextInfo](#) are also retrieved from the user settings. If the user settings are incompatible with the culture associated with the [CultureInfo](#) object (for example, if the selected calendar is not one of the calendars listed by the [OptionalCalendars](#) property), the results of the methods and the values of the properties are undefined.

Instantiate a [NumberFormatInfo](#) object for the invariant culture

The invariant culture represents a culture that is culture-insensitive. It is based on the English language but not on any specific English-speaking country/region. Although the data of specific cultures can be dynamic and can change to reflect new cultural conventions or user preferences, the data of the invariant culture does not change. A [NumberFormatInfo](#) object that represents the formatting conventions of the invariant culture can be used for formatting operations in which result strings should not vary by culture.

You can instantiate a [NumberFormatInfo](#) object that represents the formatting conventions of the invariant culture in the following ways:

- By retrieving the value of the [InvariantInfo](#) property. The returned [NumberFormatInfo](#) object is read-only.
- By retrieving the value of the [CultureInfo.NumberFormat](#) property from the [CultureInfo](#) object that is returned by the [CultureInfo.InvariantCulture](#) property. The returned [NumberFormatInfo](#) object is read-only.
- By calling the parameterless [NumberFormatInfo](#) class constructor. The returned [NumberFormatInfo](#) object is read/write.

The following example uses each of these methods to instantiate a [NumberFormatInfo](#) object that represents the invariant culture. It then indicates whether the object is read-only,

```

using System;
using System.Globalization;

public class InstantiateEx4
{
    public static void Main()
    {
        NumberFormatInfo nfi;

        nfi = System.Globalization.NumberFormatInfo.InvariantInfo;
        Console.WriteLine(nfi.IsReadOnly);

        nfi = CultureInfo.InvariantCulture.NumberFormat;
        Console.WriteLine(nfi.IsReadOnly);

        nfi = new NumberFormatInfo();
        Console.WriteLine(nfi.IsReadOnly);
    }
}

// The example displays the following output:
//      True
//      True
//      False

```

Instantiate a `NumberFormatInfo` object for a specific culture

A specific culture represents a language that is spoken in a particular country/region. For example, en-US is a specific culture that represents the English language spoken in the United States, and en-CA is a specific culture that represents the English language spoken in Canada. You can instantiate a `NumberFormatInfo` object that represents the formatting conventions of a specific culture in the following ways:

- By calling the `CultureInfo.GetCultureInfo(String)` method and retrieving the value of the returned `CultureInfo` object's `NumberFormat` property. The returned `NumberFormatInfo` object is read-only.
- By passing a `CultureInfo` object that represents the culture whose `NumberFormatInfo` object you want to retrieve to the static `GetInstance` method. The returned `NumberFormatInfo` object is read/write.
- By calling the `CultureInfo.CreateSpecificCulture` method and retrieving the value of the returned `CultureInfo` object's `NumberFormat` property. The returned `NumberFormatInfo` object is read/write.

- By calling one of the `CultureInfo.CultureInfo` class constructors and retrieving the value of the returned `CultureInfo` object's `NumberFormat` property. The returned `NumberFormatInfo` object is read/write.

The following example uses these four ways to create a `NumberFormatInfo` object that reflects the formatting conventions of the Indonesian (Indonesia) culture. It also indicates whether each object is read-only.

C#

```
using System;
using System.Globalization;

public class InstantiateEx5
{
    public static void Main()
    {
        CultureInfo culture;
        NumberFormatInfo nfi;

        nfi = CultureInfo.GetCultureInfo("id-ID").NumberFormat;
        Console.WriteLine("Read-only: {0}", nfi.IsReadOnly);

        culture = new CultureInfo("id-ID");
        nfi = NumberFormatInfo.GetInstance(culture);
        Console.WriteLine("Read-only: {0}", nfi.IsReadOnly);

        culture = CultureInfo.CreateSpecificCulture("id-ID");
        nfi = culture.NumberFormat;
        Console.WriteLine("Read-only: {0}", nfi.IsReadOnly);

        culture = new CultureInfo("id-ID");
        nfi = culture.NumberFormat;
        Console.WriteLine("Read-only: {0}", nfi.IsReadOnly);
    }
}

// The example displays the following output:
//      Read-only: True
//      Read-only: False
//      Read-only: False
//      Read-only: False
```

Instantiate a `NumberFormatInfo` object for a neutral culture

A neutral culture represents a culture or language that is independent of a country/region. It is typically the parent of one or more specific cultures. For example, fr is a neutral culture for the French language and the parent of the fr-FR culture. You

create a [NumberFormatInfo](#) object that represents the formatting conventions of a neutral culture in the same way that you create a [NumberFormatInfo](#) object that represents the formatting conventions of a specific culture.

However, because it is independent of a specific country/region, a neutral culture lacks culture-specific formatting information. Rather than populating the [NumberFormatInfo](#) object with generic values, .NET returns a [NumberFormatInfo](#) object that reflects the formatting conventions of a specific culture that is a child of the neutral culture. For example, the [NumberFormatInfo](#) object for the neutral en culture reflects the formatting conventions of the en-US culture, and the [NumberFormatInfo](#) object for the fr culture reflects the formatting conventions of the fr-FR culture.

You can use code like the following to determine which specific culture's formatting conventions each neutral culture represents.

C#

```
using System;
using System.Collections;
using System.Collections.Generic;
using System.Globalization;
using System.Reflection;

public class InstantiateEx6
{
    public static void Main()
    {
        // Get all the neutral cultures
        List<String> names = new List<String>();
        Array.ForEach(CultureInfo.GetCultures(CultureTypes.NeutralCultures),
                     culture => names.Add(culture.Name));
        names.Sort();
        foreach (var name in names)
        {
            // Ignore the invariant culture.
            if (name == "") continue;

            ListSimilarChildCultures(name);
        }
    }

    private static void ListSimilarChildCultures(string name)
    {
        // Create the neutral NumberFormatInfo object.
        NumberFormatInfo nfi =
        CultureInfo.GetCultureInfo(name).NumberFormat;
        // Retrieve all specific cultures of the neutral culture.
        CultureInfo[] cultures =
        Array.FindAll(CultureInfo.GetCultures(CultureTypes.SpecificCultures),
                     culture => culture.Name.StartsWith(name +
```

```

"-", StringComparison.OrdinalIgnoreCase));
// Create an array of NumberFormatInfo properties
PropertyInfo[] properties =
typeof(NumberFormatInfo).GetProperties(BindingFlags.Instance |
BindingFlags.Public);
bool hasOneMatch = false;

foreach (var ci in cultures)
{
    bool match = true;
    // Get the NumberFormatInfo for a specific culture.
    NumberFormatInfo specificNfi = ci.NumberFormat;
    // Compare the property values of the two.
    foreach (var prop in properties)
    {
        // We're not interested in the value of IsReadOnly.
        if (prop.Name == "IsReadOnly") continue;

        // For arrays, iterate the individual elements to see if
they are the same.
        if (prop.PropertyType.IsArray)
        {
            IList nList = (IList)prop.GetValue(nfi, null);
            IList sList = (IList)prop.GetValue(specificNfi, null);
            if (nList.Count != sList.Count)
            {
                match = false;
                break;
            }

            for (int ctr = 0; ctr < nList.Count; ctr++)
            {
                if (!nList[ctr].Equals(sList[ctr]))
                {
                    match = false;
                    break;
                }
            }
        }
        else if
(!prop.GetValue(specificNfi).Equals(prop.GetValue(nfi)))
        {
            match = false;
            break;
        }
    }
    if (match)
    {
        Console.WriteLine("NumberFormatInfo object for '{0}' matches
'{1}'",
                           name, ci.Name);
        hasOneMatch = true;
    }
}
if (!hasOneMatch)

```

```
        Console.WriteLine("NumberFormatInfo object for '{0}' --> No  
Match", name);  
  
        Console.WriteLine();  
    }  
}
```

Dynamic data

The culture-specific data for formatting numeric values provided by the [NumberFormatInfo](#) class is dynamic, just like the cultural data provided by the [CultureInfo](#) class. You should not make any assumptions about the stability of values for [NumberFormatInfo](#) objects that are associated with particular [CultureInfo](#) objects. Only the data provided by the invariant culture and its associated [NumberFormatInfo](#) object is stable. Other data can change between application sessions, or even within a single session, for the following reasons:

- **System updates.** Cultural preferences such as the currency symbol or currency formats change over time. When this happens, Windows Update includes changes to the [NumberFormatInfo](#) property value for a particular culture.
- **Replacement cultures.** The [CultureAndRegionInfoBuilder](#) class can be used to replace the data of an existing culture.
- **Cascading changes to property values.** A number of culture-related properties can change at run time, which, in turn, causes [NumberFormatInfo](#) data to change. For example, the current culture can be changed either programmatically or through user action. When this happens, the [NumberFormatInfo](#) object returned by the [CurrentInfo](#) property changes to an object associated with the current culture.
- **User preferences.** Users of your application might override some of the values associated with the current system culture through the region and language options in Control Panel. For example, users might choose a different currency symbol or a different decimal separator symbol. If the [CultureInfo.UseUserOverride](#) property is set to `true` (its default value), the properties of the [NumberFormatInfo](#) object are also retrieved from the user settings.

All user-overridable properties of a [NumberFormatInfo](#) object are initialized when the object is created. There is still a possibility of inconsistency, because neither object creation nor the user override process is atomic, and the relevant values may change during object creation. However, these inconsistencies should be extremely rare.

You can control whether user overrides are reflected in [NumberFormatInfo](#) objects that represent the same culture as the current culture. The following table lists the ways in which a [NumberFormatInfo](#) object can be retrieved and indicates whether the resulting object reflects user overrides.

 Expand table

| Source of CultureInfo and NumberFormatInfo object | Reflects user overrides |
|---|--|
| <code>CultureInfo.CurrentCulture.NumberFormat</code> property | Yes |
| <code>NumberFormatInfo.CurrentInfo</code> property | Yes |
| <code>CultureInfo.CreateSpecificCulture</code> method | Yes |
| <code>CultureInfo.GetCultureInfo</code> method | No |
| <code>CultureInfo(String)</code> constructor | Yes |
| <code>CultureInfo.CultureInfo(String, Boolean)</code> constructor | Depends on value of <code>useUserOverride</code> parameter |

Unless there is a compelling reason to do otherwise, you should respect user overrides when you use the [NumberFormatInfo](#) object in client applications to format and parse user input or to display numeric data. For server applications or unattended applications, you should not respect user overrides. However, if you are using the [NumberFormatInfo](#) object either explicitly or implicitly to persist numeric data in string form, you should either use a [NumberFormatInfo](#) object that reflects the formatting conventions of the invariant culture, or you should specify a custom numeric format string that you use regardless of culture.

IFormatProvider, NumberFormatInfo, and numeric formatting

A [NumberFormatInfo](#) object is used implicitly or explicitly in all numeric formatting operations. These include calls to the following methods:

- All numeric formatting methods, such as [Int32.ToString](#), [Double.ToString](#), and [Convert.ToString\(Int32\)](#).
- The major composite formatting method, [String.Format](#).
- Other composite formatting methods, such as [Console.WriteLine\(String, Object\[\]\)](#) and [StringBuilder.AppendFormat\(String, Object\[\]\)](#).

All numeric formatting operations make use of an [IFormatProvider](#) implementation. The [IFormatProvider](#) interface includes a single method, [GetFormat\(Type\)](#). This is a callback method that is passed a [Type](#) object that represents the type needed to provide formatting information. The method is responsible for returning either an instance of that type or `null`, if it cannot provide an instance of the type. .NET provides two [IFormatProvider](#) implementations for formatting numbers:

- The [CultureInfo](#) class, which represents a specific culture (or a specific language in a specific country/region). In a numeric formatting operation, the [CultureInfo.GetFormat](#) method returns the [NumberFormatInfo](#) object associated with its [CultureInfo.NumberFormat](#) property.
- The [NumberFormatInfo](#) class, which provides information about the formatting conventions of its associated culture. The [NumberFormatInfo.GetFormat](#) method returns an instance of itself.

If an [IFormatProvider](#) implementation is not provided to a formatting method explicitly, a [CultureInfo](#) object returned by the [CultureInfo.CurrentCulture](#) property that represents the current culture is used.

The following example illustrates the relationship between the [IFormatProvider](#) interface and the [NumberFormatInfo](#) class in formatting operations by defining a custom [IFormatProvider](#) implementation. Its [GetFormat](#) method displays the type name of the object requested by the formatting operation. If the interface is requesting a [NumberFormatInfo](#) object, this method provides the [NumberFormatInfo](#) object for the current culture. As the output from the example shows, the [Decimal.ToString\(IFormatProvider\)](#) method requests a [NumberFormatInfo](#) object to provide formatting information, whereas the [String.Format\(IFormatProvider, String, Object\[\]\)](#) method requests [NumberFormatInfo](#) and [DateTimeFormatInfo](#) objects as well as an [ICustomFormatter](#) implementation.

C#

```
using System;
using System.Globalization;

public class CurrentCultureFormatProvider : IFormatProvider
{
    public Object GetFormat(Type formatType)
    {
        Console.WriteLine("Requesting an object of type {0}",
            formatType.Name);
        if (formatType == typeof(NumberFormatInfo))
            return NumberFormatInfo.CurrentInfo;
        else if (formatType == typeof(DateTimeFormatInfo))
            return DateTimeFormatInfo.CurrentInfo;
```

```

        else
            return null;
    }

public class FormatProviderEx
{
    public static void Main()
    {
        Decimal amount = 1203.541m;
        string value = amount.ToString("C2", new
CurrentCultureFormatProvider());
        Console.WriteLine(value);
        Console.WriteLine();
        string composite = String.Format(new CurrentCultureFormatProvider(),
                                         "Date: {0}    Amount: {1}
Description: {2}",
                                         DateTime.Now, 1264.03m, "Service
Charge");
        Console.WriteLine(composite);
        Console.WriteLine();
    }
}

// The example displays output like the following:
// Requesting an object of type NumberFormatInfo
// $1,203.54
//
// Requesting an object of type ICustomFormatter
// Requesting an object of type DateTimeFormatInfo
// Requesting an object of type NumberFormatInfo
// Date: 11/15/2012 2:00:01 PM    Amount: 1264.03    Description: Service
Charge

```

If an [IFormatProvider](#) implementation is not explicitly provided in a numeric formatting method call, the method calls the `CultureInfo.CurrentCulture.GetFormat` method, which returns the [NumberFormatInfo](#) object that corresponds to the current culture.

Format strings and NumberFormatInfo properties

Every formatting operation uses either a standard or a custom numeric format string to produce a result string from a number. In some cases, the use of a format string to produce a result string is explicit, as in the following example. This code calls the `Decimal.ToString(IFormatProvider)` method to convert a [Decimal](#) value to a number of different string representations by using the formatting conventions of the en-US culture.

```

using System;
using System.Globalization;

public class PropertiesEx1
{
    public static void Main()
    {
        string[] formatStrings = { "C2", "E1", "F", "G3", "N",
                                   "#,##0.000", "0,000,000,000.0##" };
        CultureInfo culture = CultureInfo.CreateSpecificCulture("en-US");
        Decimal[] values = { 1345.6538m, 1921651.16m };

        foreach (var value in values)
        {
            foreach (var formatString in formatStrings)
            {
                string resultString = value.ToString(formatString, culture);
                Console.WriteLine("{0,-18} --> {1}", formatString,
resultString);
            }
            Console.WriteLine();
        }
    }
}

// The example displays the following output:
//      C2          --> $1,345.65
//      E1          --> 1.3E+003
//      F           --> 1345.65
//      G3          --> 1.35E+03
//      N           --> 1,345.65
//      #,##0.000    --> 1,345.654
//      0,000,000,000.0## --> 0,000,001,345.654
//
//      C2          --> $1,921,651.16
//      E1          --> 1.9E+006
//      F           --> 1921651.16
//      G3          --> 1.92E+06
//      N           --> 1,921,651.16
//      #,##0.000    --> 1,921,651.160
//      0,000,000,000.0## --> 0,001,921,651.16

```

In other cases, the use of a format string is implicit. For example, in the following method calls to the default or parameterless `Decimal.ToString()` method, the value of the `Decimal` instance is formatted by using the general ("G") format specifier and the conventions of the current culture, which in this case is the en-US culture.

C#

```

using System;

public class PropertiesEx2

```

```

{
    public static void Main()
    {
        Decimal[] values = { 1345.6538m, 1921651.16m };

        foreach (var value in values)
        {
            string resultString = value.ToString();
            Console.WriteLine(resultString);
            Console.WriteLine();
        }
    }
}

// The example displays the following output:
//      1345.6538
//
//      1921651.16

```

Each standard numeric format string uses one or more [NumberFormatInfo](#) properties to determine the pattern or the symbols used in the result string. Similarly, each custom numeric format specifier except "0" and "#" insert symbols in the result string that are defined by [NumberFormatInfo](#) properties. The following table lists the standard and custom numeric format specifiers and their associated [NumberFormatInfo](#) properties. To change the appearance of the result string for a particular culture, see the [Modify NumberFormatInfo properties](#) section. For details about the use of these format specifiers, see [Standard Numeric Format Strings](#) and [Custom Numeric Format Strings](#).

[] [Expand table](#)

| Format specifier | Associated properties |
|--|--|
| "C" or "c" (currency format specifier) | CurrencyDecimalDigits , to define the default number of fractional digits. CurrencyDecimalSeparator , to define the decimal separator symbol. CurrencyGroupSeparator , to define the group or thousands separator. CurrencyGroupSizes , to define the sizes of integral groups. |
| | CurrencyNegativePattern , to define the pattern of negative currency values. |
| | CurrencyPositivePattern , to define the pattern of positive currency values. |

| Format specifier | Associated properties |
|---|---|
| | <p>CurrencySymbol, to define the currency symbol.</p> <p>NegativeSign, to define the negative sign symbol.</p> |
| "D" or "d" (decimal format specifier) | <p>NegativeSign, to define the negative sign symbol.</p> |
| "E" or "e" (exponential or scientific format specifier) | <p>NegativeSign, to define the negative sign symbol in the mantissa and exponent.</p> <p>NumberDecimalSeparator, to define the decimal separator symbol.</p> <p>PositiveSign, to define the positive sign symbol in the exponent.</p> |
| "F" or "f" (fixed-point format specifier) | <p>NegativeSign, to define the negative sign symbol.</p> <p>NumberDecimalDigits, to define the default number of fractional digits.</p> <p>NumberDecimalSeparator, to define the decimal separator symbol.</p> |
| "G" or "g" (general format specifier) | <p>NegativeSign, to define the negative sign symbol.</p> <p>NumberDecimalSeparator, to define the decimal separator symbol.</p> <p>PositiveSign, to define the positive sign symbol for result strings in exponential format.</p> |
| "N" or "n" (number format specifier) | <p>NegativeSign, to define the negative sign symbol.</p> <p>NumberDecimalDigits, to define the default number of fractional digits.</p> <p>NumberDecimalSeparator, to define the decimal separator symbol.</p> <p>NumberGroupSeparator, to define the group separator (thousands) symbol.</p> <p>NumberGroupSizes, to define the number of integral digits in a group.</p> <p>NumberNegativePattern, to define the format of negative values.</p> |
| "P" or "p" (percent format specifier) | <p>NegativeSign, to define the negative sign symbol.</p> |

| | |
|--|---|
| Format specifier | <p>PercentDecimalDigits, to define the default number of fractional digits.</p> <p>PercentDecimalSeparator, to define the decimal separator symbol.</p> <p>PercentGroupSeparator, to define the group separator symbol.</p> <p>PercentGroupSizes, to define the number of integral digits in a group.</p> <p>PercentNegativePattern, to define the placement of the percent symbol and the negative symbol for negative values.</p> <p>PercentPositivePattern, to define the placement of the percent symbol for positive values.</p> <p>PercentSymbol, to define the percent symbol.</p> |
| "R" or "r" (round-trip format specifier) | <p>NegativeSign, to define the negative sign symbol.</p> <p>NumberDecimalSeparator, to define the decimal separator symbol.</p> <p>PositiveSign, to define the positive sign symbol in an exponent.</p> |
| "X" or "x" (hexadecimal format specifier) | None. |
| "." (decimal point custom format specifier) | NumberDecimalSeparator , to define the decimal separator symbol. |
| "," (group separator custom format specifier) | NumberGroupSeparator , to define the group (thousands) separator symbol. |
| "%" (percentage placeholder custom format specifier) | PercentSymbol , to define the percent symbol. |
| "‰" (per mille placeholder custom format specifier) | PerMilleSymbol , to define the per mille symbol. |
| "E" (exponential notation custom format specifier) | <p>NegativeSign, to define the negative sign symbol in the mantissa and exponent.</p> <p>PositiveSign, to define the positive sign symbol in the exponent.</p> |

Note that the [NumberFormatInfo](#) class includes a [NativeDigits](#) property that specifies the base 10 digits used by a specific culture. However, the property is not used in formatting operations; only the Basic Latin digits 0 (U+0030) through 9 (U+0039) are

used in the result string. In addition, for [Single](#) and [Double](#) values of `NaN`, `PositiveInfinity`, and `NegativeInfinity`, the result string consists exclusively of the symbols defined by the [NaNSymbol](#), [PositiveInfinitySymbol](#), and [NegativeInfinitySymbol](#) properties, respectively.

Modify NumberFormatInfo properties

You can modify the properties of a [NumberFormatInfo](#) object to customize the result string produced in a numeric formatting operation. To do this:

1. Create a read/write copy of a [NumberFormatInfo](#) object whose formatting conventions you want to modify. For more information, see the [Instantiate a NumberFormatInfo object](#) section.
2. Modify the property or properties that are used to produce the desired result string. For information about how formatting methods use [NumberFormatInfo](#) properties to define result strings, see the [Format strings and NumberFormatInfo properties](#) section.
3. Use the custom [NumberFormatInfo](#) object as the [IFormatProvider](#) argument in calls to formatting methods.

ⓘ Note

Instead of dynamically modifying a culture's property values each time an application is started, you can use the [CultureAndRegionInfoBuilder](#) class to define either a custom culture (a culture that has a unique name and that supplements existing cultures) or a replacement culture (one that is used instead of a specific culture).

The following sections provide some examples.

Modify the currency symbol and pattern

The following example modifies a [NumberFormatInfo](#) object that represents the formatting conventions of the en-US culture. It assigns the ISO-4217 currency symbol to the [CurrencySymbol](#) property and defines a pattern for currency values that consists of the currency symbol followed by a space and a numeric value.

C#

```

using System;
using System.Globalization;

public class Example
{
    public static void Main()
    {
        // Retrieve a writable NumberFormatInfo object.
        CultureInfo enUS = CultureInfo.CreateSpecificCulture("en-US");
        NumberFormatInfo nfi = enUS.NumberFormat;

        // Use the ISO currency symbol instead of the native currency
        symbol.
        nfi.CurrencySymbol = (new RegionInfo(enUS.Name)).ISOCurrencySymbol;
        // Change the positive currency pattern to <code><space><value>.
        nfi.CurrencyPositivePattern = 2;
        // Change the negative currency pattern to <code><space><sign>
        <value>.
        nfi.CurrencyNegativePattern = 12;

        // Produce the result strings by calling ToString.
        Decimal[] values = { 1065.23m, 19.89m, -.03m, -175902.32m };
        foreach (var value in values)
            Console.WriteLine(value.ToString("C", enUS));

        Console.WriteLine();

        // Produce the result strings by calling a composite formatting
        method.
        foreach (var value in values)
            Console.WriteLine(String.Format(enUS, "{0:C}", value));
    }
}

// The example displays the following output:
//      USD 1,065.23
//      USD 19.89
//      USD -0.03
//      USD -175,902.32
//
//      USD 1,065.23
//      USD 19.89
//      USD -0.03
//      USD -175,902.32

```

Format a national identification number

Many national identification numbers consist exclusively of digits and so can easily be formatted by modifying the properties of a [NumberFormatInfo](#) object. For example, a social security number in the United States consists of 9 digits arranged as follows: xxx-

xx-xxxx. The following example assumes that social security numbers are stored as integer values and formats them appropriately.

C#

```
using System;
using System.Globalization;

public class CustomizeSSNEx
{
    public static void Main()
    {
        // Instantiate a read-only NumberFormatInfo object.
        CultureInfo enUS = CultureInfo.CreateSpecificCulture("en-US");
        NumberFormatInfo nfi = enUS.NumberFormat;

        // Modify the relevant properties.
        nfi.NumberGroupSeparator = "-";
        nfi.NumberGroupSizes = new int[] { 3, 2, 4 };
        nfi.NumberDecimalDigits = 0;

        int[] ids = { 111223333, 999776666 };

        // Produce the result string by calling ToString.
        foreach (var id in ids)
            Console.WriteLine(id.ToString("N", enUS));

        Console.WriteLine();

        // Produce the result string using composite formatting.
        foreach (var id in ids)
            Console.WriteLine(String.Format(enUS, "{0:N}", id));
    }
}

// The example displays the following output:
//      1112-23-333
//      9997-76-666
//
//      1112-23-333
//      9997-76-666
```

Parse numeric strings

Parsing involves converting the string representation of a number to a number. Each numeric type in .NET includes two overloaded parsing methods: `Parse` and `TryParse`. The `Parse` method converts a string to a number and throws an exception if the conversion fails. The `TryParse` method converts a string to a number, assigns the number to an `out` argument, and returns a `Boolean` value that indicates whether the conversion succeeded.

The parsing methods implicitly or explicitly use a [NumberStyles](#) enumeration value to determine what style elements (such as group separators, a decimal separator, or a currency symbol) can be present in a string if the parsing operation is to succeed. If a [NumberStyles](#) value is not provided in the method call, the default is a [NumberStyles](#) value that includes the [Float](#) and [AllowThousands](#) flags, which specifies that the parsed string can include group symbols, a decimal separator, a negative sign, and white-space characters, or it can be the string representation of a number in exponential notation.

The parsing methods also implicitly or explicitly use a [NumberFormatInfo](#) object that defines the specific symbols and patterns that can occur in the string to be parsed. If a [NumberFormatInfo](#) object is not provided, the default is the [NumberFormatInfo](#) for the current culture. For more information about parsing, see the individual parsing methods, such as [Int16.Parse\(String\)](#), [Int32.Parse\(String, NumberStyles\)](#), [Int64.Parse\(String, IFormatProvider\)](#), [Decimal.Parse\(String, NumberStyles, IFormatProvider\)](#), [Double.TryParse\(String, Double\)](#), and [BigInteger.TryParse\(String, NumberStyles, IFormatProvider, BigInteger\)](#).

The following example illustrates the culture-sensitive nature of parsing strings. It tries to parse a string that include thousands separators by using the conventions of the en-US, fr-FR, and invariant cultures. A string that includes the comma as a group separator and the period as a decimal separator fails to parse in the fr-FR culture, and a string with white space as a group separator and a comma as a decimal separator fails to parse in the en-US and invariant cultures.

C#

```
using System;
using System.Globalization;

public class ParseEx1
{
    public static void Main()
    {
        String[] values = { "1,034,562.91", "9 532 978,07" };
        String[] cultureNames = { "en-US", "fr-FR", "" };

        foreach (var value in values)
        {
            foreach (var cultureName in cultureNames)
            {
                CultureInfo culture =
CultureInfo.CreateSpecificCulture(cultureName);
                String name = culture.Name == "" ? "Invariant" :
culture.Name;
                try
                {
                    Decimal amount = Decimal.Parse(value, culture);
                }
            }
        }
    }
}
```

```

                Console.WriteLine("'{0}' --> {1} ({2})", value, amount,
name);
            }
            catch (FormatException)
            {
                Console.WriteLine("'{0}': FormatException ({1})",
value, name);
            }
        }
        Console.WriteLine();
    }
}
// The example displays the following output:
//      '1,034,562.91' --> 1034562.91 (en-US)
//      '1,034,562.91': FormatException (fr-FR)
//      '1,034,562.91' --> 1034562.91 (Invariant)
//
//      '9 532 978,07': FormatException (en-US)
//      '9 532 978,07' --> 9532978.07 (fr-FR)
//      '9 532 978,07': FormatException (Invariant)

```

Parsing generally occurs in two contexts:

- As an operation that is designed to convert user input into a numeric value.
- As an operation that is designed to round-trip a numeric value; that is, to deserialize a numeric value that was previously serialized as a string.

The following sections discuss these two operations in greater detail.

Parse user strings

When you are parsing numeric strings input by the user, you should always instantiate a [NumberFormatInfo](#) object that reflects the user's cultural settings. For information about how to instantiate a [NumberFormatInfo](#) object that reflects user customizations, see the [Dynamic data](#) section.

The following example illustrates the difference between a parsing operation that reflects user cultural settings and one that does not. In this case, the default system culture is en-US, but the user has defined "," as the decimal symbol and "." as the group separator in Control Panel, **Region and Language**. Ordinarily, these symbols are reversed in the default en-US culture. When the user enters a string that reflects user settings, and the string is parsed by a [NumberFormatInfo](#) object that also reflects user settings (overrides), the parsing operation returns a correct result. However, when the string is parsed by a [NumberFormatInfo](#) object that reflects standard en-US cultural

settings, it mistakes the comma symbol for a group separator and returns an incorrect result.

```
C#  
  
using System;  
using System.Globalization;  
  
public class ParseUserEx  
{  
    public static void Main()  
    {  
        CultureInfo stdCulture = CultureInfo.GetCultureInfo("en-US");  
        CultureInfo custCulture = CultureInfo.CreateSpecificCulture("en-US");  
  
        String value = "310,16";  
        try  
        {  
            Console.WriteLine("{0} culture reflects user overrides: {1}",  
                stdCulture.Name, stdCulture.UseUserOverride);  
            Decimal amount = Decimal.Parse(value, stdCulture);  
            Console.WriteLine("'{0}' --> {1}", value,  
                amount.ToString(CultureInfo.InvariantCulture));  
        }  
        catch (FormatException)  
        {  
            Console.WriteLine("Unable to parse '{0}'", value);  
        }  
        Console.WriteLine();  
  
        try  
        {  
            Console.WriteLine("{0} culture reflects user overrides: {1}",  
                custCulture.Name,  
                custCulture.UseUserOverride);  
            Decimal amount = Decimal.Parse(value, custCulture);  
            Console.WriteLine("'{0}' --> {1}", value,  
                amount.ToString(CultureInfo.InvariantCulture));  
        }  
        catch (FormatException)  
        {  
            Console.WriteLine("Unable to parse '{0}'", value);  
        }  
    }  
}  
// The example displays the following output:  
//      en-US culture reflects user overrides: False  
//      '310,16' --> 31016  
//  
//      en-US culture reflects user overrides: True  
//      '310,16' --> 310.16
```

Serialize and deserialize numeric data

When numeric data is serialized in string format and later deserialized and parsed, the strings should be generated and parsed by using the conventions of the invariant culture. The formatting and parsing operations should never reflect the conventions of a specific culture. If culture-specific settings are used, the portability of the data is strictly limited; it can be successfully deserialized only on a thread whose culture-specific settings are identical to those of the thread on which it was serialized. In some cases, this means that the data cannot even be successfully deserialized on the same system on which it was serialized.

The following example illustrates what can happen when this principle is violated. Floating-point values in an array are converted to strings when the current thread uses the culture-specific settings of the en-US culture. The data is then parsed by a thread that uses the culture-specific settings of the pt-BR culture. In this case, although each parsing operation succeeds, the data doesn't round-trip successfully and data corruption occurs. In other cases, a parsing operation could fail and a [FormatException](#) exception could be thrown.

C#

```
using System;
using System.Collections.Generic;
using System.Globalization;
using System.IO;
using System.Threading;

public class ParsePersistedEx
{
    public static void Main()
    {
        CultureInfo.CurrentCulture = CultureInfo.CreateSpecificCulture("en-US");
        PersistData();

        CultureInfo.CurrentCulture = CultureInfo.CreateSpecificCulture("pt-BR");
        RestoreData();
    }

    private static void PersistData()
    {
        // Define an array of floating-point values.
        Double[] values = { 160325.972, 8631.16, 1.304e5, 98017554.385,
                           8.5938287084321676e94 };
        Console.WriteLine("Original values: ");
        foreach (var value in values)
            Console.WriteLine(value.ToString("R",
                CultureInfo.InvariantCulture));
    }
}
```

```

// Serialize an array of doubles to a file
StreamWriter sw = new StreamWriter(@".\NumericData.bin");
for (int ctr = 0; ctr < values.Length; ctr++)
{
    sw.Write(values[ctr].ToString("R"));
    if (ctr < values.Length - 1) sw.Write("|");
}
sw.Close();
Console.WriteLine();
}

private static void RestoreData()
{
    // Deserialize the data
    StreamReader sr = new StreamReader(@".\NumericData.bin");
    String data = sr.ReadToEnd();
    sr.Close();

    String[] stringValues = data.Split('|');
    List<Double> newValueList = new List<Double>();

    foreach (var stringValue in stringValues)
    {
        try
        {
            newValueList.Add(Double.Parse(stringValue));
        }
        catch (FormatException)
        {
            newValueList.Add(Double.NaN);
        }
    }

    Console.WriteLine("Restored values:");
    foreach (var newValue in newValueList)
        Console.WriteLine(newValue.ToString("R",
NumberFormatInfo.InvariantInfo));
}

// The example displays the following output:
//      Original values:
//      160325.972
//      8631.16
//      130400
//      98017554.385
//      8.5938287084321671E+94
//
//      Restored values:
//      160325972
//      863116
//      130400
//      98017554385
//      8.5938287084321666E+110

PersianCalendar class

Article • 12/30/2023

This article provides supplementary remarks to the reference documentation for this API.

The Persian calendar is used in most countries/regions where Persian is spoken, although some regions use different month names. The Persian calendar is the official calendar of Iran and Afghanistan, and it is one of the alternative calendars in regions such as Kazakhstan and Tajikistan.

ⓘ Note

For information about using the [PersianCalendar](#) class and the other calendar classes in .NET, see [Working with Calendars](#).

The Persian calendar is a solar Hijri calendar, and starts from the year of the Hijra, which corresponds to 622 C.E. the year when Muhammad (PBUH) migrated from Mecca to Medina.

The Persian calendar is based on a solar year and is approximately 365 days long. A year cycles through four seasons, and a new year begins when the sun appears to cross the equator from the southern hemisphere to the northern hemisphere as viewed from the center of the Earth. The new year marks the first day of the month of Farvardeen, which is the first day of spring in the northern hemisphere. For example, the date March 21, 2002 C.E. corresponds to the first day of the month of Farvardeen in the year 1381 Anno Persico.

Each of the first six months in the Persian calendar has 31 days, each of the next five months has 30 days, and the last month has 29 days in a common year and 30 days in a leap year. A leap year is a year that, when divided by 33, has a remainder of 1, 5, 9, 13, 17, 22, 26, or 30. For example, the year 1370 is a leap year because dividing it by 33 yields a remainder of 17. There are approximately eight leap years in every 33-year cycle.

The PersianCalendar class and .NET Framework versions

Starting with .NET Framework 4.6, the [PersianCalendar](#) class uses the Hijri solar astronomical algorithm rather than an observational algorithm to calculate dates. This makes the [PersianCalendar](#) implementation consistent with the Persian calendar in use

in Iran and Afghanistan, the two countries in which the Persian calendar is in most widespread use. The change affects all apps running on the .NET Framework 4 or later if the .NET Framework 4.6 is installed.

As a result of the changed algorithm:

- The two algorithms should return identical results when converting dates between 1800 and 2123 in the Gregorian calendar.
- The two algorithms may return different results when converting dates before 1800 and after 2123 in the Gregorian calendar.
- The [MinSupportedDateTime](#) property value has changed from March 21, 0622 in the Gregorian calendar to March 22, 0622 in the Gregorian calendar.
- The [MaxSupportedDateTime](#) property value has changed from the 10th day of the 10th month of the year 9378 in the Persian calendar to the 13th day of the 10th month of the year 9378 in the Persian calendar.
- The [IsLeapYear](#) method may return a different result than it did previously.

Use the [PersianCalendar](#) class

Applications use a [PersianCalendar](#) object to calculate dates in the Persian calendar or convert Persian dates to and from Gregorian dates.

You cannot use a [PersianCalendar](#) object as the default calendar for a culture. The default calendar is specified by the [CultureInfo.Calendar](#) property and must be one of the calendars returned by the [CultureInfo.OptionalCalendars](#) property. Currently, the [PersianCalendar](#) class is not an optional calendar for any culture supported by the [CultureInfo](#) class and consequently cannot be a default calendar.

RegionInfo class

Article • 12/30/2023

This article provides supplementary remarks to the reference documentation for this API.

Unlike the [CultureInfo](#) class, the [RegionInfo](#) class does not represent user preferences and does not depend on the user's language or culture.

Names associated with a RegionInfo object

The name of a [RegionInfo](#) object is one of the two-letter codes defined in ISO 3166 for country/region. Case is not significant. The [Name](#), [TwoLetterISORegionName](#), and [ThreeLetterISORegionName](#) properties return the appropriate codes in uppercase. For the current list of [RegionInfo](#) names, see [ISO 3166: Country codes ↗](#).

Instantiate a RegionInfo object

To instantiate a [RegionInfo](#) object, you pass the [RegionInfo\(String\)](#) constructor either a two-letter region name, such as "US" for the United States, or the name of a specific culture, such as "en-US" for English (United States). However, we recommend that you use a specific culture name instead of a two-letter region name, because a [RegionInfo](#) object is not completely language-independent. Several [RegionInfo](#) properties, including [DisplayName](#), [NativeName](#), and [CurrencyNativeName](#), depend on culture names.

The following example illustrates the difference in [RegionInfo](#) property values for three objects that represent Belgium. The first is instantiated from a region name (`BE`) only, while the second and third are instantiated from culture names (`fr-BE` for French (Belgium) and `nl-BE` for Dutch (Belgium), respectively). The example uses reflection to retrieve the property values of each [RegionInfo](#) object.

C#

```
using System;
using System.Globalization;
using System.Reflection;

public class Example
{
    public static void Main()
    {
```

```

        // Instantiate three Belgian RegionInfo objects.
        RegionInfo BE = new RegionInfo("BE");
        RegionInfo frBE = new RegionInfo("fr-BE");
        RegionInfo nlBE = new RegionInfo("nl-BE");

        RegionInfo[] regions = { BE, frBE, nlBE };
        PropertyInfo[] props =
typeof(RegionInfo).GetProperties(BindingFlags.Instance |
BindingFlags.Public);

        Console.WriteLine("{0,-30}{1,18}{2,18}{3,18}\n",
                        "RegionInfo Property", "BE", "fr-BE", "nl-BE");
        foreach (var prop in props)
        {
            Console.Write("{0,-30}", prop.Name);
            foreach (var region in regions)
                Console.Write("{0,18}", prop.GetValue(region, null));

            Console.WriteLine();
        }
    }
}

// The example displays the following output:
//      RegionInfo Property           BE          fr-BE
nl-BE
//
//      Name                      BE          fr-BE
nl-BE
//      EnglishName               Belgium     Belgium
Belgium
//      DisplayName               Belgium     Belgium
Belgium
//      NativeName                België     Belgique
België
//      TwoLetterISORegionName    BE          BE
BE
//      ThreeLetterISORegionName BEL         BEL
BEL
//      ThreeLetterWindowsRegionName BEL         BEL
BEL
//      IsMetric                  True        True
True
//      GeoId                     21          21
21
//      CurrencyEnglishName      Euro        Euro
Euro
//      CurrencyNativeName       euro        euro
euro
//      CurrencySymbol            €           €
€
//      ISOCurrencySymbol        EUR        EUR
EUR

```

In scenarios such as the following, use culture names instead of country/region names when you instantiate a [RegionInfo](#) object:

- When the language name is of primary importance. For example, for the `es-US` culture name, you'll probably want your application to display "Estados Unidos" instead of "United States". Using the country/region name (`us`) alone yields "United States" regardless of the language, so you should work with the culture name instead.
- When script differences must be considered. For example, the country/region `AZ` deals with Azerbaijani cultures that have the names `az-Latn-AZ` and `az-Cyr1-AZ`, and the Latin and Cyrillic scripts can be very different for this country/region.
- When maintenance of detail is important. The values returned by [RegionInfo](#) members can differ depending on whether the [RegionInfo](#) object was instantiated by using a culture name or a region name. For example, the following table lists the differences in return values when a [RegionInfo](#) object is instantiated by using the "US" region, the "en-US" culture, and the "es-US" culture.

 Expand table

| Member | "US" | "en-US" | "es-US" |
|------------------------------------|---------------|---------------|-----------------|
| CurrencyNativeName | US Dollar | US Dollar | Dólar de EE.UU. |
| Name | US | en-US | es-US |
| NativeName | United States | United States | Estados Unidos |
| ToString | US | en-US | es-US |

SortKey class

Article • 12/30/2023

This article provides supplementary remarks to the reference documentation for this API.

A culture-sensitive comparison of two strings depends on each character in the strings having several categories of sort weights, including script, alphabetic, case, and diacritic weights. A sort key serves as the repository of these weights for a particular string.

The [CompareInfo.GetSortKey](#) method returns an instance of the [SortKey](#) class that reflects the culture-sensitive mapping of characters in a specified string. The value of a [SortKey](#) object is its key data, which is returned by the [KeyData](#) property. This key data consists of a series of bytes that encode the string, culture-specific sorting rules, and user-specified comparison options. A comparison using sort keys consists of a bitwise comparison of the corresponding key data in each sort key. For example, if you create a sort key by calling the [GetSortKey\(String, CompareOptions\)](#) method with a value of [CompareOptions.IgnoreCase](#), a string comparison operation that uses the sort key is case-insensitive.

After you create a sort key for a string, you compare sort keys by calling the static [SortKey.Compare](#) method. This method performs a simple byte-by-byte comparison, so it is much faster than the [String.Compare](#) or [CompareInfo.Compare](#) method.

ⓘ Note

You can download the [Sorting Weight Tables](#), a set of text files that contain information on the character weights used in sorting and comparison operations for Windows operating systems, the [Default Unicode Collation Element Table](#), the sort weight table for Linux and macOS.

Performance considerations

When performing a string comparison, the [Compare](#) and [CompareInfo.Compare](#) methods yield the same results, but they target different scenarios.

At a high level, the [CompareInfo.Compare](#) method generates the sort key for each string, performs the comparison, and then discards the sort key and returns the result of the comparison. However, the [CompareInfo.Compare](#) method actually doesn't generate an entire sort key to perform the comparison. Instead, the method generates the key

data for each text element (that is, base character, surrogate pair, or combining character sequence) in each string. The method then compares the key data for the corresponding text elements. The operation terminates as soon as the ultimate result of the comparison is determined. Sort key information is computed, but no [SortKey](#) object is created. This strategy is economical in terms of performance if both strings are compared once, but becomes expensive if the same strings are compared many times.

The [Compare](#) method requires generation of a [SortKey](#) object for each string before performing the comparison. This strategy is expensive in terms of performance for the first comparison because of the time and memory invested to generate the [SortKey](#) objects. However, it becomes economical if the same sort keys are compared many times.

For example, suppose you write an application that searches a database table for the row in which the string-based index column matches a specified search string. The table contains thousands of rows, and comparing the search string to the index in each row will take a long time. Therefore, when the application stores a row and its index column, it also generates and stores the sort key for the index in a column dedicated to improving search performance. When the application searches for a target row, it compares the sort key for the search string to the sort key for the index string, instead of comparing the search string to the index string.

Security considerations

The [CompareInfo.GetSortKey\(String, CompareOptions\)](#) method returns a [SortKey](#) object with the value based on a specified string and [CompareOptions](#) value, and the culture associated with the underlying [CompareInfo](#) object. If a security decision depends on a string comparison or case change, you should use the [CompareInfo.GetSortKey\(String, CompareOptions\)](#) method of the invariant culture to ensure that the behavior of the operation is consistent, regardless of the culture settings of the operating system.

Use the following steps to obtain a sort key:

1. Retrieve the invariant culture from the [CultureInfo.InvariantCulture](#) property.
2. Retrieve a [CompareInfo](#) object for the invariant culture from the [CultureInfo.CompareInfo](#) property.
3. Call the [CompareInfo.GetSortKey\(String, CompareOptions\)](#) method.

Working with the value of a [SortKey](#) object is equivalent to calling the Windows [LCMapString](#) method with the LCMAP_SORTKEY value specified. However, for the

[SortKey](#) object, the sort keys for English characters precede the sort keys for Korean characters.

[SortKey](#) objects can be serialized, but only so that they can cross [AppDomain](#) objects. If an application serializes a [SortKey](#) object, the application must regenerate all the sort keys when there is a new version of the .NET Framework.

For more information about sort keys, see Unicode Technical Standard #10, "Unicode Collation Algorithm" on the [Unicode Consortium website](#).

SortVersion class

Article • 12/30/2023

This article provides supplementary remarks to the reference documentation for this API.

Sorting and string comparison in .NET Framework

Through .NET Framework 4, each version of .NET Framework included tables that contained sort weights and data on string normalization and that are based on a particular version of Unicode. In .NET Framework 4.5 and later versions, the presence of these tables depends on the operating system:

- On Windows 7 and previous versions, the tables continue to be used for comparing and ordering strings.
- On Windows 8, .NET Framework delegates string comparison and ordering operations to the operating system.

Consequently, the result of a string comparison can depend not only on the .NET Framework version, but also on the operating system version, as the following table shows. Note that this list of supported Unicode versions applies to character comparison and sorting only; it does not apply to classification of Unicode characters by category.

[+] Expand table

| .NET Framework version | Operating system | Unicode version |
|------------------------|------------------------------|-----------------|
| 4 | All operating systems | Unicode 5.0 |
| 4.5 and later versions | Windows 7 | Unicode 5.0 |
| 4.5 and later versions | Windows 8 and later versions | Unicode 6.0 |

On Windows 8, because the version of Unicode used in string comparison and ordering depends on the version of the operating system, the results of string comparison may differ even for applications that run on a specific version of .NET Framework.

Sorting and string comparison in .NET Core

All versions of .NET (Core) rely on the underlying operating system when performing string comparisons. Therefore, the results of a string comparison or the order in which strings are sorted depends on the version of Unicode used by the operating system when performing the comparison. On Linux, macOS, and Windows 10 and later versions, [International Components for Unicode](#) ↗ libraries provide the implementation for comparison and sorting APIs.

Use the `SortVersion` class

The `SortVersion` class provides information about the Unicode version used by .NET for string comparison and ordering. It enables developers to write applications that can detect and successfully handle changes in the version of Unicode that is used to compare and sort an application's strings.

You can instantiate a `SortVersion` object in two ways:

- By calling the `SortVersion` constructor, which instantiates a new `SortVersion` object based on a version number and sort ID. This constructor is most useful when recreating a `SortVersion` object from saved data.
- By retrieving the value of the `CompareInfo.Version` property. This property provides information about the Unicode version used by the .NET implementation on which the application is running.

The `SortVersion` class has two properties, `FullVersion` and `SortId`, that indicate the Unicode version and the specific culture used for string comparison. The `FullVersion` property is an arbitrary numeric value that reflects the Unicode version used for string comparison, and the `SortId` property is an arbitrary `Guid` that reflects the culture whose conventions are used for string comparison. The values of these two properties are important only when you compare two `SortVersion` objects by using the `Equals` method, the `Equality` operator, or the `Inequality` operator.

You typically use a `SortVersion` object when saving or retrieving some form of culture-sensitive, ordered string data, such as indexes or the literal strings themselves. This requires the following steps:

1. When the ordered string data is saved, the `FullVersion` and `SortId` property values are also saved.
2. When the ordered string data is retrieved, you can recreate the `SortVersion` object used for ordering the strings by calling the `SortVersion` constructor.
3. This newly instantiated `SortVersion` object is compared with a `SortVersion` object that reflects the culture whose conventions are used to order the string data.

4. If the two `SortVersion` objects are not equal, the string data must be reordered.

Resources in .NET apps

Article • 03/18/2023

Nearly every production-quality app has to use resources. A resource is any non-executable data that is logically deployed with an app. A resource might be displayed in an app as error messages or as part of the user interface. Resources can contain data in a number of forms, including strings, images, and persisted objects. (To write persisted objects to a resource file, the objects must be serializable.) Storing your data in a resource file enables you to change the data without recompiling your entire app. It also enables you to store data in a single location, and eliminates the need to rely on hard-coded data that is stored in multiple locations.

.NET provides comprehensive support for the creation and [localization](#) of resources. In addition, .NET supports a simple model for packaging and deploying localized resources.

Create and localize resources

In a non-localized app, you can use resource files as a repository for app data, particularly for strings that might otherwise be hard-coded in multiple locations in source code. Most commonly, you create resources as either text (.txt) or XML (.resx) files, and use [Resgen.exe \(Resource File Generator\)](#) to compile them into binary .resources files. These files can then be embedded in the app's executable file by a language compiler. For more information about creating resources, see [Create resource files](#).

You can also localize your app's resources for specific cultures. This enables you to build localized (translated) versions of your apps. When you develop an app that uses localized resources, you designate a culture that serves as the neutral or fallback culture whose resources are used if no suitable resources are available. Typically, the resources of the neutral culture are stored in the app's executable. The remaining resources for individual localized cultures are stored in standalone satellite assemblies. For more information, see [Create satellite assemblies](#).

Package and deploy resources

You deploy localized app resources in [satellite assemblies](#). A satellite assembly contains the resources of a single culture; it does not contain any app code. In the satellite assembly deployment model, you create an app with one default assembly (which is typically the main assembly) and one satellite assembly for each culture that the app

supports. Because the satellite assemblies are not part of the main assembly, you can easily replace or update resources corresponding to a specific culture without replacing the app's main assembly.

Carefully determine which resources will make up your app's default resource assembly. Because it is a part of the main assembly, any changes to it will require you to replace the main assembly. If you do not provide a default resource, an exception will be thrown when the [resource fallback process](#) attempts to find it. In a well-designed app, using resources should never throw an exception.

For more information, see the [Packaging and Deploying Resources](#) article.

Retrieve resources

At run time, an app loads the appropriate localized resources on a per-thread basis, based on the culture specified by the [CultureInfo.CurrentCulture](#) property. This property value is derived as follows:

- By directly assigning a [CultureInfo](#) object that represents the localized culture to the [Thread.CurrentCulture](#) property.
- If a culture is not explicitly assigned, by retrieving the default thread UI culture from the [CultureInfo.DefaultThreadCurrentUICulture](#) property.
- If a default thread UI culture is not explicitly assigned, by retrieving the culture for the current user on the local computer. .NET implementations running on Windows do this by calling the Windows [GetUserDefaultUILanguage](#) function.

For more information about how the current UI culture is set, see the [CultureInfo](#) and [CultureInfo.CurrentCulture](#) reference pages.

You can then retrieve resources for the current UI culture or for a specific culture by using the [System.Resources.ResourceManager](#) class. Although the [ResourceManager](#) class is most commonly used for retrieving resources, the [System.Resources](#) namespace contains additional types that you can use to retrieve resources. These include:

- The [ResourceReader](#) class, which enables you to enumerate resources embedded in an assembly or stored in a standalone binary .resources file. It is useful when you don't know the precise names of the resources that are available at run time.
- The [ResXResourceReader](#) class, which enables you to retrieve resources from an XML (.resx) file.

- The [ResourceSet](#) class, which enables you to retrieve the resources of a specific culture without observing fallback rules. The resources can be stored in an assembly or a standalone binary .resources file. You can also develop an [IResourceReader](#) implementation that enables you to use the [ResourceSet](#) class to retrieve resources from some other source.
- The [ResXResourceSet](#) class, which enables you to retrieve all the items in an XML resource file into memory.

Create resource files for .NET apps

Article • 03/18/2023

You can include resources, such as strings, images, or object data, in resources files to make them easily available to your application. The .NET Framework offers five ways to create resources files:

- Create a text file that contains string resources. You can use [Resource File Generator \(resgen.exe\)](#) to convert the text file into a binary resource (.resources) file. You can then embed the binary resource file in an application executable or an application library by using a language compiler, or you can embed it in a satellite assembly by using [Assembly Linker \(Al.exe\)](#). For more information, see the [Resources in text files](#) section.
- Create an XML resource (.resx) file that contains string, image, or object data. You can use [Resource File Generator \(resgen.exe\)](#) to convert the .resx file into a binary resource (.resources) file. You can then embed the binary resource file in an application executable or an application library by using a language compiler, or you can embed it in a satellite assembly by using [Assembly Linker \(Al.exe\)](#). For more information, see the [Resources in .resx Files](#) section.
- Create an XML resource (.resx) file programmatically by using types in the [System.Resources](#) namespace. You can create a .resx file, enumerate its resources, and retrieve specific resources by name. For more information, see [Working with .resx Files Programmatically](#).
- Create a binary resource (.resources) file programmatically. You can then embed the file in an application executable or an application library by using a language compiler, or you can embed it in a satellite assembly by using [Assembly Linker \(Al.exe\)](#). For more information, see the [Resources in .resources Files](#) section.
- Use [Visual Studio](#) to create a resource file and include it in your project. Visual Studio provides a resource editor that lets you add, delete, and modify resources. At compile time, the resource file is automatically converted to a binary .resources file and embedded in an application assembly or satellite assembly. For more information, see the [Resource files in Visual Studio](#) section.

Resources in text files

You can use text (.txt or .restext) files to store string resources only. For non-string resources, use .resx files or create them programmatically. Text files that contain string

resources have the following format:

```
text

# This is an optional comment.
name = value

; This is another optional comment.
name = value

; The following supports conditional compilation if X is defined.
#ifndef X
name1=value1
name2=value2
#endif

# The following supports conditional compilation if Y is undefined.
#ifndef !Y
name1=value1
name2=value2
#endif
```

The resource file format of .txt and .restext files is identical. The .restext file extension merely serves to make text files immediately identifiable as text-based resource files.

String resources appear as *name/value* pairs, where *name* is a string that identifies the resource, and *value* is the resource string that is returned when you pass *name* to a resource retrieval method such as [ResourceManager.GetString](#). *name* and *value* must be separated by an equal sign (=). For example:

```
text

FileMenuName=File
EditMenuName>Edit
ViewMenuName=View
HelpMenuName=Help
```

⊗ Caution

Do not use resource files to store passwords, security-sensitive information, or private data.

Empty strings (that is, a resource whose value is [String.Empty](#)) are permitted in text files. For example:

```
text
```

```
EmptyString=
```

Starting with .NET Framework 4.5 and in all versions of .NET Core, text files support conditional compilation with the `#ifdef symbol... #endif` and `#if !symbol... #endif` constructs. You can then use the `/define` switch with [Resource File Generator \(resgen.exe\)](#) to define symbols. Each resource requires its own `#ifdef symbol... #endif` or `#if !symbol... #endif` construct. If you use an `#ifdef` statement and *symbol* is defined, the associated resource is included in the .resources file; otherwise, it is not included. If you use an `#if !` statement and *symbol* is not defined, the associated resource is included in the .resources file; otherwise, it is not included.

Comments are optional in text files and are preceded either by a semicolon (;) or by a pound sign (#) at the beginning of a line. Lines that contain comments can be placed anywhere in the file. Comments are not included in a compiled .resources file that is created by using [Resource File Generator \(resgen.exe\)](#).

Any blank lines in the text files are considered to be white space and are ignored.

The following example defines two string resources named `OKButton` and `CancelButton`.

```
text
```

```
#Define resources for buttons in the user interface.  
OKButton=OK  
CancelButton=Cancel
```

If the text file contains duplicate occurrences of *name*, [Resource File Generator \(resgen.exe\)](#) displays a warning and ignores the second name.

value cannot contain new line characters, but you can use C language-style escape characters such as `\n` to represent a new line and `\t` to represent a tab. You can also include a backslash character if it is escaped (for example, "`\`"). In addition, an empty string is permitted.

Save resources in text file format by using UTF-8 encoding or UTF-16 encoding in either little-endian or big-endian byte order. However, [Resource File Generator \(resgen.exe\)](#), which converts a .txt file to a .resources file, treats files as UTF-8 by default. If you want Resgen.exe to recognize a file that was encoded using UTF-16, you must include a Unicode byte order mark (U+FEFF) at the beginning of the file.

To embed a resource file in text format into a .NET assembly, you must convert the file to a binary resource (.resources) file by using [Resource File Generator \(resgen.exe\)](#). You

can then embed the .resources file in a .NET assembly by using a language compiler or embed it in a satellite assembly by using [Assembly Linker \(Al.exe\)](#).

The following example uses a resource file in text format named GreetingResources.txt for a simple "Hello World" console application. The text file defines two strings, `prompt` and `greeting`, that prompt the user to enter their name and display a greeting.

text

```
# GreetingResources.txt
# A resource file in text format for a "Hello World" application.
#
# Initial prompt to the user.
prompt=Enter your name:
# Format string to display the result.
greeting=Hello, {0}!
```

The text file is converted to a .resources file by using the following command:

Console

```
resgen GreetingResources.txt
```

The following example shows the source code for a console application that uses the .resources file to display messages to the user.

C#

```
using System;
using System.Reflection;
using System.Resources;

public class Example
{
    public static void Main()
    {
        ResourceManager rm = new ResourceManager("GreetingResources",
                                                typeof(Example).Assembly);
        Console.WriteLine(rm.GetString("prompt"));
        string name = Console.ReadLine();
        Console.WriteLine(rm.GetString("greeting"), name);
    }
}
// The example displays output like the following:
//      Enter your name: Wilberforce
//      Hello, Wilberforce!
```

If you are using Visual Basic, and the source code file is named Greeting.vb, the following command creates an executable file that includes the embedded .resources file:

```
Console  
vbc greeting.vb -resource:GreetingResources.resources
```

If you are using C#, and the source code file is named Greeting.cs, the following command creates an executable file that includes the embedded .resources file:

```
Console  
csc greeting.cs -resource:GreetingResources.resources
```

Resources in .resx files

Unlike text files, which can only store string resources, XML resource (.resx) files can store strings, binary data such as images, icons, and audio clips, and programmatic objects. A .resx file contains a standard header, which describes the format of the resource entries and specifies the versioning information for the XML that is used to parse the data. The resource file data follows the XML header. Each data item consists of a name/value pair that is contained in a `data` tag. Its `name` attribute defines the resource name, and the nested `value` tag contains the resource value. For string data, the `value` tag contains the string.

For example, the following `data` tag defines a string resource named `prompt` whose value is "Enter your name:".

```
XML  
<data name="prompt" xml:space="preserve">  
  <value>Enter your name:</value>  
</data>
```

⚠ Warning

Do not use resource files to store passwords, security-sensitive information, or private data.

For resource objects, the `data` tag includes a `type` attribute that indicates the data type of the resource. For objects that consist of binary data, the `data` tag also includes a `mimetype` attribute, which indicates the `base64` type of the binary data.

Note

All .resx files use a binary serialization formatter to generate and parse the binary data for a specified type. As a result, a .resx file can become invalid if the binary serialization format for an object changes in an incompatible way.

The following example shows a portion of a .resx file that includes an `Int32` resource and a bitmap image.

XML

```
<data name="i1" type="System.Int32, mscorelbin">
  <value>20</value>
</data>

<data name="flag" type="System.Drawing.Bitmap, System.Drawing,
  Version=1.0.5000.0, Culture=neutral, PublicKeyToken=b03f5f7f11d50a3a"
  mimetype="application/x-microsoft.net.object.bytearray.base64">
  <value>
    AAEAAAD/////AQAAAAAAAAMAgAAADtTeX...
  </value>
</data>
```

Important

Because .resx files must consist of well-formed XML in a predefined format, we do not recommend working with .resx files manually, particularly when the .resx files contain resources other than strings. Instead, [Visual Studio](#) provides a transparent interface for creating and manipulating .resx files. For more information, see the [Resource files in Visual Studio](#) section. You can also create and manipulate .resx files programmatically. For more information, see [Work with .resx files programmatically](#).

Resources in .resources files

You can use the [System.Resources.ResourceWriter](#) class to programmatically create a binary resource (.resources) file directly from code. You can also use [Resource File Generator \(resgen.exe\)](#) to create a .resources file from a text file or a .resx file. The

.resources file can contain binary data (byte arrays) and object data in addition to string data. Programmatically creating a .resources file requires the following steps:

1. Create a [ResourceWriter](#) object with a unique file name. You can do this by specifying either a file name or a file stream to a [ResourceWriter](#) class constructor.
2. Call one of the overloads of the [ResourceWriter.AddResource](#) method for each named resource to add to the file. The resource can be a string, an object, or a collection of binary data (a byte array).
3. Call the [ResourceWriter.Close](#) method to write the resources to the file and to close the [ResourceWriter](#) object.

 **Note**

Do not use resource files to store passwords, security-sensitive information, or private data.

The following example programmatically creates a .resources file named CarResources.resources that stores six strings, an icon, and two application-defined objects (two `Automobile` objects). The `Automobile` class, which is defined and instantiated in the example, is tagged with the [SerializableAttribute](#) attribute, which allows it to be persisted by the binary serialization formatter.

C#

```
using System;
using System.Drawing;
using System.Resources;

[Serializable()] public class Automobile
{
    private string carMake;
    private string carModel;
    private int carYear;
    private int carDoors;
    private int carCylinders;

    public Automobile(string make, string model, int year) :
        this(make, model, year, 0, 0)
    { }

    public Automobile(string make, string model, int year,
                      int doors, int cylinders)
    {
        this.carMake = make;
        this.carModel = model;
```

```
        this.carYear = year;
        this.carDoors = doors;
        this.carCylinders = cylinders;
    }

    public string Make {
        get { return this.carMake; }
    }

    public string Model {
        get { return this.carModel; }
    }

    public int Year {
        get { return this.carYear; }
    }

    public int Doors {
        get {
            return this.carDoors; }
    }

    public int Cylinders {
        get {
            return this.carCylinders; }
    }
}

public class Example
{
    public static void Main()
    {
        // Instantiate an Automobile object.
        Automobile car1 = new Automobile("Ford", "Model N", 1906, 0, 4);
        Automobile car2 = new Automobile("Ford", "Model T", 1909, 2, 4);
        // Define a resource file named CarResources.resx.
        using (ResourceWriter rw = new
ResourceWriter(@".\CarResources.resources"))
        {
            rw.AddResource("Title", "Classic American Cars");
            rw.AddResource("HeaderString1", "Make");
            rw.AddResource("HeaderString2", "Model");
            rw.AddResource("HeaderString3", "Year");
            rw.AddResource("HeaderString4", "Doors");
            rw.AddResource("HeaderString5", "Cylinders");
            rw.AddResource("Information", SystemIcons.Information);
            rw.AddResource("EarlyAuto1", car1);
            rw.AddResource("EarlyAuto2", car2);
        }
    }
}
```

After you create the .resources file, you can embed it in a run-time executable or library by including the language compiler's `/resource` switch, or embed it in a satellite assembly by using [Assembly Linker \(Al.exe\)](#).

Resource files in Visual Studio

When you add a resource file to your [Visual Studio](#) project, Visual Studio creates a .resx file in the project directory. Visual Studio provides resource editors that enable you to add strings, images, and binary objects. Because the editors are designed to handle static data only, they cannot be used to store programmatic objects; you must write object data to either a .resx file or to a .resources file programmatically. For more information, see [Work with .resx files programmatically](#) and the [Resources in .resources files](#) section.

If you're adding localized resources, give them the same root file name as the main resource file. You should also designate their culture in the file name. For example, if you add a resource file named *Resources.resx*, you might also create resource files named *Resources.en-US.resx* and *Resources.fr-FR.resx* to hold localized resources for the English (United States) and French (France) cultures, respectively. You should also designate your application's default culture. This is the culture whose resources are used if no localized resources for a particular culture can be found.

To specify the default culture, in **Solution Explorer** in Visual Studio:

- Open the project properties, right-click the project and select **Properties** (or **Alt** + **Enter** when project is selected).
- Select the **Package** tab.
- In the **General** area, select the appropriate language/culture from the **Assembly neutral language** control.
- Save your changes.

At compile time, Visual Studio first converts the .resx files in a project to binary resource (.resources) files and stores them in a subdirectory of the project's *obj* directory. Visual Studio embeds any resource files that do not contain localized resources in the main assembly that is generated by the project. If any resource files contain localized resources, Visual Studio embeds them in separate satellite assemblies for each localized culture. It then stores each satellite assembly in a directory whose name corresponds to the localized culture. For example, localized English (United States) resources are stored in a satellite assembly in the en-US subdirectory.

Work with .resx files programmatically

Article • 03/18/2023

ⓘ Note

This article applies to .NET Framework. For information that applies to .NET 5+ (including .NET Core), see [Resources in .resx files](#).

Because XML resource (.resx) files must consist of well-defined XML, including a header that must follow a specific schema followed by data in name/value pairs, you may find that creating these files manually is error-prone. As an alternative, you can create .resx files programmatically by using types and members in the .NET Class Library. You can also use the .NET Class Library to retrieve resources that are stored in .resx files. This article explains how you can use the types and members in the [System.Resources](#) namespace to work with .resx files.

This article discusses working with XML (.resx) files that contain resources. For information on working with binary resource files that have been embedded in assemblies, see [ResourceManager](#).

⚠ Warning

There are also ways to work with .resx files other than programmatically. When you add a resource file to a [Visual Studio](#) project, Visual Studio provides an interface for creating and maintaining a .resx file, and automatically converts the .resx file to a .resources file at compile time. You can also use a text editor to manipulate a .resx file directly. However, to avoid corrupting the file, be careful not to modify any binary information that is stored in the file.

Create a .resx file

You can use the [System.Resources.ResXResourceWriter](#) class to create a .resx file programmatically, by following these steps:

1. Instantiate a [ResXResourceWriter](#) object by calling the [ResXResourceWriter\(String\)](#) method and supplying the name of the .resx file. The file name must include the .resx extension. If you instantiate the [ResXResourceWriter](#) object in a `using` block, you do not explicitly have to call the [ResXResourceWriter.Close](#) method in step 3.

2. Call the [ResXResourceWriter.AddResource](#) method for each resource you want to add to the file. Use the overloads of this method to add string, object, and binary (byte array) data. If the resource is an object, it must be serializable.
3. Call the [ResXResourceWriter.Close](#) method to generate the resource file and to release all resources. If the [ResXResourceWriter](#) object was created within a `using` block, resources are written to the .resx file and the resources used by the [ResXResourceWriter](#) object are released at the end of the `using` block.

The resulting .resx file has the appropriate header and a `data` tag for each resource added by the [ResXResourceWriter.AddResource](#) method.

 **Warning**

Do not use resource files to store passwords, security-sensitive information, or private data.

The following example creates a .resx file named CarResources.resx that stores six strings, an icon, and two application-defined objects (two `Automobile` objects). The `Automobile` class, which is defined and instantiated in the example, is tagged with the [SerializableAttribute](#) attribute.

C#

```
using System;
using System.Drawing;
using System.Resources;

[Serializable()] public class Automobile
{
    private string carMake;
    private string carModel;
    private int carYear;
    private int carDoors;
    private int carCylinders;

    public Automobile(string make, string model, int year) :
        this(make, model, year, 0, 0)
    { }

    public Automobile(string make, string model, int year,
                      int doors, int cylinders)
    {
        this.carMake = make;
        this.carModel = model;
        this.carYear = year;
        this.carDoors = doors;
    }
}
```

```

        this.carCylinders = cylinders;
    }

    public string Make {
        get { return this.carMake; }
    }

    public string Model {
        get { return this.carModel; }
    }

    public int Year {
        get { return this.carYear; }
    }

    public int Doors {
        get { return this.carDoors; }
    }

    public int Cylinders {
        get { return this.carCylinders; }
    }
}

public class Example
{
    public static void Main()
    {
        // Instantiate an Automobile object.
        Automobile car1 = new Automobile("Ford", "Model N", 1906, 0, 4);
        Automobile car2 = new Automobile("Ford", "Model T", 1909, 2, 4);
        // Define a resource file named CarResources.resx.
        using (ResXResourceWriter resx = new
ResXResourceWriter(@".\CarResources.resx"))
        {
            resx.AddResource("Title", "Classic American Cars");
            resx.AddResource("HeaderString1", "Make");
            resx.AddResource("HeaderString2", "Model");
            resx.AddResource("HeaderString3", "Year");
            resx.AddResource("HeaderString4", "Doors");
            resx.AddResource("HeaderString5", "Cylinders");
            resx.AddResource("Information", SystemIcons.Information);
            resx.AddResource("EarlyAuto1", car1);
            resx.AddResource("EarlyAuto2", car2);
        }
    }
}

```

💡 Tip

You can also use **Visual Studio** to create .resx files. At compile time, Visual Studio uses the **Resource File Generator (Resgen.exe)** to convert the .resx file to a binary

resource (.resources) file, and also embeds it in either an application assembly or a satellite assembly.

You cannot embed a .resx file in a runtime executable or compile it into a satellite assembly. You must convert your .resx file into a binary resource (.resources) file by using the [Resource File Generator \(Resgen.exe\)](#). The resulting .resources file can then be embedded in an application assembly or a satellite assembly. For more information, see [Create resource files](#).

Enumerate resources

In some cases, you may want to retrieve all resources, instead of a specific resource, from a .resx file. To do this, you can use the [System.Resources.ResXResourceReader](#) class, which provides an enumerator for all resources in the .resx file. The [System.Resources.ResXResourceReader](#) class implements [IDictionaryEnumerator](#), which returns a [DictionaryEntry](#) object that represents a particular resource for each iteration of the loop. Its [DictionaryEntry.Key](#) property returns the resource's key, and its [DictionaryEntry.Value](#) property returns the resource's value.

The following example creates a [ResXResourceReader](#) object for the CarResources.resx file created in the previous example and iterates through the resource file. It adds the two `Automobile` objects that are defined in the resource file to a [System.Collections.Generic.List<T>](#) object, and it adds five of the six strings to a [SortedList](#) object. The values in the [SortedList](#) object are converted to a parameter array, which is used to display column headings to the console. The `Automobile` property values are also displayed to the console.

C#

```
using System;
using System.Collections;
using System.Collections.Generic;
using System.Resources;

public class Example
{
    public static void Main()
    {
        string resxFile = @"\CarResources.resx";
        List<Automobile> autos = new List<Automobile>();
        SortedList headers = new SortedList();

        using (ResXResourceReader resxReader = new
ResXResourceReader(resxFile))
        {
```

```

        foreach (DictionaryEntry entry in resxReader) {
            if (((string) entry.Key).StartsWith("EarlyAuto"))
                autos.Add((Automobile) entry.Value);
            else if (((string) entry.Key).StartsWith("Header"))
                headers.Add((string) entry.Key, (string) entry.Value);
        }
    }
    string[] headerColumns = new string[headers.Count];
    headers.GetValueList().CopyTo(headerColumns, 0);
    Console.WriteLine("{0,-8} {1,-10} {2,-4} {3,-5} {4,-9}\n",
                      headerColumns);
    foreach (var auto in autos)
        Console.WriteLine("{0,-8} {1,-10} {2,4} {3,5} {4,9}",
                         auto.Make, auto.Model, auto.Year,
                         auto.Doors, auto.Cylinders);
}
// The example displays the following output:
//      Make      Model      Year   Doors   Cylinders
//
//      Ford      Model N    1906      0       4
//      Ford      Model T    1909      2       4

```

Retrieve a specific resource

In addition to enumerating the items in a .resx file, you can retrieve a specific resource by name by using the [System.Resources.ResXResourceSet](#) class. The [ResourceSet.GetString\(String\)](#) method retrieves the value of a named string resource. The [ResourceSet.GetObject\(String\)](#) method retrieves the value of a named object or binary data. The method returns an object that must then be cast (in C#) or converted (in Visual Basic) to an object of the appropriate type.

The following example retrieves a form's caption string and icon by their resource names. It also retrieves the application-defined `Automobile` objects used in the previous example and displays them in a [DataGridView](#) control.

C#

```

using System;
using System.Collections.Generic;
using System.Drawing;
using System.Resources;
using System.Windows.Forms;

public class CarDisplayApp : Form
{
    private const string resxFile = @"\CarResources.resx";
    Automobile[] cars;

```

```

public static void Main()
{
    CarDisplayApp app = new CarDisplayApp();
    Application.Run(app);
}

public CarDisplayApp()
{
    // Instantiate controls.
    PictureBox pictureBox = new PictureBox();
    pictureBox.Location = new Point(10, 10);
    this.Controls.Add(pictureBox);
    DataGridView grid = new DataGridView();
    grid.Location = new Point(10, 60);
    this.Controls.Add(grid);

    // Get resources from .resx file.
    using (ResXResourceSet resxSet = new ResXResourceSet(resxFfile))
    {
        // Retrieve the string resource for the title.
        this.Text = resxSet.GetString("Title");
        // Retrieve the image.
        Icon image = (Icon) resxSet.GetObject("Information", true);
        if (image != null)
            pictureBox.Image = image.ToBitmap();

        // Retrieve Automobile objects.
        List<Automobile> carList = new List<Automobile>();
        string resName = "EarlyAuto";
        Automobile auto;
        int ctr = 1;
        do {
            auto = (Automobile) resxSet.GetObject(resName + ctr.ToString());
            ctr++;
            if (auto != null)
                carList.Add(auto);
        } while (auto != null);
        cars = carList.ToArray();
        grid.DataSource = cars;
    }
}
}

```

Convert .resx files to binary .resources files

Converting .resx files to embedded binary resource (.resources) files has significant advantages. Although .resx files are easy to read and maintain during application development, they are rarely included with finished applications. If they are distributed with an application, they exist as separate files apart from the application executable and its accompanying libraries. In contrast, .resources files are embedded in the

application executable or its accompanying assemblies. In addition, for localized applications, relying on .resx files at run time places the responsibility for handling resource fallback on the developer. In contrast, if a set of satellite assemblies that contain embedded .resources files has been created, the common language runtime handles the resource fallback process.

To convert a .resx file to a .resources file, you use [Resource File Generator \(resgen.exe\)](#), which has the following basic syntax:

Console

```
resgen.exe .resxFilename
```

The result is a binary resource file that has the same root file name as the .resx file and a .resources file extension. This file can then be compiled into an executable or a library at compile time. If you are using the Visual Basic compiler, use the following syntax to embed a .resources file in an application's executable:

Console

```
vbc filename .vb -resource: .resourcesFilename
```

If you are using C#, the syntax is as follows:

Console

```
csc filename .cs -resource: .resourcesFilename
```

The .resources file can also be embedded in a satellite assembly by using [Assembly Linker \(al.exe\)](#), which has the following basic syntax:

Console

```
al resourcesFilename -out: assemblyFilename
```

Create satellite assemblies for .NET apps

Article • 03/18/2023

Resource files play a central role in localized applications. They enable an application to display strings, images, and other data in the user's language and culture, and provide alternate data if resources for the user's language or culture are unavailable. .NET uses a hub-and-spoke model to locate and retrieve localized resources. The hub is the main assembly that contains the non-localizable executable code and the resources for a single culture, which is called the neutral or default culture. The default culture is the fallback culture for the application; it's used when no localized resources are available. You use the [NeutralResourcesLanguageAttribute](#) attribute to designate the culture of the application's default culture. Each spoke connects to a satellite assembly that contains the resources for a single localized culture but does not contain any code. Because the satellite assemblies aren't part of the main assembly, you can easily update or replace resources that correspond to a specific culture without replacing the main assembly for the application.

Note

The resources of an application's default culture can also be stored in a satellite assembly. To do this, you assign the [NeutralResourcesLanguageAttribute](#) attribute a value of [UltimateResourceFallbackLocation.Satellite](#).

Satellite assembly name and location

The hub-and-spoke model requires that you place resources in specific locations so that they can be easily located and used. If you don't compile and name resources as expected, or if you don't place them in the correct locations, the common language runtime won't be able to locate them and will use the resources of the default culture instead. The .NET resource manager is represented by the [ResourceManager](#) type, and it's used to automatically access localized resources. The resource manager requires the following:

- A single satellite assembly must include all the resources for a particular culture. In other words, you should compile multiple `.txt` or `.resx` files into a single binary `.resources` file.
- There must be a separate subdirectory in the application directory for each localized culture that stores that culture's resources. The subdirectory name must

be the same as the culture name. Alternately, you can store your satellite assemblies in the global assembly cache. In this case, the culture information component of the assembly's strong name must indicate its culture. For more information, see [Install satellite assemblies in the Global Assembly Cache](#).

 **Note**

If your application includes resources for subcultures, place each subculture in a separate subdirectory under the application directory. Do not place subcultures in subdirectories under their main culture's directory.

- The satellite assembly must have the same name as the application, and must use the file name extension ".resources.dll". For example, if an application is named *Example.exe*, the name of each satellite assembly should be *Example.resources.dll*. The satellite assembly name doesn't indicate the culture of its resource files. However, the satellite assembly appears in a directory that does specify the culture.
- Information about the culture of the satellite assembly must be included in the assembly's metadata. To store the culture name in the satellite assembly's metadata, you specify the `/culture` option when you use [Assembly Linker](#) to embed resources in the satellite assembly.

The following illustration shows a sample directory structure and location requirements for applications that you aren't installing in the [global assembly cache](#). The items with *.txt* and *.resources* extensions won't ship with the final application. These are the intermediate resource files used to create the final satellite resource assemblies. In this example, you could substitute *.resx* files for the *.txt* files. For more information, see [Package and deploy resources](#).

The following image shows the satellite assembly directory:

| | |
|----------------------|---|
| MyDir | Main directory for your application |
| MyApp.exe | Main assembly file. Strings.resources is embedded |
| strings.txt | File used to construct strings.resources |
| strings.resources | Default resources file |
| de | German subdirectory, where the German satellite is stored |
| strings.de.txt | Strings file, localized for German |
| strings.de.resources | Resources file, created from the strings file |
| MyApp.resources.dll | Satellite assembly, compiled from strings.de.resources |
| ja | Japanese subdirectory, where the Japanese satellite is stored |
| strings.ja.txt | Strings file, localized for Japanese |
| strings.ja.resources | Resources file, created from the strings file |
| MyApp.resources.dll | Satellite assembly, compiled from strings.ja.resources |
| ... | Additional subdirectories for each culture to support |

Compile satellite assemblies

You use [Resource File Generator \(*resgen.exe*\)](#) to compile text files or XML (.resx) files that contain resources to binary .resources files. You then use [Assembly Linker \(*al.exe*\)](#) to compile .resources files into satellite assemblies. *al.exe* creates an assembly from the .resources files that you specify. Satellite assemblies can contain only resources; they can't contain any executable code.

The following *al.exe* command creates a satellite assembly for the application [Example](#) from the German resources file *strings.de.resources*.

Console

```
al -target:lib -embed:strings.de.resources -culture:de -
out:Example.resources.dll
```

The following *al.exe* command also creates a satellite assembly for the application [Example](#) from the file *strings.de.resources*. The */template* option causes the satellite assembly to inherit all assembly metadata except for its culture information from the parent assembly (*Example.dll*).

Console

```
al -target:lib -embed:strings.de.resources -culture:de -
out:Example.resources.dll -template:Example.dll
```

The following table describes the *al.exe* options used in these commands in more detail:

| Option | Description |
|--|---|
| <code>-target:lib</code> | Specifies that your satellite assembly is compiled to a library (.dll) file. Because a satellite assembly doesn't contain executable code and is not an application's main assembly, you must save satellite assemblies as DLLs. |
| <code>-embed:strings.de.resources</code> | Specifies the name of the resource file to embed when <i>al.exe</i> compiles the assembly. You can embed multiple .resources files in a satellite assembly, but if you are following the hub-and-spoke model, you must compile one satellite assembly for each culture. However, you can create separate .resources files for strings and objects. |
| <code>-culture:de</code> | Specifies the culture of the resource to compile. The common language runtime uses this information when it searches for the resources for a specified culture. If you omit this option, <i>al.exe</i> will still compile the resource, but the runtime won't be able to find it when a user requests it. |
| <code>-out:Example.resources.dll</code> | Specifies the name of the output file. The name must follow the naming standard <i>baseName.resources.extension</i> , where <i>baseName</i> is the name of the main assembly and <i>extension</i> is a valid file name extension (such as .dll). The runtime is not able to determine the culture of a satellite assembly based on its output file name; you must use the <code>/culture</code> option to specify it. |
| <code>-template:Example.dll</code> | Specifies an assembly from which the satellite assembly will inherit all assembly metadata except the culture field. This option affects satellite assemblies only if you specify an assembly that has a strong name . |

For a complete list of options available with *al.exe*, see [Assembly Linker \(*al.exe*\)](#).

ⓘ Note

There may be times when you want to use the .NET Core MSBuild task to compile satellite assemblies, even though you're targeting .NET Framework. For example, you may want to use the C# compiler **deterministic** option to be able to compare assemblies from different builds. In this case, set `GenerateSatelliteAssembliesForCore` to `true` in the `.csproj` file to generate satellite assemblies using `csc.exe` instead of `Al.exe (Assembly Linker)`.

XML

```
<Project>
  <PropertyGroup>
```

```
<GenerateSatelliteAssembliesForCore>true</GenerateSatelliteAssembliesFo  
rCore>  
  </PropertyGroup>  
</Project>
```

The .NET Core MSBuild task uses `csc.exe` instead of `al.exe` to generate satellite assemblies, by default. For more information, see [Make it easier to opt into "Core" satellite assembly generation](#).

Satellite assemblies example

The following is a simple "Hello world" example that displays a message box containing a localized greeting. The example includes resources for the English (United States), French (France), and Russian (Russia) cultures, and its fallback culture is English. To create the example, do the following:

1. Create a resource file named `Greeting.resx` or `Greeting.txt` to contain the resource for the default culture. Store a single string named `HelloString` whose value is "Hello world!" in this file.
2. To indicate that English (en) is the application's default culture, add the following `System.Resources.NeutralResourcesLanguageAttribute` attribute to the application's `AssemblyInfo` file or to the main source code file that will be compiled into the application's main assembly.

C#

```
[assembly: NeutralResourcesLanguage("en")]
```

3. Add support for additional cultures (`en-US`, `fr-FR`, and `ru-RU`) to the application as follows:

- To support the `en-US` or English (United States) culture, create a resource file named `Greeting.en-US.resx` or `Greeting.en-US.txt`, and store in it a single string named `HelloString` whose value is "Hi world!".
- To support the `fr-FR` or French (France) culture, create a resource file named `Greeting.fr-FR.resx` or `Greeting.fr-FR.txt`, and store in it a single string named `HelloString` whose value is "Salut tout le monde!".
- To support the `ru-RU` or Russian (Russia) culture, create a resource file named `Greeting.ru-RU.resx` or `Greeting.ru-RU.txt`, and store in it a single string named

`HelloString` whose value is "Всем привет!".

4. Use `resgen.exe` to compile each text or XML resource file to a binary `.resources` file. The output is a set of files that have the same root file name as the `.resx` or `.txt` files, but a `.resources` extension. If you create the example with Visual Studio, the compilation process is handled automatically. If you aren't using Visual Studio, run the following commands to compile the `.resx` files into `.resources` files:

Console

```
resgen Greeting.resx
resgen Greeting.en-us.resx
resgen Greeting.fr-FR.resx
resgen Greeting.ru-RU.resx
```

If your resources are in text files instead of XML files, replace the `.resx` extension with `.txt`.

5. Compile the following source code along with the resources for the default culture into the application's main assembly:

 **Important**

If you are using the command line rather than Visual Studio to create the example, you should modify the call to the `ResourceManager` class constructor to the following: `ResourceManager rm = new ResourceManager("Greeting", typeof(Example).Assembly);`

C#

```
using System;
using System.Globalization;
using System.Reflection;
using System.Resources;
using System.Threading;
using System.Windows.Forms;

class Example
{
    static void Main()
    {
        // Create array of supported cultures
        string[] cultures = {"en-CA", "en-US", "fr-FR", "ru-RU"};
        Random rnd = new Random();
        int cultureNdx = rnd.Next(0, cultures.Length);
        CultureInfo originalCulture =
```

```
Thread.CurrentCulture;

try {
    CultureInfo newCulture = new
CultureInfo(cultures[cultureNdx]);
    Thread.CurrentCulture.CurrentCulture = newCulture;
    Thread.CurrentCulture.CurrentUICulture = newCulture;
    ResourceManager rm = new ResourceManager("Example.Greeting",
typeof(Example).Assembly);
    string greeting = String.Format("The current culture is
{0}.\n{1}",

Thread.CurrentCulture.CurrentCulture.Name,
rm.GetString("HelloString"));

    MessageBox.Show(greeting);
}
catch (CultureNotFoundException e) {
    Console.WriteLine("Unable to instantiate culture {0}",
e.InvalidCultureName);
}
finally {
    Thread.CurrentCulture.CurrentCulture = originalCulture;
    Thread.CurrentCulture.CurrentUICulture = originalCulture;
}
}
```

If the application is named **Example** and you're compiling from the command line, the command for the C# compiler is:

Console

The corresponding Visual Basic compiler command is:

Console

6. Create a subdirectory in the main application directory for each localized culture supported by the application. You should create an *en-US*, an *fr-FR*, and an *ru-RU* subdirectory. Visual Studio creates these subdirectories automatically as part of the compilation process.
 7. Embed the individual culture-specific *.resources* files into satellite assemblies and save them to the appropriate directory. The command to do this for each

.resources file is:

Console

```
al -target:lib -embed:Greeting.culture.resources -culture:culture -  
out:culture\Example.resources.dll
```

where *culture* is the name of the culture whose resources the satellite assembly contains. Visual Studio handles this process automatically.

You can then run the example. It will randomly make one of the supported cultures the current culture and display a localized greeting.

Install satellite assemblies in the Global Assembly Cache

Instead of installing assemblies in a local application subdirectory, you can install them in the global assembly cache. This is particularly useful if you have class libraries and class library resource assemblies that are used by multiple applications.

Installing assemblies in the global assembly cache requires that they have strong names. Strong-named assemblies are signed with a valid public/private key pair. They contain version information that the runtime uses to determine which assembly to use to satisfy a binding request. For more information about strong names and versioning, see [Assembly versioning](#). For more information about strong names, see [Strong-named assemblies](#).

When you're developing an application, it's unlikely that you'll have access to the final public/private key pair. To install a satellite assembly in the global assembly cache and ensure that it works as expected, you can use a technique called delayed signing. When you delay sign an assembly, at build time you reserve space in the file for the strong name signature. The actual signing is delayed until later, when the final public/private key pair is available. For more information about delayed signing, see [Delay signing an assembly](#).

Obtain the public key

To delay sign an assembly, you must have access to the public key. You can either obtain the real public key from the organization in your company that will do the eventual signing, or create a public key by using the [Strong Name tool \(sn.exe\)](#).

The following *Sn.exe* command creates a test public/private key pair. The **-k** option specifies that *Sn.exe* should create a new key pair and save it in a file named *TestKeyPair.snk*.

Console

```
sn -k TestKeyPair.snk
```

You can extract the public key from the file that contains the test key pair. The following command extracts the public key from *TestKeyPair.snk* and saves it in *PublicKey.snk*:

Console

```
sn -p TestKeyPair.snk PublicKey.snk
```

Delay signing an Assembly

After you obtain or create the public key, you use the [Assembly Linker \(*al.exe*\)](#) to compile the assembly and specify delayed signing.

The following *al.exe* command creates a strong-named satellite assembly for the application StringLibrary from the *strings.ja.resources* file:

Console

```
al -target:lib -embed:strings.ja.resources -culture:ja -  
out:StringLibrary.resources.dll -delay+ -keyfile:PublicKey.snk
```

The **-delay+** option specifies that the Assembly Linker should delay sign the assembly. The **-keyfile** option specifies the name of the key file that contains the public key to use to delay sign the assembly.

Re-signing an Assembly

Before you deploy your application, you must re-sign the delay signed satellite assembly with the real key pair. You can do this by using *Sn.exe*.

The following *Sn.exe* command signs *StringLibrary.resources.dll* with the key pair stored in the file *RealKeyPair.snk*. The **-R** option specifies that a previously signed or delay signed assembly is to be re-signed.

Console

```
sn -R StringLibrary.resources.dll RealKeyValuePair.snk
```

Install a satellite assembly in the Global Assembly Cache

When the runtime searches for resources in the resource fallback process, it looks in the [global assembly cache](#) first. (For more information, see the "Resource Fallback Process" section of [Package and deploy resources](#).) As soon as a satellite assembly is signed with a strong name, it can be installed in the global assembly cache by using the [Global Assembly Cache tool \(gacutil.exe\)](#).

The following *Gacutil.exe* command installs *StringLibrary.resources.dll** in the global assembly cache:

Console

```
gacutil -i:StringLibrary.resources.dll
```

The */i* option specifies that *Gacutil.exe* should install the specified assembly into the global assembly cache. After the satellite assembly is installed in the cache, the resources it contains become available to all applications that are designed to use the satellite assembly.

Resources in the Global Assembly Cache: An Example

The following example uses a method in a .NET class library to extract and return a localized greeting from a resource file. The library and its resources are registered in the global assembly cache. The example includes resources for the English (United States), French (France), Russian (Russia), and English cultures. English is the default culture; its resources are stored in the main assembly. The example initially delay-signs the library and its satellite assemblies with a public key, then re-signs them with a public/private key pair. To create the example, do the following:

1. If you aren't using Visual Studio, use the following [Strong Name Tool \(Sn.exe\)](#) command to create a public/private key pair named *ResKey.snk*:

Console

```
sn -k ResKey.snk
```

If you're using Visual Studio, use the **Signing** tab of the project **Properties** dialog box to generate the key file.

2. Use the following [Strong Name Tool \(Sn.exe\)](#) command to create a public key file named `PublicKey.snk`:

```
Console
```

```
sn -p ResKey.snk PublicKey.snk
```

3. Create a resource file named `Strings.resx` to contain the resource for the default culture. Store a single string named `Greeting` whose value is "How do you do?" in that file.
4. To indicate that "en" is the application's default culture, add the following [System.Resources.NeutralResourcesLanguageAttribute](#) attribute to the application's `AssemblyInfo` file or to the main source code file that will be compiled into the application's main assembly:

```
C#
```

```
[assembly:NeutralResourcesLanguageAttribute("en")]
```

5. Add support for additional cultures (the en-US, fr-FR, and ru-RU cultures) to the application as follows:

- To support the "en-US" or English (United States) culture, create a resource file named `Strings.en-US.resx` or `Strings.en-US.txt`, and store in it a single string named `Greeting` whose value is "Hello!".
- To support the "fr-FR" or French (France) culture, create a resource file named `Strings.fr-FR.resx` or `Strings.fr-FR.txt` and store in it a single string named `Greeting` whose value is "Bon jour!".
- To support the "ru-RU" or Russian (Russia) culture, create a resource file named `Strings.ru-RU.resx` or `Strings.ru-RU.txt` and store in it a single string named `Greeting` whose value is "Привет!".

6. Use [resgen.exe](#) to compile each text or XML resource file to a binary .resources file. The output is a set of files that have the same root file name as the .resx or .txt files, but a .resources extension. If you create the example with Visual Studio, the compilation process is handled automatically. If you aren't using Visual Studio, run the following command to compile the .resx files into .resources files:

```
Console
```

```
resgen filename
```

Where *filename* is the optional path, file name, and extension of the .resx or text file.

7. Compile the following source code for *StringLibrary.vb* or *StringLibrary.cs* along with the resources for the default culture into a delay signed library assembly named *StringLibrary.dll*:

 **Important**

If you are using the command line rather than Visual Studio to create the example, you should modify the call to the **ResourceManager** class constructor to `ResourceManager rm = new ResourceManager("Strings", typeof(Example).Assembly);`.

C#

```
using System;
using System.Globalization;
using System.Reflection;
using System.Resources;
using System.Threading;

[assembly:NeutralResourcesLanguageAttribute("en")]

public class StringLibrary
{
    public string GetGreeting()
    {
        ResourceManager rm = new ResourceManager("Strings",
Assembly.GetAssembly(typeof(StringLibrary)));
        string greeting = rm.GetString("Greeting");
        return greeting;
    }
}
```

The command for the C# compiler is:

Console

```
csc -t:library -resource:Strings.resources -delaysign+ -
keyfile:publickey.snk StringLibrary.cs
```

The corresponding Visual Basic compiler command is:

Console

```
vbc -t:library -resource:Strings.resources -delaysign+ -  
keyfile:publickey.snk StringLibrary.vb
```

8. Create a subdirectory in the main application directory for each localized culture supported by the application. You should create an *en-US*, an *fr-FR*, and an *ru-RU* subdirectory. Visual Studio creates these subdirectories automatically as part of the compilation process. Because all satellite assemblies have the same file name, the subdirectories are used to store individual culture-specific satellite assemblies until they're signed with a public/private key pair.
9. Embed the individual culture-specific *.resources* files into delay signed satellite assemblies and save them to the appropriate directory. The command to do this for each *.resources* file is:

Console

```
al -target:lib -embed:Strings.culture.resources -culture:culture -  
out:culture\StringLibrary.resources.dll -delay+ -keyfile:publickey.snk
```

where *culture* is the name of a culture. In this example, the culture names are *en-US*, *fr-FR*, and *ru-RU*.

10. Re-sign *StringLibrary.dll* by using the [Strong Name tool \(*sn.exe*\)](#) as follows:

Console

```
sn -R StringLibrary.dll RealKeyValuePair.snk
```

11. Re-sign the individual satellite assemblies. To do this, use the [Strong Name tool \(*sn.exe*\)](#) as follows for each satellite assembly:

Console

```
sn -R StringLibrary.resources.dll RealKeyValuePair.snk
```

12. Register *StringLibrary.dll* and each of its satellite assemblies in the global assembly cache by using the following command:

Console

```
gacutil -i filename
```

where *filename* is the name of the file to register.

13. If you're using Visual Studio, create a new **Console Application** project named `Example`, add a reference to *StringLibrary.dll* and the following source code to it, and compile.

C#

```
using System;
using System.Globalization;
using System.Threading;

public class Example
{
    public static void Main()
    {
        string[] cultureNames = { "en-GB", "en-US", "fr-FR", "ru-RU" };
        Random rnd = new Random();
        string cultureName = cultureNames[rnd.Next(0,
cultureNames.Length)];
        Thread.CurrentThread.CurrentCulture =
CultureInfo.CreateSpecificCulture(cultureName);
        Console.WriteLine("The current UI culture is {0}",
                           Thread.CurrentThread.CurrentCulture.Name);
        StringLibrary strLib = new StringLibrary();
        string greeting = strLib.GetGreeting();
        Console.WriteLine(greeting);
    }
}
```

To compile from the command line, use the following command for the C# compiler:

Console

```
csc Example.cs -r:StringLibrary.dll
```

The command line for the Visual Basic compiler is:

Console

```
vbc Example.vb -r:StringLibrary.dll
```

14. Run *Example.exe*.

Package and deploy resources in .NET apps

Article • 03/18/2023

Applications rely on the .NET Framework Resource Manager, represented by the [ResourceManager](#) class, to retrieve localized resources. The Resource Manager assumes that a hub and spoke model is used to package and deploy resources. The hub is the main assembly that contains the nonlocalizable executable code and the resources for a single culture, called the neutral or default culture. The default culture is the fallback culture for the application; it is the culture whose resources are used if localized resources cannot be found. Each spoke connects to a satellite assembly that contains the resources for a single culture, but does not contain any code.

There are several advantages to this model:

- You can incrementally add resources for new cultures after you have deployed an application. Because subsequent development of culture-specific resources can require a significant amount of time, this allows you to release your main application first, and deliver culture-specific resources at a later date.
- You can update and change an application's satellite assemblies without recompiling the application.
- An application needs to load only those satellite assemblies that contain the resources needed for a particular culture. This can significantly reduce the use of system resources.

However, there are also disadvantages to this model:

- You must manage multiple sets of resources.
- The initial cost of testing an application increases, because you must test several configurations. Note that in the long term it will be easier and less expensive to test one core application with several satellites, than to test and maintain several parallel international versions.

Resource naming conventions

When you package your application's resources, you must name them using the resource naming conventions that the common language runtime expects. The runtime identifies a resource by its culture name. Each culture is given a unique name, which is usually a combination of a two-letter, lowercase culture name associated with a language and, if required, a two-letter, uppercase subculture name associated with a

country or region. The subculture name follows the culture name, separated by a dash (-). Examples include ja-JP for Japanese as spoken in Japan, en-US for English as spoken in the United States, de-DE for German as spoken in Germany, or de-AT for German as spoken in Austria. See the [Language tag](#) column in the [list of language/region names supported by Windows](#). Culture names follow the standard defined by [BCP 47](#).

Note

There are some exceptions for the two-letter culture names, such as `zh-Hans` for Chinese (Simplified).

For more information, see [Create resource files](#) and [Create satellite assemblies](#).

The resource fallback process

The hub and spoke model for packaging and deploying resources uses a fallback process to locate appropriate resources. If an application requests a localized resource that's unavailable, the common language runtime searches the hierarchy of cultures for an appropriate fallback resource that most closely matches the user's application's request, and throws an exception only as a last resort. At each level of the hierarchy, if an appropriate resource is found, the runtime uses it. If the resource is not found, the search continues at the next level.

To improve lookup performance, apply the [NeutralResourcesLanguageAttribute](#) attribute to your main assembly, and pass it the name of the neutral language that will work with your main assembly.

.NET Framework resource fallback process

The .NET Framework resource fallback process involves the following steps:

Tip

You may be able to use the `<relativeBindForResources>` configuration element to optimize the resource fallback process and the process by which the runtime probes for resource assemblies. For more information, see [Optimizing the resource fallback process](#).

1. The runtime first checks the [global assembly cache](#) for an assembly that matches the requested culture for your application.

The global assembly cache can store resource assemblies that are shared by many applications. This frees you from having to include specific sets of resources in the directory structure of every application you create. If the runtime finds a reference to the assembly, it searches the assembly for the requested resource. If it finds the entry in the assembly, it uses the requested resource. If it doesn't find the entry, it continues the search.

2. The runtime next checks the directory of the currently executing assembly for a subdirectory that matches the requested culture. If it finds the subdirectory, it searches that subdirectory for a valid satellite assembly for the requested culture. The runtime then searches the satellite assembly for the requested resource. If it finds the resource in the assembly, it uses it. If it doesn't find the resource, it continues the search.
3. The runtime next queries the Windows Installer to determine whether the satellite assembly is to be installed on demand. If so, it handles the installation, loads the assembly, and searches it for the requested resource. If it finds the resource in the assembly, it uses it. If it doesn't find the resource, it continues the search.
4. The runtime raises the [AppDomain.AssemblyResolve](#) event to indicate that it is unable to find the satellite assembly. If you choose to handle the event, your event handler can return a reference to the satellite assembly whose resources will be used for the lookup. Otherwise, the event handler returns `null` and the search continues.
5. The runtime next searches the global assembly cache again, this time for the parent assembly of the requested culture. If the parent assembly exists in the global assembly cache, the runtime searches the assembly for the requested resource.

The parent culture is defined as the appropriate fallback culture. Consider parents as fallback candidates, because providing any resource is preferable to throwing an exception. This process also allows you to reuse resources. You should include a particular resource at the parent level only if the child culture doesn't need to localize the requested resource. For example, if you supply satellite assemblies for `en` (neutral English), `en-GB` (English as spoken in the United Kingdom), and `en-US` (English as spoken in the United States), the `en` satellite would contain the common terminology, and the `en-GB` and `en-US` satellites could provide overrides for only those terms that differ.

6. The runtime next checks the directory of the currently executing assembly to see if it contains a parent directory. If a parent directory exists, the runtime searches the

directory for a valid satellite assembly for the parent culture. If it finds the assembly, the runtime searches the assembly for the requested resource. If it finds the resource, it uses it. If it doesn't find the resource, it continues the search.

7. The runtime next queries the Windows Installer to determine whether the parent satellite assembly is to be installed on demand. If so, it handles the installation, loads the assembly, and searches it or the requested resource. If it finds the resource in the assembly, it uses it. If it doesn't find the resource, it continues the search.
8. The runtime raises the [AppDomain.AssemblyResolve](#) event to indicate that it is unable to find an appropriate fallback resource. If you choose to handle the event, your event handler can return a reference to the satellite assembly whose resources will be used for the lookup. Otherwise, the event handler returns `null` and the search continues.
9. The runtime next searches parent assemblies, as in the previous three steps, through many potential levels. Each culture has only one parent, which is defined by the [CultureInfo.Parent](#) property, but a parent might have its own parent. The search for parent cultures stops when a culture's [Parent](#) property returns [CultureInfo.InvariantCulture](#); for resource fallback, the invariant culture is not considered a parent culture or a culture that can have resources.
10. If the culture that was originally specified and all parents have been searched and the resource is still not found, the resource for the default (fallback) culture is used. Typically, the resources for the default culture are included in the main application assembly. However, you can specify a value of [Satellite](#) for the [Location](#) property of the [NeutralResourcesLanguageAttribute](#) attribute to indicate that the ultimate fallback location for resources is a satellite assembly, rather than the main assembly.

Note

The default resource is the only resource that can be compiled with the main assembly. Unless you specify a satellite assembly by using the [NeutralResourcesLanguageAttribute](#) attribute, it is the ultimate fallback (final parent). Therefore, we recommend that you always include a default set of resources in your main assembly. This helps prevent exceptions from being thrown. By including a default resource, file you provide a fallback for all resources and ensure that at least one resource is always present for the user, even if it is not culturally specific.

11. Finally, if the runtime doesn't find a resource for a default (fallback) culture, a [MissingManifestResourceException](#) or [MissingSatelliteAssemblyException](#) exception is thrown to indicate that the resource could not be found.

For example, suppose the application requests a resource localized for Spanish (Mexico) (the `es-MX` culture). The runtime first searches the global assembly cache for the assembly that matches `es-MX`, but doesn't find it. The runtime then searches the directory of the currently executing assembly for an `es-MX` directory. Failing that, the runtime searches the global assembly cache again for a parent assembly that reflects the appropriate fallback culture — in this case, `es` (Spanish). If the parent assembly is not found, the runtime searches all potential levels of parent assemblies for the `es-MX` culture until it finds a corresponding resource. If a resource isn't found, the runtime uses the resource for the default culture.

Optimize the .NET Framework resource fallback process

Under the following conditions, you can optimize the process by which the runtime searches for resources in satellite assemblies:

- Satellite assemblies are deployed in the same location as the code assembly. If the code assembly is installed in the [Global Assembly Cache](#), satellite assemblies are also installed in the global assembly cache. If the code assembly is installed in a directory, satellite assemblies are installed in culture-specific folders of that directory.
- Satellite assemblies are not installed on demand.
- Application code does not handle the [AppDomain.AssemblyResolve](#) event.

You optimize the probe for satellite assemblies by including the `<relativeBindForResources>` element and setting its `enabled` attribute to `true` in the application configuration file, as shown in the following example.

XML

```
<configuration>
  <runtime>
    <relativeBindForResources enabled="true" />
  </runtime>
</configuration>
```

The optimized probe for satellite assemblies is an opt-in feature. That is, the runtime follows the steps documented in [The resource fallback process](#) unless the

`<relativeBindForResources>` element is present in the application's configuration file and its `enabled` attribute is set to `true`. If this is the case, the process of probing for a satellite assembly is modified as follows:

- The runtime uses the location of the parent code assembly to probe for the satellite assembly. If the parent assembly is installed in the global assembly cache, the runtime probes in the cache but not in the application's directory. If the parent assembly is installed in an application directory, the runtime probes in the application directory but not in the global assembly cache.
- The runtime doesn't query the Windows Installer for on-demand installation of satellite assemblies.
- If the probe for a particular resource assembly fails, the runtime does not raise the `AppDomain.AssemblyResolve` event.

.NET Core resource fallback process

The .NET Core resource fallback process involves the following steps:

1. The runtime attempts to load a satellite assembly for the requested culture.
 - Checks the directory of the currently executing assembly for a subdirectory that matches the requested culture. If it finds the subdirectory, it searches that subdirectory for a valid satellite assembly for the requested culture and loads it.

(!) Note

On operating systems with case-sensitive file systems (that is, Linux and macOS), the culture name subdirectory search is case-sensitive. The subdirectory name must exactly match the case of the `CultureInfo.Name` (for example, `es` or `es-MX`).

(!) Note

If the programmer has derived a custom assembly load context from `AssemblyLoadContext`, the situation is complicated. If the executing assembly was loaded into the custom context, the runtime loads the satellite assembly into the custom context. The details are out of scope for this document. See `AssemblyLoadContext`.

- If a satellite assemble has not been found, the [AssemblyLoadContext](#) raises the [AssemblyLoadContext.Resolving](#) event to indicate that it is unable to find the satellite assembly. If you choose to handle the event, your event handler can load and return a reference to the satellite assembly.
- If a satellite assembly still has not been found, the AssemblyLoadContext causes the AppDomain to trigger an [AppDomain.AssemblyResolve](#) event to indicate that it is unable to find the satellite assembly. If you choose to handle the event, your event handler can load and return a reference to the satellite assembly.

2. If a satellite assembly is found, the runtime searches it for the requested resource. If it finds the resource in the assembly, it uses it. If it doesn't find the resource, it continues the search.

 **Note**

To find a resource within the satellite assembly, the runtime searches for the resource file requested by the [ResourceManager](#) for the current [CultureInfo.Name](#). Within the resource file it searches for the requested resource name. If either is not found, the resource is treated as not found.

3. The runtime next searches the parent culture assemblies through many potential levels, each time repeating steps 1 & 2.

The parent culture is defined as an appropriate fallback culture. Consider parents as fallback candidates, because providing any resource is preferable to throwing an exception. This process also allows you to reuse resources. You should include a particular resource at the parent level only if the child culture doesn't need to localize the requested resource. For example, if you supply satellite assemblies for `en` (neutral English), `en-GB` (English as spoken in the United Kingdom), and `en-US` (English as spoken in the United States), the `en` satellite contains the common terminology, and the `en-GB` and `en-US` satellites provides overrides for only those terms that differ.

Each culture has only one parent, which is defined by the [CultureInfo.Parent](#) property, but a parent might have its own parent. The search for parent cultures stops when a culture's [Parent](#) property returns [CultureInfo.InvariantCulture](#). For resource fallback, the invariant culture is not considered a parent culture or a culture that can have resources.

4. If the culture that was originally specified and all parents have been searched and the resource is still not found, the resource for the default (fallback) culture is used. Typically, the resources for the default culture are included in the main application assembly. However, you can specify a value of [Satellite](#) for the [Location](#) property to indicate that the ultimate fallback location for resources is a satellite assembly rather than the main assembly.

 **Note**

The default resource is the only resource that can be compiled with the main assembly. Unless you specify a satellite assembly by using the [NeutralResourcesLanguageAttribute](#) attribute, it is the ultimate fallback (final parent). Therefore, we recommend that you always include a default set of resources in your main assembly. This helps prevent exceptions from being thrown. By including a default resource file, you provide a fallback for all resources and ensure that at least one resource is always present for the user, even if it is not culturally specific.

5. Finally, if the runtime doesn't find a resource file for a default (fallback) culture, a [MissingManifestResourceException](#) or [MissingSatelliteAssemblyException](#) exception is thrown to indicate that the resource could not be found. If the resource file is found but the requested resource is not present the request returns `null`.

Ultimate fallback to satellite assembly

You can optionally remove resources from the main assembly and specify that the runtime should load the ultimate fallback resources from a satellite assembly that corresponds to a specific culture. To control the fallback process, you use the [NeutralResourcesLanguageAttribute\(String, UltimateResourceFallbackLocation\)](#) constructor and supply a value for the [UltimateResourceFallbackLocation](#) parameter that specifies whether Resource Manager should extract the fallback resources from the main assembly or from a satellite assembly.

The following .NET Framework example uses the [NeutralResourcesLanguageAttribute](#) attribute to store an application's fallback resources in a satellite assembly for the French (`fr`) language. The example has two text-based resource files that define a single string resource named `Greeting`. The first, `resources.fr.txt`, contains a French language resource.

text

```
Greeting=Bonjour!
```

The second, resources.ru.txt, contains a Russian language resource.

```
text
```

```
Greeting=Добрый день
```

These two files are compiled to .resources files by running [Resource File Generator \(resgen.exe\)](#) from the command line. For the French language resource, the command is:

```
Console
```

```
resgen.exe resources.fr.txt
```

For the Russian language resource, the command is:

```
Console
```

```
resgen.exe resources.ru.txt
```

The .resources files are embedded into dynamic link libraries by running [Assembly Linker \(al.exe\)](#) from the command line for the French language resource as follows:

```
Console
```

```
al /t:lib /embed:resources.fr.resources /culture:fr  
/out:fr\Example1.resources.dll
```

and for the Russian language resource as follows:

```
Console
```

```
al /t:lib /embed:resources.ru.resources /culture:ru  
/out:ru\Example1.resources.dll
```

The application source code resides in a file named Example1.cs or Example1.vb. It includes the [NeutralResourcesLanguageAttribute](#) attribute to indicate that the default application resource is in the fr subdirectory. It instantiates the Resource Manager, retrieves the value of the `Greeting` resource, and displays it to the console.

```
C#
```

```
using System;
using System.Reflection;
using System.Resources;

[assembly:NeutralResourcesLanguage("fr",
UltimateResourceFallbackLocation.Satellite)]

public class Example
{
    public static void Main()
    {
        ResourceManager rm = new ResourceManager("resources",
                                                typeof(Example).Assembly);
        string greeting = rm.GetString("Greeting");
        Console.WriteLine(greeting);
    }
}
```

You can then compile C# source code from the command line as follows:

```
Console
csc Example1.cs
```

The command for the Visual Basic compiler is very similar:

```
Console
vbc Example1.vb
```

Because there are no resources embedded in the main assembly, you do not have to compile by using the `/resource` switch.

When you run the example from a system whose language is anything other than Russian, it displays the following output:

```
Output
Bon jour!
```

Suggested packaging alternative

Time or budget constraints might prevent you from creating a set of resources for every subculture that your application supports. Instead, you can create a single satellite assembly for a parent culture that all related subcultures can use. For example, you can

provide a single English satellite assembly (en) that is retrieved by users who request region-specific English resources, and a single German satellite assembly (de) for users who request region-specific German resources. For example, requests for German as spoken in Germany (de-DE), Austria (de-AT), and Switzerland (de-CH) would fall back to the German satellite assembly (de). The default resources are the final fallback and therefore should be the resources that will be requested by the majority of your application's users, so choose these resources carefully. This approach deploys resources that are less culturally specific, but can significantly reduce your application's localization costs.

Retrieve resources in .NET apps

Article • 03/18/2023

When you work with localized resources in .NET apps, you should ideally package the resources for the default or neutral culture with the main assembly and create a separate satellite assembly for each language or culture that your app supports. You can then use the [ResourceManager](#) class as described in the next section to access named resources. If you choose not to embed your resources in the main assembly and satellite assemblies, you can also access binary *.resources* files directly, as discussed in the section [Retrieve resources from .resources files](#) later in this article.

Retrieve resources from assemblies

The [ResourceManager](#) class provides access to resources at run time. You use the [ResourceManager.GetString](#) method to retrieve string resources and the [ResourceManager.GetObject](#) or [ResourceManager.GetStream](#) method to retrieve non-string resources. Each method has two overloads:

- An overload whose single parameter is a string that contains the name of the resource. The method attempts to retrieve that resource for the current culture. For more information, see the [GetString\(String\)](#), [GetObject\(String\)](#), and [GetStream\(String\)](#) methods.
- An overload that has two parameters: a string containing the name of the resource, and a [CultureInfo](#) object that represents the culture whose resource is to be retrieved. If a resource set for that culture cannot be found, the resource manager uses fallback rules to retrieve an appropriate resource. For more information, see the [GetString\(String, CultureInfo\)](#), [GetObject\(String, CultureInfo\)](#), and [GetStream\(String, CultureInfo\)](#) methods.

The resource manager uses the resource fallback process to control how the app retrieves culture-specific resources. For more information, see the "Resource Fallback Process" section in [Package and deploy resources](#). For information about instantiating a [ResourceManager](#) object, see the "Instantiating a ResourceManager Object" section in the [ResourceManager](#) class topic.

Retrieve string data example

The following example calls the [GetString\(String\)](#) method to retrieve the string resources of the current UI culture. It includes a neutral string resource for the English (United

States) culture and localized resources for the French (France) and Russian (Russia) cultures. The following English (United States) resource is in a file named Strings.txt:

```
text
```

```
TimeHeader=The current time is
```

The French (France) resource is in a file named Strings.fr-FR.txt:

```
text
```

```
TimeHeader=L'heure actuelle est
```

The Russian (Russia) resource is in a file named Strings.ru-RU.txt:

```
text
```

```
TimeHeader=Текущее время –
```

The source code for this example, which is in a file named GetString.cs for the C# version of the code and GetString.vb for the Visual Basic version, defines a string array that contains the name of four cultures: the three cultures for which resources are available and the Spanish (Spain) culture. A loop that executes five times randomly selects one of these cultures and assigns it to the [Thread.CurrentCulture](#) and [CultureInfo.CurrentUICulture](#) properties. It then calls the [GetString\(String\)](#) method to retrieve the localized string, which it displays along with the time of day.

```
C#
```

```
using System;
using System.Globalization;
using System.Resources;
using System.Threading;

[assembly: NeutralResourcesLanguageAttribute("en-US")]

public class Example
{
    public static void Main()
    {
        string[] cultureNames = { "en-US", "fr-FR", "ru-RU", "es-ES" };
        Random rnd = new Random();
        ResourceManager rm = new ResourceManager("Strings",
                                                typeof(Example).Assembly);

        for (int ctr = 0; ctr <= cultureNames.Length; ctr++) {
            string cultureName = cultureNames[rnd.Next(0,
```

```

cultureNames.Length)];
    CultureInfo culture =
CultureInfo.CreateSpecificCulture(cultureName);
    Thread.CurrentThread.CurrentCulture = culture;
    Thread.CurrentThread.CurrentUICulture = culture;

    Console.WriteLine("Current culture: {0}", culture.NativeName);
    string timeString = rm.GetString("TimeHeader");
    Console.WriteLine("{0} {1:T}\n", timeString, DateTime.Now);
}
}

// The example displays output like the following:
// Current culture: English (United States)
// The current time is 9:34:18 AM
//
// Current culture: Español (España, alfabetización internacional)
// The current time is 9:34:18
//
// Current culture: русский (Россия)
// Текущее время – 9:34:18
//
// Current culture: français (France)
// L'heure actuelle est 09:34:18
//
// Current culture: русский (Россия)
// Текущее время – 9:34:18

```

The following batch (.bat) file compiles the example and generates satellite assemblies in the appropriate directories. The commands are provided for the C# language and compiler. For Visual Basic, change `csc` to `vbc`, and change `GetString.cs` to `GetString.vb`.

```

Console

resgen strings.txt
csc GetString.cs -resource:string.resources

resgen strings.fr-FR.txt
md fr-FR
al -embed:string.resources -culture:fr-FR -out:fr-
FR\GetString.resources.dll

resgen strings.ru-RU.txt
md ru-RU
al -embed:string.resources -culture:ru-RU -out:ru-
RU\GetString.resources.dll

```

When the current UI culture is Spanish (Spain), note that the example displays English language resources, because Spanish language resources are unavailable, and English is

the example's default culture.

Retrieve object data examples

You can use the [GetObject](#) and [GetStream](#) methods to retrieve object data. This includes primitive data types, serializable objects, and objects that are stored in binary format (such as images).

The following example uses the [GetStream\(String\)](#) method to retrieve a bitmap that is used in an app's opening splash window. The following source code in a file named CreateResources.cs (for C#) or CreateResources.vb (for Visual Basic) generates a .resx file that contains the serialized image. In this case, the image is loaded from a file named SplashScreen.jpg; you can modify the file name to substitute your own image.

C#

```
using System;
using System.Drawing;
using System.Drawing.Imaging;
using System.IO;
using System.Resources;

public class Example
{
    public static void Main()
    {
        Bitmap bmp = new Bitmap(@".\SplashScreen.jpg");
        MemoryStream imageStream = new MemoryStream();
        bmp.Save(imageStream, ImageFormat.Jpeg);

        ResXResourceWriter writer = new
ResXResourceWriter("AppResources.resx");
        writer.AddResource("SplashScreen", imageStream);
        writer.Generate();
        writer.Close();
    }
}
```

The following code retrieves the resource and displays the image in a [PictureBox](#) control.

C#

```
using System;
using System.Drawing;
using System.IO;
using System.Resources;
using System.Windows.Forms;
```

```
public class Example
{
    public static void Main()
    {
        ResourceManager rm = new ResourceManager("AppResources",
typeof(Example).Assembly);
        Bitmap screen = (Bitmap)
Image.FromStream(rm.GetStream("SplashScreen"));

        Form frm = new Form();
        frm.Size = new Size(300, 300);

        PictureBox pic = new PictureBox();
        pic.Bounds = frm.RestoreBounds;
        pic.BorderStyle = BorderStyle.Fixed3D;
        pic.Image = screen;
        pic.SizeMode = PictureBoxSizeMode.StretchImage;

        frm.Controls.Add(pic);
        pic.Anchor = AnchorStyles.Top | AnchorStyles.Bottom |
            AnchorStyles.Left | AnchorStyles.Right;

        frm.ShowDialog();
    }
}
```

You can use the following batch file to build the C# example. For Visual Basic, change `csc` to `vbc`, and change the extension of the source code file from `.cs` to `.vb`.

```
Console

csc CreateResources.cs
CreateResources

resgen AppResources.resx

csc GetStream.cs -resource:AppResources.resources
```

The following example uses the [ResourceManager.GetObject\(String\)](#) method to deserialize a custom object. The example includes a source code file named `UIElements.cs` (`UIElements.vb` for Visual Basic) that defines the following structure named `PersonTable`. This structure is intended to be used by a general table display routine that displays the localized names of table columns. Note that the `PersonTable` structure is marked with the [SerializableAttribute](#) attribute.

C#

```
using System;

[Serializable] public struct PersonTable
{
    public readonly int nColumns;
    public readonly string column1;
    public readonly string column2;
    public readonly string column3;
    public readonly int width1;
    public readonly int width2;
    public readonly int width3;

    public PersonTable(string column1, string column2, string column3,
                      int width1, int width2, int width3)
    {
        this.column1 = column1;
        this.column2 = column2;
        this.column3 = column3;
        this.width1 = width1;
        this.width2 = width2;
        this.width3 = width3;
        this.nColumns = typeof(PersonTable).GetFields().Length / 2;
    }
}
```

The following code from a file named CreateResources.cs (CreateResources.vb for Visual Basic) creates an XML resource file named UIResources.resx that stores a table title and a `PersonTable` object that contains information for an app that is localized for the English language.

C#

```
using System;
using System.Resources;

public class CreateResource
{
    public static void Main()
    {
        PersonTable table = new PersonTable("Name", "Employee Number",
                                             "Age", 30, 18, 5);
        ResXResourceWriter rr = new ResXResourceWriter(@".\UIResources.resx");
        rr.AddResource("TableName", "Employees of Acme Corporation");
        rr.AddResource("Employees", table);
        rr.Generate();
        rr.Close();
    }
}
```

The following code in a source code file named GetObject.cs (GetObject.vb) then retrieves the resources and displays them to the console.

C#

```
using System;
using System.Resources;

[assembly: NeutralResourcesLanguageAttribute("en")]

public class Example
{
    public static void Main()
    {
        string fmtString = String.Empty;
        ResourceManager rm = new ResourceManager("UIResources",
typeof(Example).Assembly);
        string title = rm.GetString("TableName");
        PersonTable tableInfo = (PersonTable) rm.GetObject("Employees");

        if (! String.IsNullOrEmpty(title)) {
            fmtString = "{0," + ((Console.WindowWidth + title.Length) /
2).ToString() + "}";
            Console.WriteLine(fmtString, title);
            Console.WriteLine();
        }

        for (int ctr = 1; ctr <= tableInfo.nColumns; ctr++) {
            string columnName = "column" + ctr.ToString();
            string widthName = "width" + ctr.ToString();
            string value =
tableInfo.GetType().GetField(columnName).GetValue(tableInfo).ToString();
            int width = (int)
tableInfo.GetType().GetField(widthName).GetValue(tableInfo);
            fmtString = "{0,-" + width.ToString() + "}";
            Console.Write(fmtString, value);
        }
        Console.WriteLine();
    }
}
```

You can build the necessary resource file and assemblies and run the app by executing the following batch file. You must use the `/r` option to supply Resgen.exe with a reference to UIElements.dll so that it can access information about the `PersonTable` structure. If you're using C#, replace the `vbc` compiler name with `csc`, and replace the `.vb` extension with `.cs`.

Console

```
vbc -t:library UIElements.vb  
vbc CreateResources.vb -r:UIElements.dll  
CreateResources  
  
resgen UIResources.resx -r:UIElements.dll  
vbc GetObject.vb -r:UIElements.dll -resource:UIResources.resources  
  
GetObject.exe
```

Version support for satellite assemblies

By default, when the [ResourceManager](#) object retrieves requested resources, it looks for satellite assemblies that have version numbers that match the version number of the main assembly. After you have deployed an app, you might want to update the main assembly or specific resource satellite assemblies. The .NET Framework provides support for versioning the main assembly and satellite assemblies.

The [SatelliteContractVersionAttribute](#) attribute provides versioning support for a main assembly. Specifying this attribute on an app's main assembly enables you to update and redeploy a main assembly without updating its satellite assemblies. After you update the main assembly, increment the main assembly's version number but leave the satellite contract version number unchanged. When the resource manager retrieves requested resources, it loads the satellite assembly version specified by this attribute.

Publisher policy assemblies provide support for versioning satellite assemblies. You can update and redeploy a satellite assembly without updating the main assembly. After you update a satellite assembly, increment its version number and ship it with a publisher policy assembly. In the publisher policy assembly, specify that your new satellite assembly is backward-compatible with its previous version. The resource manager will use the [SatelliteContractVersionAttribute](#) attribute to determine the version of the satellite assembly, but the assembly loader will bind to the satellite assembly version specified by the publisher policy. For more information about publisher policy assemblies, see [Create a publisher policy file](#).

To enable full assembly versioning support, we recommend that you deploy strong-named assemblies in the [global assembly cache](#) and deploy assemblies that don't have strong names in the application directory. If you want to deploy strong-named assemblies in the application directory, you will not be able to increment a satellite assembly's version number when you update the assembly. Instead, you must perform an in-place update where you replace the existing code with the updated code and maintain the same version number. For example, if you want to update version 1.0.0.0 of a satellite assembly with the fully specified assembly name "myApp.resources,

Version=1.0.0.0, Culture=de, PublicKeyToken=b03f5f11d50a3a", overwrite it with the updated myApp.resources.dll that has been compiled with the same, fully specified assembly name "myApp.resources, Version=1.0.0.0, Culture=de, PublicKeyToken=b03f5f11d50a3a". Note that using in-place updates on satellite assembly files makes it difficult for an app to accurately determine the version of a satellite assembly.

For more information about assembly versioning, see [Assembly versioning](#) and [How the Runtime locates assemblies](#).

Retrieve resources from .resources Files

If you choose not to deploy resources in satellite assemblies, you can still use a [ResourceManager](#) object to access resources from .resources files directly. To do this, you must deploy the .resources files correctly. Then you use the [ResourceManager.CreateFileBasedResourceManager](#) method to instantiate a [ResourceManager](#) object and specify the directory that contains the standalone .resources files.

Deploy .resources Files

When you embed .resources files in an application assembly and satellite assemblies, each satellite assembly has the same file name, but is placed in a subdirectory that reflects the satellite assembly's culture. In contrast, when you access resources from .resources files directly, you can place all the .resources files in a single directory, usually a subdirectory of the application directory. The name of the app's default .resources file consists of a root name only, with no indication of its culture (for example, strings.resources). The resources for each localized culture are stored in a file whose name consists of the root name followed by the culture (for example, strings.ja.resources or strings.de-DE.resources).

The following illustration shows where resource files should be located in the directory structure. It also gives the naming conventions for .resource files.

Use the resource manager

After you have created your resources and placed them in the appropriate directory, you create a [ResourceManager](#) object to use the resources by calling the [CreateFileBasedResourceManager\(String, String, Type\)](#) method. The first parameter specifies the root name of the app's default .resources file (this would be "strings" for the example in the previous section). The second parameter specifies the location of the resources ("Resources" for the previous example). The third parameter specifies the [ResourceSet](#) implementation to use. If the third parameter is `null`, the default runtime [ResourceSet](#) is used.

ⓘ Note

Do not deploy ASP.NET apps using standalone .resources files. This can cause locking issues and breaks XCOPY deployment. We recommend that you deploy ASP.NET resources in satellite assemblies. For more information, see [ASP.NET Web Page Resources Overview](#).

After you instantiate the [ResourceManager](#) object, you use the [GetString](#), [GetObject](#), and [GetStream](#) methods as discussed earlier to retrieve the resources. However, the retrieval of resources directly from .resources files differs from the retrieval of embedded resources from assemblies. When you retrieve resources from .resources files, the [GetString\(String\)](#), [GetObject\(String\)](#), and [GetStream\(String\)](#) methods always retrieve the default culture's resources regardless of the current culture. To retrieve the resources of either the app's current culture or a specific culture, you must call the [GetString\(String, CultureInfo\)](#), [GetObject\(String, CultureInfo\)](#), or [GetStream\(String, CultureInfo\)](#) method and specify the culture whose resources are to be retrieved. To retrieve the resources of the current culture, specify the value of the [CultureInfo.CurrentCulture](#) property as the `culture` argument. If the resource manager cannot retrieve the resources of `culture`, it uses the standard resource fallback rules to retrieve the appropriate resources.

An example

The following example illustrates how the resource manager retrieves resources directly from .resources files. The example consists of three text-based resource files for the English (United States), French (France), and Russian (Russia) cultures. English (United States) is the example's default culture. Its resources are stored in the following file named *Strings.txt*:

```
text
```

```
Greeting=Hello  
Prompt=What is your name?
```

Resources for the French (France) culture are stored in the following file, which is named Strings.fr-FR.txt:

```
text  
  
Greeting=Bon jour  
Prompt=Comment vous appelez-vous?
```

Resources for the Russian (Russia) culture are stored in the following file, which is named Strings.ru-RU.txt:

```
text  
  
Greeting=Здравствуйте  
Prompt=Как вас зовут?
```

The following is the source code for the example. The example instantiates [CultureInfo](#) objects for the English (United States), English (Canada), French (France), and Russian (Russia) cultures, and makes each the current culture. The [ResourceManager.GetString\(String, CultureInfo\)](#) method then supplies the value of the [CultureInfo.CurrentCulture](#) property as the `culture` argument to retrieve the appropriate culture-specific resources.

```
C#  
  
using System;  
using System.Globalization;  
using System.Resources;  
using System.Threading;  
  
[assembly: NeutralResourcesLanguage("en-US")]  
  
public class Example  
{  
    public static void Main()  
    {  
        string[] cultureNames = { "en-US", "en-CA", "ru-RU", "fr-FR" };  
        ResourceManager rm =  
        ResourceManager.CreateFileBasedResourceManager("Strings", "Resources",  
        null);  
  
        foreach (var cultureName in cultureNames) {  
            Thread.CurrentThread.CurrentCulture =  
            CultureInfo.CreateSpecificCulture(cultureName);  
        }  
    }  
}
```

```

        string greeting = rm.GetString("Greeting",
CultureInfo.CurrentCulture);
        Console.WriteLine("\n{0}!", greeting);
        Console.Write(rm.GetString("Prompt", CultureInfo.CurrentCulture));
        string name = Console.ReadLine();
        if (! String.IsNullOrEmpty(name))
            Console.WriteLine("{0}, {1}!", greeting, name);
    }
    Console.WriteLine();
}
}

// The example displays output like the following:
//      Hello!
//      What is your name? Dakota
//      Hello, Dakota!

//
//      Hello!
//      What is your name? Koani
//      Hello, Koani!

//
//      Здравствуйте!
//      Как вас зовут?Samuel
//      Здравствуйте, Samuel!

//
//      Bon jour!
//      Comment vous appelez-vous?Yiska
//      Bon jour, Yiska!

```

You can compile the C# version of the example by running the following batch file. If you're using Visual Basic, replace `csc` with `vbc`, and replace the `.cs` extension with `.vb`.

Console

```

md Resources
resgen Strings.txt Resources\Strings.resources
resgen Strings.fr-FR.txt Resources\Strings.fr-FR.resources
resgen Strings.ru-RU.txt Resources\Strings.ru-RU.resources

csc Example.cs

```

System.Resources.MissingManifestResourceException class

Article • 01/08/2024

This article provides supplementary remarks to the reference documentation for this API.

A [MissingManifestResourceException](#) exception is thrown for different reasons in .NET versus UWP apps.

.NET apps

In .NET apps, [MissingManifestResourceException](#) is thrown when the attempt to retrieve a resource fails because the resource set for the neutral culture could not be loaded from a particular assembly. Although the exception is thrown when you try to retrieve a particular resource, it is caused by the failure to load the resource set rather than the failure to find the resource.

Note

For additional information, see the "Handling a MissingManifestResourceException Exception" section in the [ResourceManager](#) class topic.

The main causes of the exception include the following:

- The resource set is not identified by its fully qualified name. For example, if the `baseName` parameter in the call to the [ResourceManager.ResourceManager\(String, Assembly\)](#) method specifies the root name of the resource set without a namespace, but the resource set is assigned a namespace when it is stored in its assembly, the call to the [ResourceManager.GetString](#) method throws this exception.

If you've embedded the .resources file that contains the default culture's resources in your executable and your app is throwing a [MissingManifestResourceException](#), you can use a reflection tool such as the [IL Disassembler \(Ildasm.exe\)](#) to determine the fully qualified name of the resource. In ILDasm, double click the executable's **MANIFEST** label to open the **MANIFEST** window. Resources appear as `.mresource` items and are listed after external assembly references and custom assembly-level attributes. You can also compile the following simple utility, which lists the fully

qualified names of embedded resources in the assembly whose name is passed to it as a command-line parameter.

```
C#  
  
using System;  
using System.IO;  
using System.Reflection;  
using System.Resources;  
  
public class Example  
{  
    public static void Main()  
    {  
        if (Environment.GetCommandLineArgs().Length == 1) {  
            Console.WriteLine("No filename.");  
            return;  
        }  
  
        string filename = Environment.GetCommandLineArgs()[1].Trim();  
        // Check whether the file exists.  
        if (!File.Exists(filename)) {  
            Console.WriteLine("{0} does not exist.", filename);  
            return;  
        }  
  
        // Try to load the assembly.  
        Assembly assem = Assembly.LoadFrom(filename);  
        Console.WriteLine("File: {0}", filename);  
  
        // Enumerate the resource files.  
        string[] resNames = assem.GetManifestResourceNames();  
        if (resNames.Length == 0)  
            Console.WriteLine("No resources found.");  
  
        foreach (var resName in resNames)  
            Console.WriteLine("Resource: {0}",  
                resName.Replace(".resources", ""));  
  
        Console.WriteLine();  
    }  
}
```

- You identify the resource set by its resource file name (along with its optional namespace) and its file extension rather than by its namespace and root file name alone. For example, this exception is thrown if the neutral culture's resource set is named `GlobalResources` and you supply a value of `GlobalResources.resources` (instead of `GlobalResources`) to the `baseName` parameter of the `ResourceManager.ResourceManager(String, Assembly)` constructor.

- The culture-specific resource set that is identified in a method call cannot be found, and the fallback resource set cannot be loaded. For example, if you create satellite assemblies for the English (United States) and Russia (Russian) cultures but you fail to provide a resource set for the neutral culture, this exception is thrown if your app's current culture is English (United Kingdom).

[MissingManifestResourceException](#) uses the HRESULT `COR_E_MISSINGMANIFESTRESOURCE`, which has the value 0x80131532.

[MissingManifestResourceException](#) uses the default `Equals` implementation, which supports reference equality.

For a list of initial property values for an instance of [MissingManifestResourceException](#), see the [MissingManifestResourceException](#) constructors.

 **Note**

We recommend that you include a neutral set of resources in your main assembly, so your app won't fail if a satellite assembly is unavailable.

Universal Windows Platform (UWP) apps

UWP apps deploy resources for multiple cultures, including the neutral culture, in a single package resource index (.pri) file. As a result, in a UWP app, if resources for the preferred culture cannot be found, the [MissingManifestResourceException](#) is thrown under either of the following conditions:

- The app does not include a .pri file, or the .pri file could not be opened.
- The app's .pri file does not contain a resource set for the given root name.

System.Resources.NeutralResourcesLanguageAttribute class

Article • 01/08/2024

This article provides supplementary remarks to the reference documentation for this API.

In desktop apps, the [NeutralResourcesLanguageAttribute](#) attribute informs the resource manager of an app's default culture and the location of its resources. By default, resources are embedded in the main app assembly, and you can use the attribute as follows. This statement specifies that the English (United States) is the app's default culture.

C#

```
[assembly: NeutralResourcesLanguage("en-US")]
```

You can also use the [NeutralResourcesLanguageAttribute](#) attribute to indicate where [ResourceManager](#) can find the resources of the default culture by providing an [UltimateResourceFallbackLocation](#) enumeration value in the attribute statement. This is most commonly done to indicate that the resources reside in a satellite assembly. For example, the following statement specifies that English (United States) is the app's default or neutral culture and that its resources reside in a satellite assembly. The [ResourceManager](#) object will look for them in a subdirectory named en-US.

C#

```
[assembly: NeutralResourcesLanguage("en-US",
UltimateResourceFallbackLocation.Satellite)]
```

Tip

We recommend that you always use the [NeutralResourcesLanguageAttribute](#) attribute to define the default culture of your app.

The attribute performs two roles:

- If the default culture's resources are embedded in the app's main assembly and [ResourceManager](#) has to retrieve resources that belong to the same culture as the default culture, the [ResourceManager](#) automatically uses the resources located in

the main assembly instead of searching for a satellite assembly. This bypasses the usual assembly probe, improves lookup performance for the first resource you load, and can reduce your working set. See [Packaging and Deploying Resources](#) for the process [ResourceManager](#) uses to probe for resource files.

- If the default culture's resources are located in a satellite assembly rather than in the main app assembly, the [NeutralResourcesLanguageAttribute](#) attribute specifies the culture and the directory from which the runtime can load the resources.

Windows 8.x Store apps

In Windows 8.x Store apps whose resources are loaded and retrieved by using the [ResourceManager](#) class, the [NeutralResourcesLanguageAttribute](#) attribute defines the neutral culture whose resources are used in the event of a failed probe. It does not specify the location of the resources. By default, [ResourceManager](#) uses the app's package resource index (PRI) file to locate the resources of the default culture. The neutral culture that is defined by the [NeutralResourcesLanguageAttribute](#) attribute is added to the end of the UI language list to simulate this effect.

If you load and retrieve resources by using the Windows Runtime [Windows.ApplicationModel.Resources.ResourceLoader](#) class or the types in the [Windows.ApplicationModel.Resources.Core](#) namespace, the [NeutralResourcesLanguageAttribute](#) attribute is ignored.

Examples

The following example uses a simple "Hello World" app to illustrate the use of the [NeutralResourcesLanguageAttribute](#) attribute to define a default or fallback culture. It requires the creation of separate resource files for the English (en), English (United States) (en-US), and French (France) (fr-FR) cultures. The following shows the contents of a text file named ExampleResources.txt for the English culture.

```
# Resources for the default (en) culture.  
Greeting=Hello
```

To use the resource file in an app, you must use the [Resource File Generator \(Resgen.exe\)](#) to convert the file from its text (.txt) format to a binary (.resources) format as follows:

```
resgen ExampleResources.txt
```

When the app is compiled, the binary resource file will be embedded in the main app assembly.

The following shows the contents of a text file named ExampleResources.en-US.txt that provides resources for the English (United States) culture.

```
# Resources for the en-US culture.  
Greeting=Hi
```

The text file can be converted to a binary resources file by using the [Resource File Generator \(ResGen.exe\)](#) at the command line as follows:

```
resgen ExampleResources.en-US.txt ExampleResources.en-US.resources
```

The binary resource file should then be compiled into an assembly by using [Assembly Linker \(Al.exe\)](#) and placed in the en-US subdirectory of the app directory by issuing the following command:

```
al /t:lib /embed:ExampleResources.en-US.resources /culture:en-US /out:en-US\Example.resources.dll
```

The following shows the contents of a text file named ExampleResources.fr-FR.txt that provides resources for the French (France) culture.

```
# Resources for the fr-FR culture.  
Greeting=Bonjour
```

The text file can be converted to a binary resource file by using ResGen.exe at the command line as follows:

```
resgen ExampleResources.fr-FR.txt ExampleResources.fr-FR.resources
```

The binary resources file should then be compiled into an assembly by using Assembly Linker and placed in the fr-FR subdirectory of the app directory by issuing the following command:

```
al /t:lib /embed:ExampleResources.fr-FR.resources /culture:fr-FR /out:fr-FR\Example.resources.dll
```

The following example provides the executable code that sets the current culture, prompts for the user's name, and displays a localized string.

C#

```
using System;
using System.Globalization;
using System.Reflection;
using System.Resources;
using System.Threading;

[assembly: NeutralResourcesLanguageAttribute("en")]
public class Example
{
    public static void Main()
    {
        // Select the current culture randomly to test resource fallback.
        string[] cultures = { "de-DE", "en-us", "fr-FR" };
        Random rnd = new Random();
        int index = rnd.Next(0, cultures.Length);
        Thread.CurrentThread.CurrentCulture =
CultureInfo.CreateSpecificCulture(cultures[index]);
        Console.WriteLine("The current culture is {0}",
                           CultureInfo.CurrentCulture.Name);

        // Retrieve the resource.
        ResourceManager rm = new ResourceManager("ExampleResources",
                                                typeof(Example).Assembly);
        string greeting = rm.GetString("Greeting");

        Console.Write("Enter your name: ");
        string name = Console.ReadLine();
        Console.WriteLine("{0} {1}!", greeting, name);
    }
}
```

It can be compiled by using the following command in Visual Basic:

```
vbc Example.vb /resource:ExampleResources.resources
```

or by using the following command in C#:

```
csc Example.cs /resource:ExampleResources.resources
```

System.Resources.ResourceManager class

Article • 01/08/2024

This article provides supplementary remarks to the reference documentation for this API.

ⓘ Important

Calling methods from this class with untrusted data is a security risk. Call the methods from this class only with trusted data. For more information, see [Validate All Inputs](#).

The [ResourceManager](#) class retrieves resources from a binary .resources file that is embedded in an assembly or from a standalone .resources file. If an app has been localized and localized resources have been deployed in [satellite assemblies](#), it looks up culture-specific resources, provides resource fallback when a localized resource does not exist, and supports resource serialization.

Desktop apps

For desktop apps, the [ResourceManager](#) class retrieves resources from binary resource (.resources) files. Typically, a language compiler or the [Assembly Linker \(AL.exe\)](#) embeds these resource files in an assembly. You can also use a [ResourceManager](#) object to retrieve resources directly from a .resources file that is not embedded in an assembly, by calling the [CreateFileBasedResourceManager](#) method.

✖ Caution

Using standalone .resources files in an ASP.NET app will break XCOPY deployment, because the resources remain locked until they are explicitly released by the [ReleaseAllResources](#) method. If you want to deploy resources with your ASP.NET apps, you should compile your .resources files into satellite assemblies.

In a resource-based app, one .resources file contains the resources of the default culture whose resources are used if no culture-specific resources can be found. For example, if an app's default culture is English (en), the English language resources are used whenever localized resources cannot be found for a specific culture, such as English

(United States) (en-US) or French (France) (fr-FR). Typically, the resources for the default culture are embedded in the main app assembly, and resources for other localized cultures are embedded in satellite assemblies. Satellite assemblies contain only resources. They have the same root file name as the main assembly and an extension of .resources.dll. For apps whose assemblies are not registered in the global assembly cache, satellite assemblies are stored in an app subdirectory whose name corresponds to the assembly's culture.

Create resources

When you develop a resource-based app, you store resource information in text files (files that have a .txt or .restext extension) or XML files (files that have a .resx extension). You then compile the text or XML files with the [Resource File Generator \(Resgen.exe\)](#) to create a binary .resources file. You can then embed the resulting .resources file in an executable or library by using a compiler option such as `/resources` for the C# and Visual Basic compilers, or you can embed it in a satellite assembly by using the [Assembly Linker \(Al.exe\)](#). If you include a .resx file in your Visual Studio project, Visual Studio handles the compilation and embedding of default and localized resources automatically as part of the build process.

Ideally, you should create resources for every language your app supports, or at least for a meaningful subset of each language. The binary .resources file names follow the naming convention *basename.cultureName.resources*, where *basename* is the name of the app or the name of a class, depending on the level of detail you want. The [CultureInfo.Name](#) property is used to determine *cultureName*. A resource for the app's default culture should be named *basename.resources*.

For example, suppose that an assembly has several resources in a resource file that has the base name MyResources. These resource files should have names such as MyResources.ja-JP.resources for the Japan (Japanese) culture, MyResources.de.resources for the German culture, MyResources.zh-CHS.resources for the simplified Chinese culture, and MyResources.fr-BE.resources for the French (Belgium) culture. The default resource file should be named MyResources.resources. The culture-specific resource files are commonly packaged in satellite assemblies for each culture. The default resource file should be embedded in the app's main assembly.

Note that [Assembly Linker](#) allows resources to be marked as private, but you should always mark them as public so they can be accessed by other assemblies. (Because a satellite assembly contains no code, resources that are marked as private are unavailable to your app through any mechanism.)

For more information about creating, packaging, and deploying resources, see the articles [Creating Resource Files](#), [Creating Satellite Assemblies](#), and [Packaging and Deploying Resources](#).

Instantiate a ResourceManager object

You instantiate a [ResourceManager](#) object that retrieves resources from an embedded .resources file by calling one of its class constructor overloads. This tightly couples a [ResourceManager](#) object with a particular .resources file and with any associated localized .resources files in satellite assemblies.

The two most commonly called constructors are:

- [ResourceManager\(String, Assembly\)](#) looks up resources based on two pieces of information that you supply: the base name of the .resources file, and the assembly in which the default .resources file resides. The base name includes the namespace and root name of the .resources file, without its culture or extension. Note that .resources files that are compiled from the command line typically do not include a namespace name, whereas .resources files that are created in the Visual Studio environment do. For example, if a resource file is named MyCompany.StringResources.resources and the [ResourceManager](#) constructor is called from a static method named `Example.Main`, the following code instantiates a [ResourceManager](#) object that can retrieve resources from the .resources file:

C#

```
ResourceManager rm = new ResourceManager("MyCompany.StringResources",
                                         typeof(Example).Assembly);
```

- [ResourceManager\(Type\)](#) looks up resources in satellite assemblies based on information from a type object. The type's fully qualified name corresponds to the base name of the .resources file without its file name extension. In desktop apps that are created by using the Visual Studio Resource Designer, Visual Studio creates a wrapper class whose fully qualified name is the same as the root name of the .resources file. For example, if a resource file is named MyCompany.StringResources.resources and there is a wrapper class named `MyCompany.StringResources`, the following code instantiates a [ResourceManager](#) object that can retrieve resources from the .resources file:

C#

```
ResourceManager rm = new
```

```
ResourceManager(typeof(MyCompany.StringResources));
```

If the appropriate resources cannot be found, the constructor call creates a valid `ResourceManager` object. However, the attempt to retrieve a resource throws a `MissingManifestResourceException` exception. For information about dealing with the exception, see the [Handle MissingManifestResourceException and MissingSatelliteAssembly Exceptions](#) section later in this article.

The following example shows how to instantiate a `ResourceManager` object. It contains the source code for an executable named ShowTime.exe. It also includes the following text file named Strings.txt that contains a single string resource, `TimeHeader`:

```
TimeHeader=The current time is
```

You can use a batch file to generate the resource file and embed it into the executable. Here's the batch file to generate an executable by using the C# compiler:

```
resgen strings.txt
csc ShowTime.cs /resource:strings.resources
```

For the Visual Basic compiler, you can use the following batch file:

```
resgen strings.txt
vbc ShowTime.vb /resource:strings.resources
```

C#

```
using System;
using System.Resources;

public class ShowTimeEx
{
    public static void Main()
    {
        ResourceManager rm = new ResourceManager("Strings",
                                                typeof(Example).Assembly);
        string timeString = rm.GetString("TimeHeader");
        Console.WriteLine("{0} {1:T}", timeString, DateTime.Now);
    }
}
```

```
// The example displays output like the following:  
//           The current time is 2:03:14 PM
```

ResourceManager and culture-specific resources

A localized app requires resources to be deployed, as discussed in the article [Packaging and Deploying Resources](#). If the assemblies are properly configured, the resource manager determines which resources to retrieve based on the current thread's [Thread.CurrentCulture](#) property. (That property also returns the current thread's UI culture.) For example, if an app is compiled with default English language resources in the main assembly and with French and Russian language resources in two satellite assemblies, and the [Thread.CurrentCulture](#) property is set to fr-FR, the resource manager retrieves the French resources.

You can set the [CurrentCulture](#) property explicitly or implicitly. The way you set it determines how the [ResourceManager](#) object retrieves resources based on culture:

- If you explicitly set the [Thread.CurrentCulture](#) property to a specific culture, the resource manager always retrieves the resources for that culture, regardless of the user's browser or operating system language. Consider an app that is compiled with default English language resources and three satellite assemblies that contain resources for English (United States), French (France), and Russian (Russia). If the [CurrentCulture](#) property is set to fr-FR, the [ResourceManager](#) object always retrieves the French (France) resources, even if the user's operating system language is not French. Make sure that this is the desired behavior before you set the property explicitly.

In ASP.NET apps, you must set the [Thread.CurrentCulture](#) property explicitly, because it is unlikely that the setting on the server will match incoming client requests. An ASP.NET app can set the [Thread.CurrentCulture](#) property explicitly to the user's browser accept language.

Explicitly setting the [Thread.CurrentCulture](#) property defines the current UI culture for that thread. It does not affect the current UI culture of any other threads in an app.

- You can set the UI culture of all threads in an app domain by assigning a [CultureInfo](#) object that represents that culture to the static [CultureInfo.DefaultThreadCurrentCulture](#) property.
- If you do not explicitly set the current UI culture and you do not define a default culture for the current app domain, the [CultureInfo.CurrentCulture](#) property is

set implicitly by the Windows `GetUserDefaultUILanguage` function. This function is provided by the Multilingual User Interface (MUI), which enables the user to set the default language. If the UI language is not set by the user, it defaults to the system-installed language, which is the language of operating system resources.

The following simple "Hello world" example sets the current UI culture explicitly. It contains resources for three cultures: English (United States) or en-US, French (France) or fr-FR, and Russian (Russia) or ru-RU. The en-US resources are contained in a text file named Greetings.txt:

```
HelloString=Hello world!
```

The fr-FR resources are contained in a text file named Greetings.fr-FR.txt:

```
HelloString=Salut tout le monde!
```

The ru-RU resources are contained in a text file named Greetings.ru-RU.txt:

```
HelloString=Всем привет!
```

Here's the source code for the example (Example.vb for the Visual Basic version or Example.cs for the C# version):

```
C#
```

```
using System;
using System.Globalization;
using System.Resources;
using System.Threading;

public class Example
{
    public static void Main()
    {
        // Create array of supported cultures
        string[] cultures = { "en-CA", "en-US", "fr-FR", "ru-RU" };
        Random rnd = new Random();
        int cultureNdx = rnd.Next(0, cultures.Length);
        CultureInfo originalCulture = Thread.CurrentThread.CurrentCulture;
        ResourceManager rm = new ResourceManager("Greetings",
typeof(Example).Assembly);
```

```

try
{
    CultureInfo newCulture = new CultureInfo(cultures[cultureNdx]);
    Thread.CurrentThread.CurrentCulture = newCulture;
    Thread.CurrentThread.CurrentUICulture = newCulture;
    string greeting = String.Format("The current culture is
{0}.\n{1}",

Thread.CurrentThread.CurrentUICulture.Name,
                                         rm.GetString("HelloString"));
    Console.WriteLine(greeting);
}
catch (CultureNotFoundException e)
{
    Console.WriteLine("Unable to instantiate culture {0}",
e.InvalidCultureName);
}
finally
{
    Thread.CurrentThread.CurrentCulture = originalCulture;
    Thread.CurrentThread.CurrentUICulture = originalCulture;
}
}

// The example displays output like the following:
//      The current culture is ru-RU.
//      Всем привет!

```

To compile this example, create a batch (.bat) file that contains the following commands and run it from the command prompt. If you're using C#, specify `csc` instead of `vbc` and `Example.cs` instead of `Example.vb`.

```

resgen Greetings.txt
vbc Example.vb /resource:Greetings.resources

resgen Greetings.fr-FR.txt
Md fr-FR
al /embed:Greetings.fr-FR.resources /culture:fr-FR /out:fr-
FR\Example.resources.dll

resgen Greetings.ru-RU.txt
Md ru-RU
al /embed:Greetings.ru-RU.resources /culture:ru-RU /out:ru-
RU\Example.resources.dll

```

Retrieve resources

You call the [GetObject\(String\)](#) and [GetString\(String\)](#) methods to access a specific resource. You can also call the [GetStream\(String\)](#) method to retrieve non-string resources as a byte array. By default, in an app that has localized resources, these methods return the resource for the culture determined by the current UI culture of the thread that made the call. See the previous section, [ResourceManager and culture-specific resources](#), for more information about how the current UI culture of a thread is defined. If the resource manager cannot find the resource for the current thread's UI culture, it uses a fallback process to retrieve the specified resource. If the resource manager cannot find any localized resources, it uses the resources of the default culture. For more information about resource fallback rules, see the "Resource Fallback Process" section of the article [Packaging and Deploying Resources](#).

Note

If the .resources file specified in the [ResourceManager](#) class constructor cannot be found, the attempt to retrieve a resource throws a [MissingManifestResourceException](#) or [MissingSatelliteAssemblyException](#) exception. For information about dealing with the exception, see the [Handle MissingManifestResourceException and MissingSatelliteAssemblyException Exceptions](#) section later in this article.

The following example uses the [GetString](#) method to retrieve culture-specific resources. It consists of resources compiled from .txt files for the English (en), French (France) (fr-FR), and Russian (Russia) (ru-RU) cultures. The example changes the current culture and current UI culture to English (United States), French (France), Russian (Russia), and Swedish (Sweden). It then calls the [GetString](#) method to retrieve the localized string, which it displays along with the current day and month. Notice that the output displays the appropriate localized string except when the current UI culture is Swedish (Sweden). Because Swedish language resources are unavailable, the app instead uses the resources of the default culture, which is English.

The example requires the text-based resource files listed in following table. Each has a single string resource named `DateStart`.

 Expand table

| Culture | File name | Resource name | Resource value |
|---------|-----------------------|---------------|-----------------------|
| en-US | DateStrings.txt | DateStart | Today is |
| fr-FR | DateStrings.fr-FR.txt | DateStart | Aujourd'hui, c'est le |

| Culture | File name | Resource name | Resource value |
|---------|-----------------------|---------------|----------------|
| ru-RU | DateStrings.ru-RU.txt | DateStart | Сегодня |

Here's the source code for the example (ShowDate.vb for the Visual Basic version or ShowDate.cs for the C# version of the code).

C#

```

using System;
using System.Globalization;
using System.Resources;
using System.Threading;

[assembly: NeutralResourcesLanguage("en")]

public class ShowDateEx
{
    public static void Main()
    {
        string[] cultureNames = { "en-US", "fr-FR", "ru-RU", "sv-SE" };
        ResourceManager rm = new ResourceManager("DateStrings",
                                                typeof(Example).Assembly);

        foreach (var cultureName in cultureNames)
        {
            CultureInfo culture =
CultureInfo.CreateSpecificCulture(cultureName);
            Thread.CurrentThread.CurrentCulture = culture;
            Thread.CurrentThread.CurrentUICulture = culture;

            Console.WriteLine("Current UI Culture: {0}",
                              CultureInfo.CurrentCulture.Name);
            string dateString = rm.GetString("DateStart");
            Console.WriteLine("{0} {1:M}.\\n", dateString, DateTime.Now);
        }
    }
}

// The example displays output similar to the following:
//      Current UI Culture: en-US
//      Today is February 03.
//
//      Current UI Culture: fr-FR
//      Aujourd'hui, c'est le 3 février
//
//      Current UI Culture: ru-RU
//      Сегодня февраля 03.
//
//      Current UI Culture: sv-SE
//      Today is den 3 februari.

```

To compile this example, create a batch file that contains the following commands and run it from the command prompt. If you're using C#, specify `csc` instead of `vbc` and `showdate.cs` instead of `showdate.vb`.

```
resgen DateStrings.txt
vbc showdate.vb /resource:DateStrings.resources

md fr-FR
resgen DateStrings.fr-FR.txt
al /out:fr-FR>Showdate.resources.dll /culture:fr-FR /embed:DateStrings.fr-
FR.resources

md ru-RU
resgen DateStrings.ru-RU.txt
al /out:ru-RU>Showdate.resources.dll /culture:ru-RU /embed:DateStrings.ru-
RU.resources
```

There are two ways to retrieve the resources of a specific culture other than the current UI culture:

- You can call the [GetString\(String, CultureInfo\)](#), [GetObject\(String, CultureInfo\)](#), or [GetStream\(String, CultureInfo\)](#) method to retrieve a resource for a specific culture. If a localized resource cannot be found, the resource manager uses the resource fallback process to locate an appropriate resource.
- You can call the [GetResourceSet](#) method to obtain a [ResourceSet](#) object that represents the resources for a particular culture. In the method call, you can determine whether the resource manager probes for parent cultures if it is unable to find localized resources, or whether it simply falls back to the resources of the default culture. You can then use the [ResourceSet](#) methods to access the resources (localized for that culture) by name, or to enumerate the resources in the set.

Handle [MissingManifestResourceException](#) and [MissingSatelliteAssemblyException](#) exceptions

If you try to retrieve a specific resource, but the resource manager cannot find that resource and either no default culture has been defined or the resources of the default culture cannot be located, the resource manager throws a [MissingManifestResourceException](#) exception if it expects to find the resources in the main assembly or a [MissingSatelliteAssemblyException](#) if it expects to find the resources in a satellite assembly. Note that the exception is thrown when you call a resource retrieval method such as [GetString](#) or [GetObject](#), and not when you instantiate a [ResourceManager](#) object.

The exception is typically thrown under the following conditions:

- The appropriate resource file or satellite assembly does not exist. If the resource manager expects the app's default resources to be embedded in the main app assembly, they are absent. If the [NeutralResourcesLanguageAttribute](#) attribute indicates that the app's default resources reside in a satellite assembly, that assembly cannot be found. When you compile your app, make sure that resources are embedded in the main assembly or that the necessary satellite assembly is generated and is named appropriately. Its name should take the form *appName.resources.dll*, and it should be located in a directory named after the culture whose resources it contains.
- Your app doesn't have a default or neutral culture defined. Add the [NeutralResourcesLanguageAttribute](#) attribute to a source code file or to the project information file (AssemblyInfo.vb for a Visual Basic app or AssemblyInfo.cs for a C# app) file.
- The `baseName` parameter in the [ResourceManager\(String, Assembly\)](#) constructor does not specify the name of a .resources file. The name should include the resource file's fully qualified namespace but not its file name extension. Typically, resource files that are created in Visual Studio include namespace names, but resource files that are created and compiled at the command prompt do not. You can determine the names of embedded .resources files by compiling and running the following utility. This is a console app that accepts the name of a main assembly or satellite assembly as a command-line parameter. It displays the strings that should be provided as the `baseName` parameter so that the resource manager can correctly identify the resource.

C#

```
using System;
using System.IO;
using System.Reflection;
using System.Resources;

public class Example
{
    public static void Main()
    {
        if (Environment.GetCommandLineArgs().Length == 1) {
            Console.WriteLine("No filename.");
            return;
        }

        string filename = Environment.GetCommandLineArgs()[1].Trim();
        // Check whether the file exists.
```

```

if (! File.Exists(filename)) {
    Console.WriteLine("{0} does not exist.", filename);
    return;
}

// Try to load the assembly.
Assembly assem = Assembly.LoadFrom(filename);
Console.WriteLine("File: {0}", filename);

// Enumerate the resource files.
string[] resNames = assem.GetManifestResourceNames();
if (resNames.Length == 0)
    Console.WriteLine("No resources found.");

foreach (var resName in resNames)
    Console.WriteLine("Resource: {0}",
        resName.Replace(".resources", ""));
}

Console.WriteLine();
}
}

```

If you are changing the current culture of your application explicitly, you should also remember that the resource manager retrieves a resource set based on the value of the [CultureInfo.CurrentCulture](#) property, and not the [CultureInfo.CurrentCulture](#) property. Typically, if you change one value, you should also change the other.

Resource versioning

Because the main assembly that contains an app's default resources is separate from the app's satellite assemblies, you can release a new version of your main assembly without redeploying the satellite assemblies. You use the [SatelliteContractVersionAttribute](#) attribute to use existing satellite assemblies and instruct the resource manager not to redeploy them with a new version of your main assembly.

For more information about versioning support for satellite assemblies, see the article [Retrieving Resources](#).

<satelliteassemblies> configuration file node

Note

This section is specific to .NET Framework apps.

For executables that are deployed and run from a website (HREF .exe files), the [ResourceManager](#) object may probe for satellite assemblies over the web, which can hurt your app's performance. To eliminate the performance problem, you can limit this probing to the satellite assemblies that you have deployed with your app. To do this, you create a `<satelliteassemblies>` node in your app's configuration file to specify that you have deployed a specific set of cultures for your app, and that the [ResourceManager](#) object should not try to probe for any culture that is not listed in that node.

 **Note**

The preferred alternative to creating a `<satelliteassemblies>` node is to use the [ClickOnce Deployment Manifest](#) feature.

In your app's configuration file, create a section similar to the following:

XML

```
<?xml version ="1.0"?>
<configuration>
  <satelliteassemblies>
    <assembly name="MainAssemblyName, Version=versionNumber,
Culture=neutral, PublicKeyToken=null|yourPublicKeyToken">
      <culture>cultureName1</culture>
      <culture>cultureName2</culture>
      <culture>cultureName3</culture>
    </assembly>
  </satelliteassemblies>
</configuration>
```

Edit this configuration information as follows:

- Specify one or more `<assembly>` nodes for each main assembly that you deploy, where each node specifies a fully qualified assembly name. Specify the name of your main assembly in place of *MainAssemblyName*, and specify the `Version`, `PublicKeyToken`, and `Culture` attribute values that correspond to your main assembly.

For the `Version` attribute, specify the version number of your assembly. For example, the first release of your assembly might be version number 1.0.0.0.

For the `PublicKeyToken` attribute, specify the keyword `null` if you have not signed your assembly with a strong name, or specify your public key token if you have signed your assembly.

For the `Culture` attribute, specify the keyword `neutral` to designate the main assembly and cause the [ResourceManager](#) class to probe only for the cultures listed in the `<culture>` nodes.

For more information about fully qualified assembly names, see the article [Assembly Names](#). For more information about strong-named assemblies, see the article [Create and use strong-named assemblies](#).

- Specify one or more `<culture>` nodes with a specific culture name, such as "fr-FR", or a neutral culture name, such as "fr".

If resources are needed for any assembly not listed under the `<satelliteassemblies>` node, the [ResourceManager](#) class probes for cultures using standard probing rules.

Windows 8.x apps

Important

Although the [ResourceManager](#) class is supported in Windows 8.x apps, we do not recommend its use. Use this class only when you develop Portable Class Library projects that can be used with Windows 8.x apps. To retrieve resources from Windows 8.x apps, use the [Windows.ApplicationModel.Resources.ResourceLoader](#) class instead.

For Windows 8.x apps, the [ResourceManager](#) class retrieves resources from package resource index (PRI) files. A single PRI file (the application package PRI file) contains the resources for both the default culture and any localized cultures. You use the MakePRI utility to create a PRI file from one or more resource files that are in XML resource (.resw) format. For resources that are included in a Visual Studio project, Visual Studio handles the process of creating and packaging the PRI file automatically. You can then use the .NET [ResourceManager](#) class to access the app's or library's resources.

You can instantiate a [ResourceManager](#) object for a Windows 8.x app in the same way that you do for a desktop app.

You can then access the resources for a particular culture by passing the name of the resource to be retrieved to the [GetString\(String\)](#) method. By default, this method returns the resource for the culture determined by the current UI culture of the thread that made the call. You can also retrieve the resources for a specific culture by passing the name of the resource and a [CultureInfo](#) object that represents the culture whose resource is to be retrieved to the [GetString\(String, CultureInfo\)](#) method. If the resource

for the current UI culture or the specified culture cannot be found, the resource manager uses a UI language fallback list to locate a suitable resource.

Examples

The following example demonstrates how to use an explicit culture and the implicit current UI culture to obtain string resources from a main assembly and a satellite assembly. For more information, see the "Directory Locations for Satellite Assemblies Not Installed in the Global Assembly Cache" section of the [Creating Satellite Assemblies](#) topic.

To run this example:

1. In the app directory, create a file named rmc.txt that contains the following resource strings:

```
day=Friday  
year=2006  
holiday="Cinco de Mayo"
```

2. Use the [Resource File Generator](#) to generate the rmc.resources resource file from the rmc.txt input file as follows:

```
resgen rmc.txt
```

3. Create a subdirectory of the app directory and name it "es-MX". This is the culture name of the satellite assembly that you will create in the next three steps.
4. Create a file named rmc.es-MX.txt in the es-MX directory that contains the following resource strings:

```
day=Viernes  
year=2006  
holiday="Cinco de Mayo"
```

5. Use the [Resource File Generator](#) to generate the rmc.es-MX.resources resource file from the rmc.es-MX.txt input file as follows:

```
resgen rmc.es-MX.txt
```

6. Assume that the filename for this example is rmc.vb or rmc.cs. Copy the following source code into a file. Then compile it and embed the main assembly resource file, rmc.resources, in the executable assembly. If you are using the Visual Basic compiler, the syntax is:

```
vbc rmc.vb /resource:rmc.resources
```

The corresponding syntax for the C# compiler is:

```
csc /resource:rmc.resources rmc.cs
```

7. Use the [Assembly Linker](#) to create a satellite assembly. If the base name of the app is rmc, the satellite assembly name must be rmc.resources.dll. The satellite assembly should be created in the es-MX directory. If es-MX is the current directory, use this command:

```
al /embed:rmc.es-MX.resources /c:es-MX /out:rmc.resources.dll
```

8. Run rmc.exe to obtain and display the embedded resource strings.

C#

```
using System;
using System.Globalization;
using System.Resources;

class Example2
{
    public static void Main()
    {
        string day;
        string year;
        string holiday;
        string celebrate = "{0} will occur on {1} in {2}.\n";
        // Create a resource manager.
```

```

ResourceManager rm = new ResourceManager("rmc",
                                         typeof(Example).Assembly);

Console.WriteLine("Obtain resources using the current UI culture.");

    // Get the resource strings for the day, year, and holiday
    // using the current UI culture.
    day = rm.GetString("day");
    year = rm.GetString("year");
    holiday = rm.GetString("holiday");
    Console.WriteLine(celebrate, holiday, day, year);

    // Obtain the es-MX culture.
    CultureInfo ci = new CultureInfo("es-MX");

    Console.WriteLine("Obtain resources using the es-MX culture.");

    // Get the resource strings for the day, year, and holiday
    // using the specified culture.
    day = rm.GetString("day", ci);
    year = rm.GetString("year", ci);
    holiday = rm.GetString("holiday", ci);
    // -----
    // Alternatively, comment the preceding 3 code statements and
    // uncomment the following 4 code statements:
    // -----
    // Set the current UI culture to "es-MX" (Spanish-Mexico).
    //     Thread.CurrentThread.CurrentCulture = ci;

    // Get the resource strings for the day, year, and holiday
    // using the current UI culture. Use those strings to
    // display a message.
    //     day = rm.GetString("day");
    //     year = rm.GetString("year");
    //     holiday = rm.GetString("holiday");
    // -----

    // Regardless of the alternative that you choose, display a message
    // using the retrieved resource strings.
    Console.WriteLine(celebrate, holiday, day, year);
}

/*
This example displays the following output:

```

Obtain resources using the current UI culture.
 "5th of May" will occur on Friday in 2006.

Obtain resources using the es-MX culture.
 "Cinco de Mayo" will occur on Viernes in 2006.

*/

System.Resources.ResourceReader class

Article • 01/08/2024

This article provides supplementary remarks to the reference documentation for this API.

ⓘ Important

Calling methods from this class with untrusted data is a security risk. Call the methods from this class only with trusted data. For more information, see [Validate All Inputs](#).

The [ResourceReader](#) class provides a standard implementation of the [IResourceReader](#) interface. A [ResourceReader](#) instance represents either a standalone .resources file or a .resources file that is embedded in an assembly. It is used to enumerate the resources in a .resources file and retrieve its name/value pairs. It differs from the [ResourceManager](#) class, which is used to retrieve specified named resources from a .resources file that is embedded in an assembly. The [ResourceManager](#) class is used to retrieve resources whose names are known in advance, whereas the [ResourceReader](#) class is useful for retrieving resources whose number or precise names are not known at compile time. For example, an application may use a resources file to store configuration information that is organized into sections and items in a section, where the number of sections or items in a section is not known in advance. Resources can then be named generically (such as `Section1`, `Section1Item1`, `Section1Item2`, and so on) and retrieved by using a [ResourceReader](#) object.

ⓘ Important

This type implements the [IDisposable](#) interface. When you have finished using the type, you should dispose of it either directly or indirectly. To dispose of the type directly, call its [Dispose](#) method in a `try/catch` block. To dispose of it indirectly, use a language construct such as `using` (in C#) or `Using` (in Visual Basic). For more information, see the "Using an Object that Implements [IDisposable](#)" section in the [IDisposable](#) interface documentation.

Instantiate a ResourceReader object

A .resources file is a binary file that has been compiled from either a text file or an XML .resx file by Resgen.exe (Resource File Generator). A [ResourceReader](#) object can represent either a standalone .resources file or a .resources file that has been embedded in an assembly.

To instantiate a [ResourceReader](#) object that reads from a standalone .resources file, use the [ResourceReader](#) class constructor with either an input stream or a string that contains the .resources file name. The following example illustrates both approaches. The first instantiates a [ResourceReader](#) object that represents a .resources file named `Resources1.resources` by using its file name. The second instantiates a [ResourceReader](#) object that represents a .resources file named `Resources2.resources` by using a stream created from the file.

C#

```
// Instantiate a standalone .resources file from its filename.  
var rr1 = new System.Resources.ResourceReader("Resources1.resources");  
  
// Instantiate a standalone .resources file from a stream.  
var fs = new System.IO.FileStream(@".\Resources2.resources",  
                           System.IO FileMode.Open);  
var rr2 = new System.Resources.ResourceReader(fs);
```

To create a [ResourceReader](#) object that represents an embedded .resources file, instantiate an [Assembly](#) object from the assembly in which the .resources file is embedded. Its [Assembly.GetManifestResourceStream](#) method returns a [Stream](#) object that can be passed to the [ResourceReader\(Stream\)](#) constructor. The following example instantiates a [ResourceReader](#) object that represents an embedded .resources file.

C#

```
System.Reflection.Assembly assem =  
    System.Reflection.Assembly.LoadFrom(@".\MyLibrary.dll");  
System.IO.Stream fs =  
  
assem.GetManifestResourceStream("MyCompany.LibraryResources.resources");  
var rr = new System.Resources.ResourceReader(fs);
```

Enumerate a ResourceReader object's resources

To enumerate the resources in a .resources file, you call the [GetEnumerator](#) method, which returns an [System.Collections.IDictionaryEnumerator](#) object. You call the [IDictionaryEnumerator.MoveNext](#) method to move from one resource to the next. The

method returns `false` when all the resources in the .resources file have been enumerated.

ⓘ Note

Although the `ResourceReader` class implements the `IEnumerable` interface and the `IEnumerable.GetEnumerator` method, the `ResourceReader.GetEnumerator` method does not provide the `IEnumerable.GetEnumerator` implementation. Instead, the `ResourceReader.GetEnumerator` method returns an `IDictionaryEnumerator` interface object that provides access to each resource's name/value pair.

You can retrieve the individual resources in the collection in two ways:

- You can iterate each resource in the `System.Collections.IDictionaryEnumerator` collection and use `System.Collections.IDictionaryEnumerator` properties to retrieve the resource name and value. We recommend this technique when all the resources are of the same type, or you know the data type of each resource.
- You can retrieve the name of each resource when you iterate the `System.Collections.IDictionaryEnumerator` collection and call the `GetResourceData` method to retrieve the resource's data. We recommend this approach when you do not know the data type of each resource or if the previous approach throws exceptions.

Retrieve resources by using `IDictionaryEnumerator` properties

The first method of enumerating the resources in a .resources file involves directly retrieving each resource's name/value pair. After you call the `IDictionaryEnumerator.MoveNext` method to move to each resource in the collection, you can retrieve the resource name from the `IDictionaryEnumerator.Key` property and the resource data from the `IDictionaryEnumerator.Value` property.

The following example shows how to retrieve the name and value of each resource in a .resources file by using the `IDictionaryEnumerator.Key` and `IDictionaryEnumerator.Value` properties. To run the example, create the following text file named ApplicationResources.txt to define string resources.

```
Title="Contact Information"  
Label1="First Name:"
```

```
Label2="Middle Name:"  
Label3="Last Name:"  
Label4="SSN:"  
Label5="Street Address:"  
Label6="City:"  
Label7="State:"  
Label8="Zip Code:"  
Label9="Home Phone:"  
Label10="Business Phone:"  
Label11="Mobile Phone:"  
Label12="Other Phone:"  
Label13="Fax:"  
Label14="Email Address:"  
Label15="Alternate Email Address:"
```

You can then convert the text resource file to a binary file named ApplicationResources.resources by using the following command:

```
resgen ApplicationResources.txt
```

The following example then uses the [ResourceReader](#) class to enumerate each resource in the standalone binary .resources file and to display its key name and corresponding value.

C#

```
using System;  
using System.Collections;  
using System.Resources;  
  
public class Example1  
{  
    public static void Run()  
    {  
        Console.WriteLine("Resources in ApplicationResources.resources:");  
        ResourceReader res = new  
ResourceReader(@"..\ApplicationResources.resources");  
        IDictionaryEnumerator dict = res.Getenumerator();  
        while (dict.MoveNext())  
            Console.WriteLine("    {0}: '{1}' (Type {2})",  
                            dict.Key, dict.Value, dict.Value.GetType().Name);  
        res.Close();  
    }  
}  
// The example displays the following output:  
//     Resources in ApplicationResources.resources:  
//         Label3: '"Last Name"' (Type String)  
//         Label2: '"Middle Name"' (Type String)  
//         Label1: '"First Name"' (Type String)  
//         Label7: '"State"' (Type String)  
//         Label6: '"City"' (Type String)  
//         Label5: '"Street Address"' (Type String)
```

```
//      Label14: '"SSN:"' (Type String)
//      Label19: '"Home Phone:"' (Type String)
//      Label18: '"Zip Code:"' (Type String)
//      Title: '"Contact Information"' (Type String)
//      Label12: '"Other Phone:"' (Type String)
//      Label13: '"Fax:"' (Type String)
//      Label10: '"Business Phone:"' (Type String)
//      Label11: '"Mobile Phone:"' (Type String)
//      Label14: '"Email Address:"' (Type String)
//      Label15: '"Alternate Email Address:"' (Type String)
```

The attempt to retrieve resource data from the [IDictionaryEnumerator.Value](#) property can throw the following exceptions:

- A [FormatException](#) if the data is not in the expected format.
- A [FileNotFoundException](#) if the assembly that contains the type to which the data belongs cannot be found.
- A [TypeLoadException](#) if the type to which the data belongs cannot be found.

Typically, these exceptions are thrown if the .resources file has been modified manually, if the assembly in which a type is defined has either not been included with an application or has been inadvertently deleted, or if the assembly is an older version that predates a type. If one of these exceptions is thrown, you can retrieve resources by enumerating each resource and calling the [GetResourceData](#) method, as the following section shows. This approach provides you with some information about the data type that the [IDictionaryEnumerator.Value](#) property attempted to return.

Retrieve resources by name with GetResourceData

The second approach to enumerating resources in a .resources file also involves navigating through the resources in the file by calling the [IDictionaryEnumerator.MoveNext](#) method. For each resource, you retrieve the resource's name from the [IDictionaryEnumerator.Key](#) property, which is then passed to the [GetResourceData\(String, String, Byte\[\]\)](#) method to retrieve the resource's data. This is returned as a byte array in the [resourceData](#) argument.

This approach is more awkward than retrieving the resource name and value from the [IDictionaryEnumerator.Key](#) and [IDictionaryEnumerator.Value](#) properties, because it returns the actual bytes that form the resource value. However, if the attempt to retrieve the resource throws an exception, the [GetResourceData](#) method can help identify the source of the exception by supplying information about the resource's data type. For more information about the string that indicates the resource's data type, see [GetResourceData](#).

The following example illustrates how to use this approach to retrieve resources and to handle any exceptions that are thrown. It programmatically creates a binary .resources file that contains four strings, one Boolean, one integer, and one bitmap. To run the example, do the following:

1. Compile and execute the following source code, which creates a .resources file named ContactResources.resources.

C#

```
using System.Drawing;
using System.Drawing.Imaging;
using System.IO;
using System.Resources;
using System.Runtime.Versioning;

public class Example5
{
    [SupportedOSPlatform("windows")]
    public static void Run()
    {
        // Bitmap as stream.
        MemoryStream bitmapStream = new MemoryStream();
        Bitmap bmp = new Bitmap(@".\ContactsIcon.jpg");
        bmp.Save(bitmapStream, ImageFormat.Jpeg);

        // Define resources to be written.
        using (ResourceWriter rw = new
        ResourceWriter(@".\ContactResources.resources"))
        {
            rw.AddResource("Title", "Contact List");
            rw.AddResource("NColumns", 5);
            rw.AddResource("Icon", bitmapStream);
            rw.AddResource("Header1", "Name");
            rw.AddResource("Header2", "City");
            rw.AddResource("Header3", "State");
            rw.AddResource("ClientVersion", true);
            rw.Generate();
        }
    }
}
```

The source code file is named CreateResources.cs. You can compile it in C# by using the following command:

```
csc CreateResources.cs /r:library.dll
```

2. Compile and run the following code to enumerate the resources in the ContactResources.resources file.

```
C#  
  
using System;  
using System.Collections;  
using System.Drawing;  
using System.IO;  
using System.Resources;  
using System.Runtime.Versioning;  
  
public class Example6  
{  
    [SupportedOSPlatform("windows")]  
    public static void Run()  
    {  
        ResourceReader rdr = new  
ResourceReader(@".\ContactResources.resources");  
        IDictionaryEnumerator dict = rdr.Getenumerator();  
        while (dict.MoveNext())  
        {  
            Console.WriteLine("Resource Name: {0}", dict.Key);  
            try  
            {  
                Console.WriteLine("    Value: {0}", dict.Value);  
            }  
            catch (FileNotFoundException)  
            {  
                Console.WriteLine("    Exception: A file cannot be  
found.");  
                DisplayResourceInfo(rdr, (string)dict.Key, false);  
            }  
            catch (FormatException)  
            {  
                Console.WriteLine("    Exception: Corrupted data.");  
                DisplayResourceInfo(rdr, (string)dict.Key, true);  
            }  
            catch (TypeLoadException)  
            {  
                Console.WriteLine("    Exception: Cannot load the data  
type.");  
                DisplayResourceInfo(rdr, (string)dict.Key, false);  
            }  
        }  
    }  
  
    [SupportedOSPlatform("windows")]  
    private static void DisplayResourceInfo(ResourceReader rr,  
                                            string key, bool loaded)  
    {  
        string dataType = null;  
        byte[] data = null;  
        rr.GetResourceData(key, out dataType, out data);
```

```

// Display the data type.
Console.WriteLine("    Data Type: {0}", dataType);
// Display the bytes that form the available data.
Console.Write("    Data: ");
int lines = 0;
foreach (var dataItem in data)
{
    lines++;
    Console.Write("{0:X2} ", dataItem);
    if (lines % 25 == 0)
        Console.WriteLine("\n");
}
Console.WriteLine();
// Try to recreate current state of data.
// Do: Bitmap, DateTimeTzI
switch (dataType)
{
    // Handle internally serialized string data
    // (ResourceTypeCode members).
    case "ResourceTypeCode.String":
        BinaryReader reader = new BinaryReader(new
MemoryStream(data));
        string binData = reader.ReadString();
        Console.WriteLine("    Recreated Value: {0}", binData);
        break;
    case "ResourceTypeCode.Int32":
        Console.WriteLine("    Recreated Value: {0}",
BitConverter.ToInt32(data, 0));
        break;
    case "ResourceTypeCode.Boolean":
        Console.WriteLine("    Recreated Value: {0}",
BitConverter.ToBoolean(data, 0));
        break;
    // .jpeg image stored as a stream.
    case "ResourceTypeCode.Stream":
        const int OFFSET = 4;
        int size = BitConverter.ToInt32(data, 0);
        Bitmap value1 = new Bitmap(new MemoryStream(data,
OFFSET, size));
        Console.WriteLine("    Recreated Value: {0}", value1);
        break;
    default:
        break;
}
Console.WriteLine();
}
}

```

After modifying the source code (for example, by deliberately throwing a `FormatException` at the end of the `try` block), you can run the example to see how

calls to [GetResourceData](#) enable you to retrieve or recreate some resource information.

System.Resources.SatelliteContractVersionAttribute class

Article • 01/08/2024

This article provides supplementary remarks to the reference documentation for this API.

In desktop apps, the [SatelliteContractVersionAttribute](#) attribute establishes a contract between a main assembly and all its satellites. You apply this attribute to your main assembly, and pass it the version number of the satellite assemblies that will work with this version of the main assembly. When the resource manager ([ResourceManager](#) object) looks up resources, it explicitly loads the satellite version specified by this attribute on the main assembly.

When you update the main assembly, you increment its assembly version number. However, you might not want to ship new copies of your satellite assemblies if the existing ones are compatible with your app. In this case, increment the main assembly's version number but leave the satellite contract version number the same. The resource manager will use your existing satellite assemblies.

If you want to revise a satellite assembly but not the main assembly, increment the version number on your satellite. In this case, ship a publisher policy assembly along with your satellite assembly stating that your new satellite assembly has backward compatibility with your old satellite assembly. The resource manager will still use the old contract number written into your main assembly based on the [SatelliteContractVersionAttribute](#) attribute; however, the loader will bind to the satellite assembly version that is specified by the policy assembly.

A vendor of a shared component uses a publisher policy assembly to make a compatibility statement about a particular version of a released assembly. A publisher policy assembly is a strongly named assembly that has a name in the format `policy.<major>.<minor>.<ComponentAssemblyName>`, and is registered in the [Global Assembly Cache \(GAC\)](#). The publisher policy is generated from an XML configuration file (see the [<bindingRedirect> Element](#)) by using the [Al.exe \(Assembly Linker\)](#) tool. The Assembly Linker is used with the `/link` option to link the XML configuration file to a manifest assembly, which is then stored in the global assembly cache. The publisher policy assemblies can be used when a vendor ships a maintenance release (service pack) that contains bug fixes.

Windows 8.x Store apps

This attribute is ignored in Windows 8.x Store apps, because package resource index (PRI) files do not have versioning semantics. In addition, the Windows 8.x Store packaging model requires all resources to ship in the same package, with no possibility of redeploying satellite assemblies or PRI files.

Worker services in .NET

Article • 12/15/2023

There are numerous reasons for creating long-running services such as:

- Processing CPU-intensive data.
- Queuing work items in the background.
- Performing a time-based operation on a schedule.

Background service processing usually doesn't involve a user interface (UI), but UIs can be built around them. In the early days with .NET Framework, Windows developers could create Windows Services for these reasons. Now with .NET, you can use the [BackgroundService](#), which is an implementation of [IHostedService](#), or implement your own.

With .NET, you're no longer restricted to Windows. You can develop cross-platform background services. Hosted services are logging, configuration, and dependency injection (DI) ready. They're a part of the extensions suite of libraries, meaning they're fundamental to all .NET workloads that work with the [generic host](#).

ⓘ Important

Installing the .NET SDK also installs the `Microsoft.NET.Sdk.Worker` and the worker template. In other words, after installing the .NET SDK, you could create a new worker by using the `dotnet new worker` command. If you're using Visual Studio, the template is hidden until the optional ASP.NET and web development workload is installed.

Terminology

Many terms are mistakenly used synonymously. In this section, there are definitions for some of these terms to make their intent more apparent.

- **Background Service:** Refers to the [BackgroundService](#) type.
- **Hosted Service:** Implementations of [IHostedService](#), or referring to the [IHostedService](#) itself.
- **Long-running Service:** Any service that runs continuously.
- **Windows Service:** The *Windows Service* infrastructure, originally .NET Framework centric but now accessible via .NET.
- **Worker Service:** Refers to the *Worker Service* template.

Worker Service template

The Worker Service template is available to the .NET CLI, and Visual Studio. For more information, see [.NET CLI, dotnet new worker - template](#). The template consists of a `Program` and `Worker` class.

C#

```
using App.WorkerService;

HostApplicationBuilder builder = Host.CreateApplicationBuilder(args);
builder.Services.AddHostedService<Worker>();

IHost host = builder.Build();
host.Run();
```

The preceding `Program` class:

- Creates a `HostApplicationBuilder`.
- Calls `AddHostedService` to register the `Worker` as a hosted service.
- Builds an `IHost` from the builder.
- Calls `Run` on the `host` instance, which runs the app.

Template defaults

The Worker template doesn't enable server garbage collection (GC) by default, as there are numerous factors that play a role in determining its necessity. All of the scenarios that require long-running services should consider performance implications of this default. To enable server GC, add the `ServerGarbageCollection` node to the project file:

XML

```
<PropertyGroup>
    <ServerGarbageCollection>true</ServerGarbageCollection>
</PropertyGroup>
```

Tradeoffs and considerations

 Expand table

| Enabled | Disabled |
|---|--|
| Efficient memory management: Automatically reclaims unused memory to prevent memory | Improved real-time performance: Avoids potential pauses or interruptions caused by |

| Enabled | Disabled |
|---|--|
| leaks and optimize resource usage. | garbage collection in latency-sensitive applications. |
| Long-term stability: Helps maintain stable performance in long-running services by managing memory over extended periods. | Resource efficiency: May conserve CPU and memory resources in resource-constrained environments. |
| Reduced maintenance: Minimizes the need for manual memory management, simplifying maintenance. | Manual memory control: Provides fine-grained control over memory for specialized applications. |
| Predictable behavior: Contributes to consistent and predictable application behavior. | Suitable for Short-lived processes: Minimizes the overhead of garbage collection for short-lived or ephemeral processes. |

For more information regarding performance considerations, see [Server GC](#). For more information on configuring server GC, see [Server GC configuration examples](#).

Worker class

As for the `Worker`, the template provides a simple implementation.

```
C#  
  
namespace App.WorkerService;  
  
public sealed class Worker(ILogger<Worker> logger) : BackgroundService  
{  
    protected override async Task ExecuteAsync(CancellationToken stoppingToken)  
    {  
        while (!stoppingToken.IsCancellationRequested)  
        {  
            logger.LogInformation("Worker running at: {time}",  
DateTimeOffset.Now);  
            await Task.Delay(1_000, stoppingToken);  
        }  
    }  
}
```

The preceding `Worker` class is a subclass of [BackgroundService](#), which implements [IHostedService](#). The [BackgroundService](#) is an `abstract class` and requires the subclass to implement `BackgroundService.ExecuteAsync(CancellationToken)`. In the template implementation, the `ExecuteAsync` loops once per second, logging the current date and time until the process is signaled to cancel.

The project file

The Worker template relies on the following project file `Sdk`:

XML

```
<Project Sdk="Microsoft.NET.Sdk.Worker">
```

For more information, see [.NET project SDKs](#).

NuGet package

An app based on the Worker template uses the `Microsoft.NET.Sdk.Worker` SDK and has an explicit package reference to the [Microsoft.Extensions.Hosting](#) package.

Containers and cloud adaptability

With most modern .NET workloads, containers are a viable option. When creating a long-running service from the Worker template in Visual Studio, you can opt in to **Docker support**. Doing so creates a *Dockerfile* that containerizes your .NET app. A [Dockerfile](#) is a set of instructions to build an image. For .NET apps, the *Dockerfile* usually sits in the root of the directory next to a solution file.

Dockerfile

```
# See https://aka.ms/containerfastmode to understand how Visual Studio uses
# this
# Dockerfile to build your images for faster debugging.

FROM mcr.microsoft.com/dotnet/runtime:8.0 AS base
WORKDIR /app

FROM mcr.microsoft.com/dotnet/sdk:8.0 AS build
WORKDIR /src
COPY ["background-service/App.WorkerService.csproj", "background-service/"]
RUN dotnet restore "background-service/App.WorkerService.csproj"
COPY .
WORKDIR "/src/background-service"
RUN dotnet build "App.WorkerService.csproj" -c Release -o /app/build

FROM build AS publish
RUN dotnet publish "App.WorkerService.csproj" -c Release -o /app/publish

FROM base AS final
WORKDIR /app
```

```
COPY --from=publish /app/publish .
ENTRYPOINT ["dotnet", "App.WorkerService.dll"]
```

The preceding *Dockerfile* steps include:

- Setting the base image from `mcr.microsoft.com/dotnet/runtime:8.0` as the alias `base`.
- Changing the working directory to `/app`.
- Setting the `build` alias from the `mcr.microsoft.com/dotnet/sdk:8.0` image.
- Changing the working directory to `/src`.
- Copying the contents and publishing the .NET app:
 - The app is published using the `dotnet publish` command.
- Relayering the .NET SDK image from `mcr.microsoft.com/dotnet/runtime:8.0` (the `base` alias).
- Copying the published build output from the `/publish`.
- Defining the entry point, which delegates to `dotnet App.BackgroundService.dll`.

💡 Tip

The MCR in `mcr.microsoft.com` stands for "Microsoft Container Registry", and is Microsoft's syndicated container catalog from the official Docker hub. The [Microsoft syndicates container catalog](#) article contains additional details.

When you target Docker as a deployment strategy for your .NET Worker Service, there are a few considerations in the project file:

XML

```
<Project Sdk="Microsoft.NET.Sdk.Worker">

<PropertyGroup>
    <TargetFramework>net8.0</TargetFramework>
    <Nullable>enable</Nullable>
    <ImplicitUsings>true</ImplicitUsings>
    <RootNamespace>App.WorkerService</RootNamespace>
    <DockerDefaultTargetOS>Linux</DockerDefaultTargetOS>
</PropertyGroup>

<ItemGroup>
    <PackageReference Include="Microsoft.Extensions.Hosting" Version="8.0.0" />
    <PackageReference
        Include="Microsoft.VisualStudio.Azure.Containers.Tools.Targets"
        Version="1.19.5" />
</ItemGroup>
```

```
</ItemGroup>  
</Project>
```

In the preceding project file, the `<DockerDefaultTargetOS>` element specifies `Linux` as its target. To target Windows containers, use `Windows` instead. The [Microsoft.VisualStudio.Azure.Containers.Tools.Targets NuGet package](#) is automatically added as a package reference when **Docker support** is selected from the template.

For more information on Docker with .NET, see [Tutorial: Containerize a .NET app](#). For more information on deploying to Azure, see [Tutorial: Deploy a Worker Service to Azure](#).

ⓘ Important

If you want to leverage *User Secrets* with the Worker template, you'd have to explicitly reference the `Microsoft.Extensions.Configuration.UserSecrets` NuGet package.

Hosted Service extensibility

The [IHostedService](#) interface defines two methods:

- [IHostedService.StartAsync\(CancellationToken\)](#)
- [IHostedService.StopAsync\(CancellationToken\)](#)

These two methods serve as *lifecycle* methods - they're called during host start and stop events respectively.

ⓘ Note

When overriding either `StartAsync` or `StopAsync` methods, you must call and `await` the `base` class method to ensure the service starts and/or shuts down properly.

ⓘ Important

The interface serves as a generic-type parameter constraint on the [AddHostedService<THostedService>\(IServiceCollection\)](#) extension method, meaning only implementations are permitted. You're free to use the provided [BackgroundService](#) with a subclass, or implement your own entirely.

Signal completion

In most common scenarios, you don't need to explicitly signal the completion of a hosted service. When the host starts the services, they're designed to run until the host is stopped. In some scenarios, however, you may need to signal the completion of the entire host application when the service completes. To signal the completion, consider the following `Worker` class:

C#

```
namespace App.SignalCompletionService;

public sealed class Worker(
    IHostApplicationLifetime hostApplicationLifetime,
    ILogger<Worker> logger) : BackgroundService
{
    protected override async Task ExecuteAsync(CancellationToken
stoppingToken)
    {
        // TODO: implement single execution logic here.
        logger.LogInformation(
            "Worker running at: {Time}", DateTimeOffset.Now);

        await Task.Delay(1_000, stoppingToken);

        // When completed, the entire app host will stop.
        hostApplicationLifetime.StopApplication();
    }
}
```

In the preceding code, the `ExecuteAsync` method doesn't loop, and when it's complete it calls `IHostApplicationLifetime.StopApplication()`.

ⓘ Important

This will signal to the host that it should stop, and without this call to `StopApplication` the host will continue to run indefinitely.

For more information, see:

- [.NET Generic Host: IHostApplicationLifetime](#)
- [.NET Generic Host: Host shutdown](#)
- [.NET Generic Host: Hosting shutdown process](#)

Create a Queue Service

Article • 12/15/2023

A queue service is a great example of a long-running service, where work items can be queued and worked on sequentially as previous work items are completed. Relying on the Worker Service template, you build out new functionality on top of the [BackgroundService](#).

In this tutorial, you learn how to:

- ✓ Create a queue service.
- ✓ Delegate work to a task queue.
- ✓ Register a console key-listener from [IHostApplicationLifetime](#) events.

💡 Tip

All of the "Workers in .NET" example source code is available in the [Samples Browser](#) for download. For more information, see [Browse code samples: Workers in .NET](#).

Prerequisites

- The [.NET 8.0 SDK or later](#)
- A .NET integrated development environment (IDE)
 - Feel free to use [Visual Studio](#)

Create a new project

To create a new Worker Service project with Visual Studio, you'd select **File > New > Project....** From the **Create a new project** dialog search for "Worker Service", and select Worker Service template. If you'd rather use the .NET CLI, open your favorite terminal in a working directory. Run the `dotnet new` command, and replace the `<Project.Name>` with your desired project name.

.NET CLI

```
dotnet new worker --name <Project.Name>
```

For more information on the .NET CLI new worker service project command, see [dotnet new worker](#).

💡 Tip

If you're using Visual Studio Code, you can run .NET CLI commands from the integrated terminal. For more information, see [Visual Studio Code: Integrated Terminal](#).

Create queuing services

You may be familiar with the

`QueueBackgroundWorkItem(Func<CancellationToken, Task>)` functionality from the `System.Web.Hosting` namespace.

💡 Tip

The functionality of the `System.Web` namespace was intentionally not ported over to .NET, and remains exclusive to .NET Framework. For more information, see [Get started with incremental ASP.NET to ASP.NET Core migration](#).

In .NET, to model a service that is inspired by the `QueueBackgroundWorkItem` functionality, start by adding an `IBackgroundTaskQueue` interface to the project:

C#

```
namespace App.QueueService;

public interface IBackgroundTaskQueue
{
    ValueTask QueueBackgroundWorkItemAsync(
        Func<CancellationToken, ValueTask> workItem);

    ValueTask<Func<CancellationToken, ValueTask>> DequeueAsync(
        CancellationToken cancellationToken);
}
```

There are two methods, one that exposes queuing functionality, and another that dequeues previously queued work items. A *work item* is a `Func<CancellationToken, ValueTask>`. Next, add the default implementation to the project.

C#

```

using System.Threading.Channels;

namespace App.QueueService;

public sealed class DefaultBackgroundTaskQueue : IBackgroundTaskQueue
{
    private readonly Channel<Func< CancellationToken, ValueTask>> _queue;

    public DefaultBackgroundTaskQueue(int capacity)
    {
        BoundedChannelOptions options = new(capacity)
        {
            FullMode = BoundedChannelFullMode.Wait
        };
        _queue = Channel.CreateBounded<Func< CancellationToken, ValueTask>>
(options);
    }

    public async ValueTask QueueBackgroundWorkItemAsync(
        Func< CancellationToken, ValueTask> workItem)
    {
        ArgumentNullException.ThrowIfNull(workItem);

        await _queue.Writer.WriteAsync(workItem);
    }

    public async ValueTask<Func< CancellationToken, ValueTask>> DequeueAsync(
        CancellationToken cancellationToken)
    {
        Func< CancellationToken, ValueTask>? workItem =
            await _queue.Reader.ReadAsync(cancellationToken);

        return workItem;
    }
}

```

The preceding implementation relies on a [Channel<T>](#) as a queue. The [BoundedChannelOptions\(Int32\)](#) is called with an explicit capacity. Capacity should be set based on the expected application load and number of concurrent threads accessing the queue. [BoundedChannelFullMode.Wait](#) causes calls to [ChannelWriter<T>.WriteAsync](#) to return a task, which completes only when space becomes available. Which leads to backpressure, in case too many publishers/calls start accumulating.

Rewrite the Worker class

In the following [QueueHostedService](#) example:

- The `ProcessTaskQueueAsync` method returns a `Task` in `ExecuteAsync`.
- Background tasks in the queue are dequeued and executed in `ProcessTaskQueueAsync`.
- Work items are awaited before the service stops in `StopAsync`.

Replace the existing `Worker` class with the following C# code, and rename the file to `QueueHostedService.cs`.

C#

```
namespace App.QueueService;

public sealed class QueuedHostedService(
    IBackgroundTaskQueue taskQueue,
    ILogger<QueuedHostedService> logger) : BackgroundService
{
    protected override Task ExecuteAsync(CancellationToken stoppingToken)
    {
        logger.LogInformation(
            "{Name} is running.
            Tap W to add a work item to the
            background queue.
            ",
            nameof(QueuedHostedService));

        return ProcessTaskQueueAsync(stoppingToken);
    }

    private async Task ProcessTaskQueueAsync(CancellationToken
stoppingToken)
    {
        while (!stoppingToken.IsCancellationRequested)
        {
            try
            {
                Func< CancellationToken, ValueTask>? workItem =
                    await taskQueue.DequeueAsync(stoppingToken);

                await workItem(stoppingToken);
            }
            catch (OperationCanceledException)
            {
                // Prevent throwing if stoppingToken was signaled
            }
            catch (Exception ex)
            {
                logger.LogError(ex, "Error occurred executing task work
item.");
            }
        }
    }
}
```

```
public override async Task StopAsync(CancellationToken stoppingToken)
{
    logger.LogInformation(
        $"{nameof(QueuedHostedService)} is stopping.");

    await base.StopAsync(stoppingToken);
}
}
```

A `MonitorLoop` service handles enqueueing tasks for the hosted service whenever the `w` key is selected on an input device:

- The `IBackgroundTaskQueue` is injected into the `MonitorLoop` service.
- `IBackgroundTaskQueue.QueueBackgroundWorkItemAsync` is called to enqueue a work item.
- The work item simulates a long-running background task:
 - Three 5-second delays are executed `Delay`.
 - A `try-catch` statement traps `OperationCanceledException` if the task is canceled.

C#

```
namespace App.QueueService;

public sealed class MonitorLoop(
    IBackgroundTaskQueue taskQueue,
    ILogger<MonitorLoop> logger,
    IHostApplicationLifetime applicationLifetime)
{
    private readonly CancellationToken _cancellationToken =
        applicationLifetime.ApplicationStopping;

    public void StartMonitorLoop()
    {
        logger.LogInformation($"{nameof(MonitorAsync)} loop is starting.");

        // Run a console user input loop in a background thread
        Task.Run(async () => await MonitorAsync());
    }

    private async ValueTask MonitorAsync()
    {
        while (!_cancellationToken.IsCancellationRequested)
        {
            var keyStroke = Console.ReadKey();
            if (keyStroke.Key == ConsoleKey.W)
            {
                // Enqueue a background work item
                await
                    taskQueue.QueueBackgroundWorkItemAsync(BuildWorkItemAsync);
            }
        }
    }
}
```

```

        }
    }

private async ValueTask BuildWorkItemAsync(CancellationToken token)
{
    // Simulate three 5-second tasks to complete
    // for each enqueued work item

    int delayLoop = 0;
    var guid = Guid.NewGuid();

    logger.LogInformation("Queued work item {Guid} is starting.", guid);

    while (!token.IsCancellationRequested && delayLoop < 3)
    {
        try
        {
            await Task.Delay(TimeSpan.FromSeconds(5), token);
        }
        catch (OperationCanceledException)
        {
            // Prevent throwing if the Delay is cancelled
        }

        ++ delayLoop;

        logger.LogInformation("Queued work item {Guid} is running.
{DelayLoop}/3", guid, delayLoop);
    }

    if (delayLoop is 3)
    {
        logger.LogInformation("Queued Background Task {Guid} is
complete.", guid);
    }
    else
    {
        logger.LogInformation("Queued Background Task {Guid} was
cancelled.", guid);
    }
}
}

```

Replace the existing `Program` contents with the following C# code:

C#

```

using App.QueueService;

HostApplicationBuilder builder = Host.CreateApplicationBuilder(args);

```

```
builder.Services.AddSingleton<MonitorLoop>();
builder.Services.AddHostedService<QueuedHostedService>();
builder.Services.AddSingleton<IBackgroundTaskQueue>(_ =>
{
    if (!int.TryParse(builder.Configuration["QueueCapacity"], out var
queueCapacity))
    {
        queueCapacity = 100;
    }

    return new DefaultBackgroundTaskQueue(queueCapacity);
});

IHost host = builder.Build();

MonitorLoop monitorLoop = host.Services.GetRequiredService<MonitorLoop>()!;
monitorLoop.StartMonitorLoop();

host.Run();
```

The services are registered in *(Program.cs)*. The hosted service is registered with the `AddHostedService` extension method. `MonitorLoop` is started in *Program.cs* top-level statement:

C#

```
MonitorLoop monitorLoop = host.Services.GetRequiredService<MonitorLoop>()!;
monitorLoop.StartMonitorLoop();
```

For more information on registering services, see [Dependency injection in .NET](#).

Verify service functionality

To run the application from Visual Studio, select `F5` or select the **Debug > Start Debugging** menu option. If you're using the .NET CLI, run the `dotnet run` command from the working directory:

.NET CLI

```
dotnet run
```

For more information on the .NET CLI run command, see [dotnet run](#).

When prompted enter the `w` (or `w`) at least once to queue an emulated work item, as shown in the example output:

Output

```
info: App.QueueService.MonitorLoop[0]
    MonitorAsync loop is starting.
info: App.QueueService.QueuedHostedService[0]
    QueuedHostedService is running.

    Tap W to add a work item to the background queue.

info: Microsoft.Hosting.Lifetime[0]
    Application started. Press Ctrl+C to shut down.
info: Microsoft.Hosting.Lifetime[0]
    Hosting environment: Development
info: Microsoft.Hosting.Lifetime[0]
    Content root path: .\queue-service
winfo: App.QueueService.MonitorLoop[0]
    Queued work item 8453f845-ea4a-4bcb-b26e-c76c0d89303e is starting.
info: App.QueueService.MonitorLoop[0]
    Queued work item 8453f845-ea4a-4bcb-b26e-c76c0d89303e is running. 1/3
info: App.QueueService.MonitorLoop[0]
    Queued work item 8453f845-ea4a-4bcb-b26e-c76c0d89303e is running. 2/3
info: App.QueueService.MonitorLoop[0]
    Queued work item 8453f845-ea4a-4bcb-b26e-c76c0d89303e is running. 3/3
info: App.QueueService.MonitorLoop[0]
    Queued Background Task 8453f845-ea4a-4bcb-b26e-c76c0d89303e is
complete.
info: Microsoft.Hosting.Lifetime[0]
    Application is shutting down...
info: App.QueueService.QueuedHostedService[0]
    QueuedHostedService is stopping.
```

If running the application from within Visual Studio, select **Debug > Stop Debugging....**. Alternatively, select **ctrl + c** from the console window to signal cancellation.

Use scoped services within a `BackgroundService`

Article • 12/13/2023

When you register implementations of [IHostedService](#) using any of the [AddHostedService](#) extension methods - the service is registered as a singleton. There may be scenarios where you'd like to rely on a scoped service. For more information, see [Dependency injection in .NET: Service lifetimes](#).

In this tutorial, you learn how to:

- ✓ Resolve scoped dependencies in a singleton [BackgroundService](#).
- ✓ Delegate work to a scoped service.
- ✓ Implement an `override` of [BackgroundService.StopAsync\(CancellationToken\)](#).

💡 Tip

All of the "Workers in .NET" example source code is available in the [Samples Browser](#) for download. For more information, see [Browse code samples: Workers in .NET](#).

Prerequisites

- The [.NET 8.0 SDK or later](#)
- A .NET integrated development environment (IDE)
 - Feel free to use [Visual Studio](#)

Create a new project

To create a new Worker Service project with Visual Studio, you'd select **File > New > Project....** From the **Create a new project** dialog search for "Worker Service", and select Worker Service template. If you'd rather use the .NET CLI, open your favorite terminal in a working directory. Run the `dotnet new` command, and replace the `<Project.Name>` with your desired project name.

.NET CLI

```
dotnet new worker --name <Project.Name>
```

For more information on the .NET CLI new worker service project command, see [dotnet new worker](#).

💡 Tip

If you're using Visual Studio Code, you can run .NET CLI commands from the integrated terminal. For more information, see [Visual Studio Code: Integrated Terminal](#).

Create scoped services

To use [scoped services](#) within a `BackgroundService`, create a scope. No scope is created for a hosted service by default. The scoped background service contains the background task's logic.

C#

```
namespace App.ScopedService;

public interface IScopedProcessingService
{
    Task DoWorkAsync(CancellationToken stoppingToken);
}
```

The preceding interface defines a single `DoWorkAsync` method. To define the default implementation:

- The service is asynchronous. The `DoWorkAsync` method returns a `Task`. For demonstration purposes, a delay of ten seconds is awaited in the `DoWorkAsync` method.
- An `ILogger` is injected into the service.:

C#

```
namespace App.ScopedService;

public sealed class DefaultScopedProcessingService(
    ILogger<DefaultScopedProcessingService> logger) :
IScopedProcessingService
{
    private int _executionCount;

    public async Task DoWorkAsync(CancellationToken stoppingToken)
    {
        while (!stoppingToken.IsCancellationRequested)
```

```

    {
        ++ _executionCount;

        logger.LogInformation(
            "{ServiceName} working, execution count: {Count}",
            nameof(DefaultScopedProcessingService),
            _executionCount);

        await Task.Delay(10_000, stoppingToken);
    }
}

```

The hosted service creates a scope to resolve the scoped background service to call its `DoworkAsync` method. `DoworkAsync` returns a `Task`, which is awaited in `ExecuteAsync`:

Rewrite the Worker class

Replace the existing `Worker` class with the following C# code, and rename the file to `ScopedBackgroundService.cs`:

C#

```

namespace App.ScopedService;

public sealed class ScopedBackgroundService(
    IServiceScopeFactory serviceScopeFactory,
    ILogger<ScopedBackgroundService> logger) : BackgroundService
{
    private const string ClassName = nameof(ScopedBackgroundService);

    protected override async Task ExecuteAsync(CancellationToken stoppingToken)
    {
        logger.LogInformation(
            "{Name} is running.", ClassName);

        await DoworkAsync(stoppingToken);
    }

    private async Task DoworkAsync(CancellationToken stoppingToken)
    {
        logger.LogInformation(
            "{Name} is working.", ClassName);
    }
}

```

```
        using (IServiceScope scope = serviceScopeFactory.CreateScope())
    {
        IScopedProcessingService scopedProcessingService =
            scope.ServiceProvider.GetRequiredService<IScopedProcessingService>();

        await scopedProcessingService.DoWorkAsync(stoppingToken);
    }
}

public override async Task StopAsync(CancellationToken stoppingToken)
{
    logger.LogInformation(
        "{Name} is stopping.", ClassName);

    await base.StopAsync(stoppingToken);
}
}
```

In the preceding code, an explicit scope is created and the `IScopedProcessingService` implementation is resolved from the dependency injection service scope factory. The resolved service instance is scoped, and its `DoWorkAsync` method is awaited.

Replace the template *Program.cs* file contents with the following C# code:

C#

```
using App.ScopedService;

HostApplicationBuilder builder = Host.CreateApplicationBuilder(args);
builder.Services.AddHostedService<ScopedBackgroundService>();
builder.Services.AddScoped<IScopedProcessingService,
DefaultScopedProcessingService>();

IHost host = builder.Build();
host.Run();
```

The services are registered in (*Program.cs*). The hosted service is registered with the `AddHostedService` extension method.

For more information on registering services, see [Dependency injection in .NET](#).

Verify service functionality

To run the application from Visual Studio, select `F5` or select the **Debug > Start Debugging** menu option. If you're using the .NET CLI, run the `dotnet run` command from the working directory:

.NET CLI

```
dotnet run
```

For more information on the .NET CLI run command, see [dotnet run](#).

Let the application run for a bit to generate several execution count increments. You will see output similar to the following:

Output

```
info: App.ScopedService.ScopedBackgroundService[0]
      ScopedBackgroundService is running.
info: App.ScopedService.ScopedBackgroundService[0]
      ScopedBackgroundService is working.
info: App.ScopedService.DefaultScopedProcessingService[0]
      DefaultScopedProcessingService working, execution count: 1
info: Microsoft.Hosting.Lifetime[0]
      Application started. Press Ctrl+C to shut down.
info: Microsoft.Hosting.Lifetime[0]
      Hosting environment: Development
info: Microsoft.Hosting.Lifetime[0]
      Content root path: .\scoped-service
info: App.ScopedService.DefaultScopedProcessingService[0]
      DefaultScopedProcessingService working, execution count: 2
info: App.ScopedService.DefaultScopedProcessingService[0]
      DefaultScopedProcessingService working, execution count: 3
info: App.ScopedService.DefaultScopedProcessingService[0]
      DefaultScopedProcessingService working, execution count: 4
info: Microsoft.Hosting.Lifetime[0]
      Application is shutting down...
info: App.ScopedService.ScopedBackgroundService[0]
      ScopedBackgroundService is stopping.
```

If running the application from within Visual Studio, select **Debug > Stop Debugging...**

Alternatively, select **Ctrl + C** from the console window to signal cancellation.

Create Windows Service using `BackgroundService`

Article • 12/13/2023

.NET Framework developers are probably familiar with Windows Service apps. Before .NET Core and .NET 5+, developers who relied on .NET Framework could create Windows Services to perform background tasks or execute long-running processes. This functionality is still available and you can create Worker Services that run as a Windows Service.

In this tutorial, you'll learn how to:

- ✓ Publish a .NET worker app as a single file executable.
- ✓ Create a Windows Service.
- ✓ Create the `BackgroundService` app as a Windows Service.
- ✓ Start and stop the Windows Service.
- ✓ View event logs.
- ✓ Delete the Windows Service.

💡 Tip

All of the "Workers in .NET" example source code is available in the [Samples Browser](#) for download. For more information, see [Browse code samples: Workers in .NET](#).

ⓘ Important

Installing the .NET SDK also installs the `Microsoft.NET.Sdk.Worker` and the worker template. In other words, after installing the .NET SDK, you could create a new worker by using the `dotnet new worker` command. If you're using Visual Studio, the template is hidden until the optional ASP.NET and web development workload is installed.

Prerequisites

- The [.NET 8.0 SDK or later](#)
- A Windows OS
- A .NET integrated development environment (IDE)

- Feel free to use [Visual Studio](#)

Create a new project

To create a new Worker Service project with Visual Studio, you'd select **File > New > Project...**. From the **Create a new project** dialog search for "Worker Service", and select Worker Service template. If you'd rather use the .NET CLI, open your favorite terminal in a working directory. Run the `dotnet new` command, and replace the `<Project.Name>` with your desired project name.

.NET CLI

```
dotnet new worker --name <Project.Name>
```

For more information on the .NET CLI new worker service project command, see [dotnet new worker](#).

💡 Tip

If you're using Visual Studio Code, you can run .NET CLI commands from the integrated terminal. For more information, see [Visual Studio Code: Integrated Terminal](#).

Install NuGet package

To interop with native Windows Services from .NET `IHostedService` implementations, you'll need to install the [Microsoft.Extensions.Hosting.WindowsServices NuGet package](#).

To install this from Visual Studio, use the **Manage NuGet Packages...** dialog. Search for "Microsoft.Extensions.Hosting.WindowsServices", and install it. If you'd rather use the .NET CLI, run the `dotnet add package` command:

.NET CLI

```
dotnet add package Microsoft.Extensions.Hosting.WindowsServices
```

For more information on the .NET CLI add package command, see [dotnet add package](#).

After successfully adding the packages, your project file should now contain the following package references:

XML

```
<ItemGroup>
  <PackageReference Include="Microsoft.Extensions.Hosting" Version="8.0.0"
/>
  <PackageReference Include="Microsoft.Extensions.Hosting.WindowsServices"
Version="8.0.0" />
</ItemGroup>
```

Update project file

This worker project makes use of C#'s [nullable reference types](#). To enable them for the entire project, update the project file accordingly:

XML

```
<Project Sdk="Microsoft.NET.Sdk.Worker">

  <PropertyGroup>
    <TargetFramework>net8.0-windows</TargetFramework>
    <Nullable>enable</Nullable>
    <ImplicitUsings>true</ImplicitUsings>
    <RootNamespace>App.WindowsService</RootNamespace>
  </PropertyGroup>

  <ItemGroup>
    <PackageReference Include="Microsoft.Extensions.Hosting" Version="8.0.0"
/>
    <PackageReference Include="Microsoft.Extensions.Hosting.WindowsServices"
Version="8.0.0" />
  </ItemGroup>
</Project>
```

The preceding project file changes add the `<Nullable>enable</Nullable>` node. For more information, see [Setting the nullable context](#).

Create the service

Add a new class to the project named *JokeService.cs*, and replace its contents with the following C# code:

C#

```
namespace App.WindowsService;

public sealed class JokeService
```

```
{  
    public string GetJoke()  
    {  
        Joke joke = _jokes.ElementAt(  
            Random.Shared.Next(_jokes.Count));  
  
        return $"{joke.Setup}{Environment.NewLine}{joke.Punchline}";  
    }  
  
    // Programming jokes borrowed from:  
    // https://github.com/eklavyadev/karljoke/blob/main/source/jokes.json  
    private readonly HashSet<Joke> _jokes = new()  
    {  
        new Joke("What's the best thing about a Boolean?", "Even if you're  
        wrong, you're only off by a bit."),  
        new Joke("What's the object-oriented way to become wealthy?",  
        "Inheritance"),  
        new Joke("Why did the programmer quit their job?", "Because they  
        didn't get arrays."),  
        new Joke("Why do programmers always mix up Halloween and  
        Christmas?", "Because Oct 31 == Dec 25"),  
        new Joke("How many programmers does it take to change a lightbulb?",  
        "None that's a hardware problem"),  
        new Joke("If you put a million monkeys at a million keyboards, one  
        of them will eventually write a Java program", "the rest of them will write  
        Perl"),  
        new Joke("[ 'hip', 'hip' ]", "(hip hip array)"),  
        new Joke("To understand what recursion is...", "You must first  
        understand what recursion is"),  
        new Joke("There are 10 types of people in this world...", "Those who  
        understand binary and those who don't"),  
        new Joke("Which song would an exception sing?", "Can't catch me -  
        Avicii"),  
        new Joke("Why do Java programmers wear glasses?", "Because they  
        don't C#"),  
        new Joke("How do you check if a webpage is HTML5?", "Try it out on  
        Internet Explorer"),  
        new Joke("A user interface is like a joke.", "If you have to explain  
        it then it is not that good."),  
        new Joke("I was gonna tell you a joke about UDP...", "...but you  
        might not get it."),  
        new Joke("The punchline often arrives before the set-up.", "Do you  
        know the problem with UDP jokes?"),  
        new Joke("Why do C# and Java developers keep breaking their  
        keyboards?", "Because they use a strongly typed language."),  
        new Joke("Knock-knock.", "A race condition. Who is there?"),  
        new Joke("What's the best part about TCP jokes?", "I get to keep  
        telling them until you get them."),  
        new Joke("A programmer puts two glasses on their bedside table  
        before going to sleep.", "A full one, in case they gets thirsty, and an  
        empty one, in case they don't."),  
        new Joke("There are 10 kinds of people in this world.", "Those who  
        understand binary, those who don't, and those who weren't expecting a base 3  
        joke."),  
        new Joke("What did the router say to the doctor?", "It hurts when
```

```
IP."),  
    new Joke("An IPv6 packet is walking out of the house.", "He goes  
nowhere."),  
    new Joke("3 SQL statements walk into a NoSQL bar. Soon, they walk  
out", "They couldn't find a table.")  
};  
}  
  
readonly record struct Joke(string Setup, string Punchline);
```

The preceding joke service source code exposes a single piece of functionality, the `GetJoke` method. This is a `string` returning method that represents a random programming joke. The class-scoped `_jokes` field is used to store the list of jokes. A random joke is selected from the list and returned.

Rewrite the Worker class

Replace the existing `Worker` from the template with the following C# code, and rename the file to *WindowsBackgroundService.cs*:

```
C#  
  
namespace App.WindowsService;  
  
public sealed class WindowsBackgroundService(  
    JokeService jokeService,  
    ILogger<WindowsBackgroundService> logger) : BackgroundService  
{  
    protected override async Task ExecuteAsync(CancellationToken  
stoppingToken)  
    {  
        try  
        {  
            while (!stoppingToken.IsCancellationRequested)  
            {  
                string joke = jokeService.GetJoke();  
                logger.LogWarning("{Joke}", joke);  
  
                await Task.Delay(TimeSpan.FromMinutes(1), stoppingToken);  
            }  
        }  
        catch (OperationCanceledException)  
        {  
            // When the stopping token is canceled, for example, a call made  
from services.msc,  
            // we shouldn't exit with a non-zero exit code. In other words,  
this is expected...  
        }  
        catch (Exception ex)  
        {
```

```

        logger.LogError(ex, "{Message}", ex.Message);

        // Terminates this process and returns an exit code to the
        // operating system.
        // This is required to avoid the
        'BackgroundServiceExceptionBehavior', which
            // performs one of two scenarios:
            // 1. When set to "Ignore": will do nothing at all, errors cause
            zombie services.
            // 2. When set to "StopHost": will cleanly stop the host, and
            log errors.
            //
            // In order for the Windows Service Management system to
            leverage configured
                // recovery options, we need to terminate the process with a
                non-zero exit code.
                Environment.Exit(1);
            }
        }
    }
}

```

In the preceding code, the `JokeService` is injected along with an `ILogger`. Both are made available to the class as `private readonly` fields. In the `ExecuteAsync` method, the joke service requests a joke and writes it to the logger. In this case, the logger is implemented by the Windows Event Log - `Microsoft.Extensions.Logging.EventLog.EventLogLogger`. Logs are written to, and available for viewing in the **Event Viewer**.

① Note

By default, the *Event Log* severity is **Warning**. This can be configured, but for demonstration purposes the `WindowsBackgroundService` logs with the **LogWarning** extension method. To specifically target the `EventLog` level, add an entry in the `appsettings.{Environment}.json`, or provide an `EventLogSettings.Filter` value.

JSON

```
{
    "Logging": {
        "LogLevel": {
            "Default": "Warning"
        },
        "EventLog": {
            "SourceName": "The Joke Service",
            "LogName": "Application",
            "LogLevel": {
                "Microsoft": "Information",
                "Microsoft.Hosting.Lifetime": "Information"
            }
        }
}
```

```
        }  
    }  
}
```

For more information on configuring log levels, see [Logging providers in .NET: Configure Windows EventLog](#).

Rewrite the `Program` class

Replace the template `Program.cs` file contents with the following C# code:

C#

```
using App.WindowsService;  
using Microsoft.Extensions.Logging.Configuration;  
using Microsoft.Extensions.Logging.EventLog;  
  
HostApplicationBuilder builder = Host.CreateApplicationBuilder(args);  
builder.Services.AddWindowsService(options =>  
{  
    options.ServiceName = ".NET Joke Service";  
});  
  
LoggerProviderOptions.RegisterProviderOptions<  
    EventLogSettings, EventLogLoggerProvider>(builder.Services);  
  
builder.Services.AddSingleton<JokeService>();  
builder.Services.AddHostedService<WindowsBackgroundService>();  
  
IHost host = builder.Build();  
host.Run();
```

The `AddWindowsService` extension method configures the app to work as a Windows Service. The service name is set to `".NET Joke Service"`. The hosted service is registered for dependency injection.

For more information on registering services, see [Dependency injection in .NET](#).

Publish the app

To create the .NET Worker Service app as a Windows Service, it's recommended that you publish the app as a single file executable. It's less error-prone to have a self-contained executable, as there aren't any dependent files lying around the file system. But you may choose a different publishing modality, which is perfectly acceptable, so long as you create an `*.exe` file that can be targeted by the Windows Service Control Manager.

ⓘ Important

An alternative publishing approach is to build the *.dll (instead of an *.exe), and when you install the published app using the Windows Service Control Manager you delegate to the .NET CLI and pass the DLL. For more information, see [.NET CLI: dotnet command](#).

PowerShell

```
sc.exe create ".NET Joke Service" binpath="C:\Path\To\dotnet.exe  
C:\Path\To\App.WindowsService.dll"
```

XML

```
<Project Sdk="Microsoft.NET.Sdk.Worker">  
  
  <PropertyGroup>  
    <TargetFramework>net8.0-windows</TargetFramework>  
    <Nullable>enable</Nullable>  
    <ImplicitUsings>true</ImplicitUsings>  
    <RootNamespace>App.WindowsService</RootNamespace>  
    <OutputType>exe</OutputType>  
    <PublishSingleFile Condition="'$(Configuration)' ==  
'Release'">true</PublishSingleFile>  
    <RuntimeIdentifier>win-x64</RuntimeIdentifier>  
    <PlatformTarget>x64</PlatformTarget>  
  </PropertyGroup>  
  
  <ItemGroup>  
    <PackageReference Include="Microsoft.Extensions.Hosting" Version="8.0.0" />  
    <PackageReference Include="Microsoft.Extensions.Hosting.WindowsServices" Version="8.0.0" />  
  </ItemGroup>  
</Project>
```

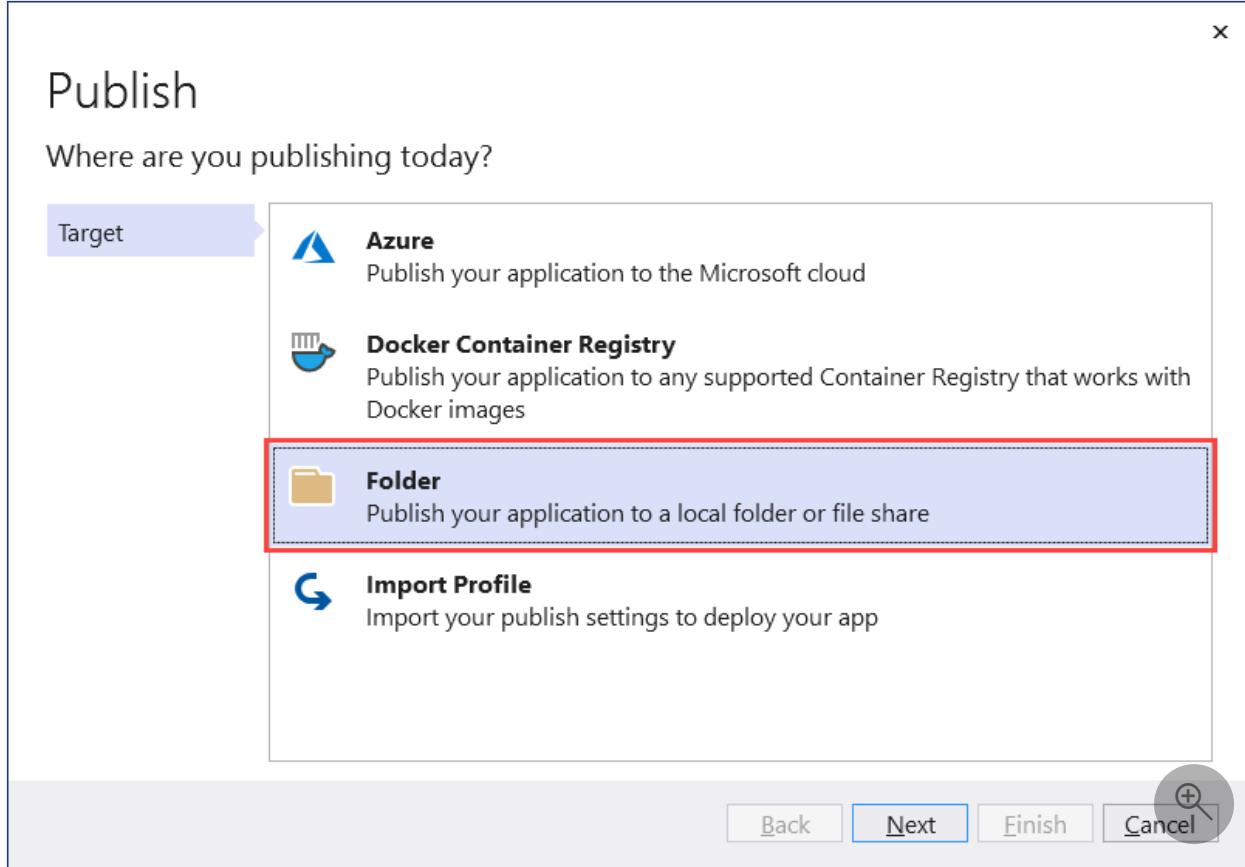

The preceding highlighted lines of the project file define the following behaviors:

- `<OutputType>exe</OutputType>`: Creates a console application.
- `<PublishSingleFile Condition="'$(Configuration)' == 'Release'">true</PublishSingleFile>`: Enables single-file publishing.
- `<RuntimeIdentifier>win-x64</RuntimeIdentifier>`: Specifies the RID of `win-x64`.
- `<PlatformTarget>x64</PlatformTarget>`: Specify the target platform CPU of 64-bit.

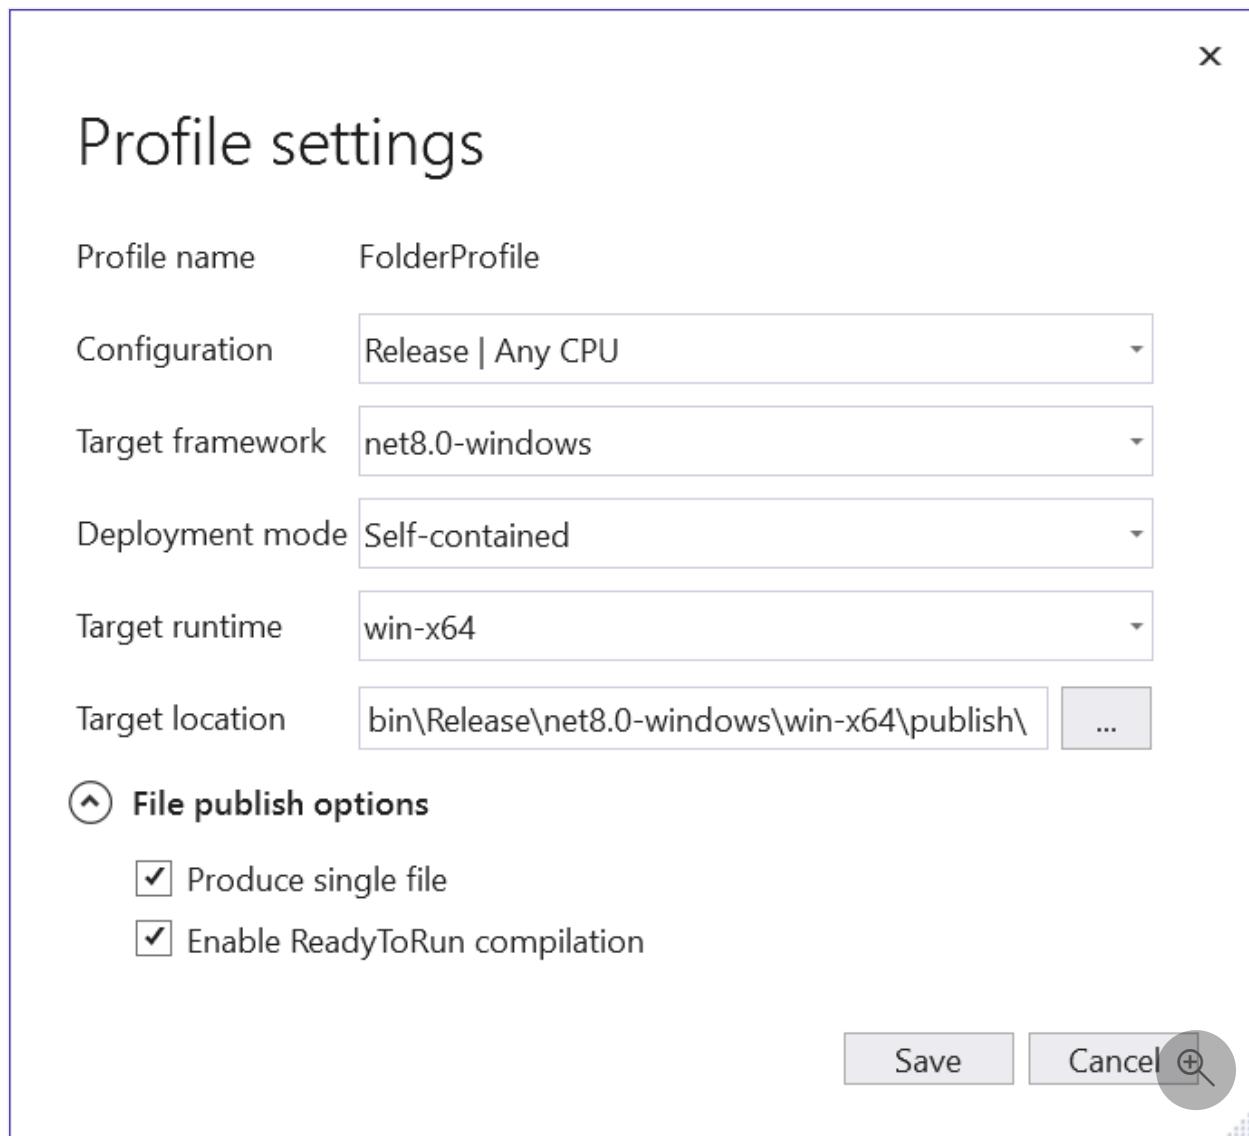

To publish the app from Visual Studio, you can create a publish profile that is persisted. The publish profile is XML-based, and has the `.pubxml` file extension. Visual Studio uses

this profile to publish the app implicitly, whereas if you're using the .NET CLI — you must explicitly specify the publish profile for it to be used.

Right-click on the project in the **Solution Explorer**, and select **Publish....** Then, select **Add a publish profile** to create a profile. From the **Publish** dialog, select **Folder** as your **Target**.

Leave the default **Location**, and then select **Finish**. Once the profile is created, select **Show all settings**, and verify your **Profile settings**.

Ensure that the following settings are specified:

- **Deployment mode:** Self-contained
- **Produce single file:** checked
- **Enable ReadyToRun compilation:** checked
- **Trim unused assemblies (in preview):** unchecked

Finally, select **Publish**. The app is compiled, and the resulting .exe file is published to the */publish* output directory.

Alternatively, you could use the .NET CLI to publish the app:

```
.NET CLI  
  
dotnet publish --output "C:\custom\publish\directory"
```

For more information, see [dotnet publish](#).

Important

With .NET 6, if you attempt to debug the app with the `<PublishSingleFile>true</PublishSingleFile>` setting, you will not be able to debug the app. For more information, see [Unable to attach to CoreCLR when debugging a 'PublishSingleFile' .NET 6 app](#).

Create the Windows Service

If you're unfamiliar with using PowerShell and you'd rather create an installer for your service, see [Create a Windows Service installer](#). Otherwise, to create the Windows Service, use the native Windows Service Control Manager's (`sc.exe`) create command. Run PowerShell as an Administrator.

PowerShell

```
sc.exe create ".NET Joke Service"
binpath="C:\Path\To\App.WindowsService.exe"
```

Tip

If you need to change the content root of the [host configuration](#), you can pass it as a command-line argument when specifying the `binpath`:

PowerShell

```
sc.exe create "Svc Name" binpath="C:\Path\To\App.exe --contentRoot
C:\Other\Path"
```

You'll see an output message:

PowerShell

```
[SC] CreateService SUCCESS
```

For more information, see [sc.exe create](#).

Configure the Windows Service

After the service is created, you can optionally configure it. If you're fine with the service defaults, skip to the [Verify service functionality](#) section.

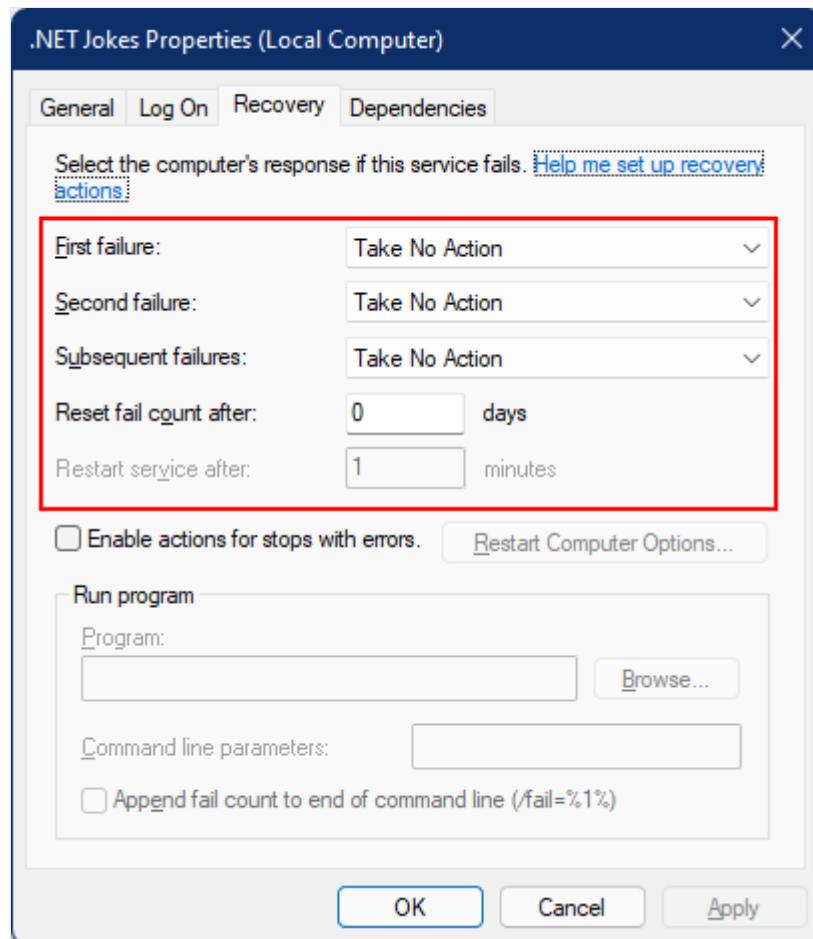

Windows Services provide recovery configuration options. You can query the current configuration using the `sc.exe qfailure "<Service Name>"` (where `<Service Name>` is your services' name) command to read the current recovery configuration values:

```
PowerShell

sc qfailure ".NET Joke Service"
[SC] QueryServiceConfig2 SUCCESS

SERVICE_NAME: .NET Joke Service
    RESET_PERIOD (in seconds)      : 0
    REBOOT_MESSAGE                 :
    COMMAND_LINE                   :
```

The command will output the recovery configuration, which is the default values—since they've not yet been configured.

To configure recovery, use the `sc.exe failure "<Service Name>"` where `<Service Name>` is the name of your service:

```
PowerShell

sc.exe failure ".NET Joke Service" reset=0
actions=restart/60000/restart/60000/run/1000
```

```
[SC] ChangeServiceConfig2 SUCCESS
```

💡 Tip

To configure the recovery options, your terminal session needs to run as an Administrator.

After it's been successfully configured, you can query the values once again using the

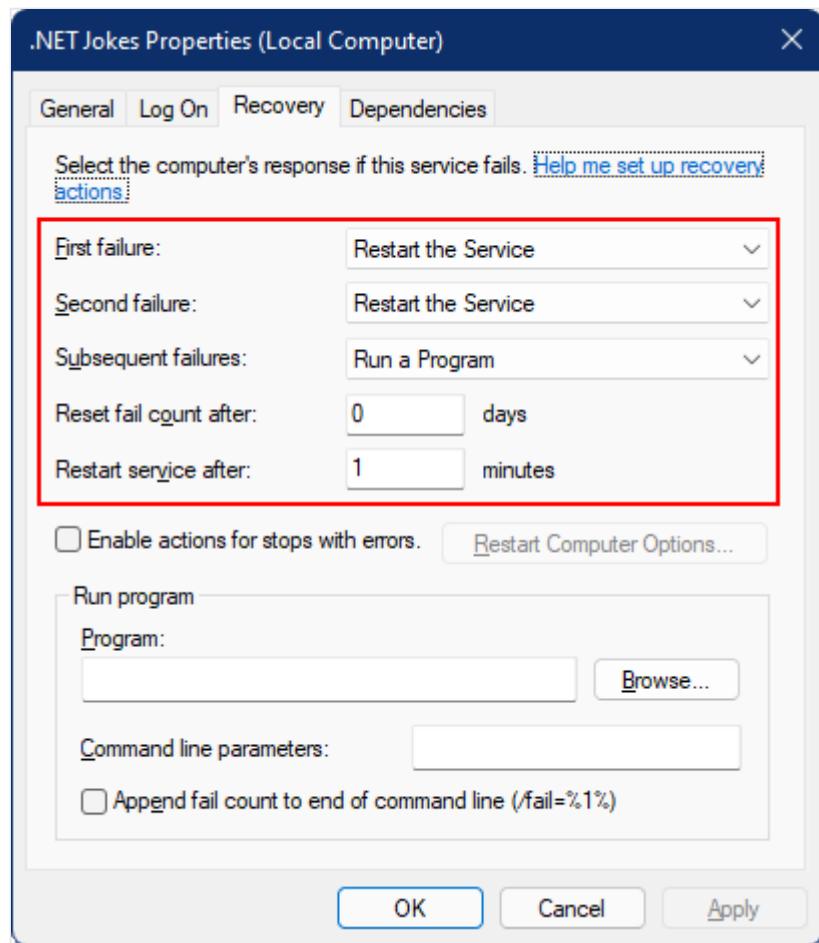

```
sc.exe qfailure "<Service Name>"
```

PowerShell

```
sc qfailure ".NET Joke Service"
[SC] QueryServiceConfig2 SUCCESS

SERVICE_NAME: .NET Joke Service
    RESET_PERIOD (in seconds)      : 0
    REBOOT_MESSAGE                 :
    COMMAND_LINE                   :
    FAILURE_ACTIONS                : RESTART -- Delay = 60000
milliseconds.
                                         RESTART -- Delay = 60000
milliseconds.
                                         RUN PROCESS -- Delay = 1000
milliseconds.
```

You will see the configured restart values.

Service recovery options and .NET `BackgroundService` instances

With .NET 6, [new hosting exception-handling behaviors](#) have been added to .NET. The `BackgroundServiceExceptionBehavior` enum was added to the `Microsoft.Extensions.Hosting` namespace, and is used to specify the behavior of the service when an exception is thrown. The following table lists the available options:

[Expand table](#)

| Option | Description |
|-----------------------|---|
| <code>Ignore</code> | Ignore exceptions thrown in <code>BackgroundService</code> . |
| <code>StopHost</code> | The <code>IHost</code> will be stopped when an unhandled exception is thrown. |

The default behavior before .NET 6 is `Ignore`, which resulted in *zombie processes* (a running process that didn't do anything). With .NET 6, the default behavior is `StopHost`, which results in the host being stopped when an exception is thrown. But it stops cleanly, meaning that the Windows Service management system will not restart the service. To correctly allow the service to be restarted, you can call `Environment.Exit` with a non-zero exit code. Consider the following highlighted `catch` block:

C#

```
namespace App.WindowsService;

public sealed class WindowsBackgroundService(
    JokeService jokeService,
    ILogger<WindowsBackgroundService> logger) : BackgroundService
{
    protected override async Task ExecuteAsync(CancellationToken stoppingToken)
    {
        try
        {
            while (!stoppingToken.IsCancellationRequested)
            {
                string joke = jokeService.GetJoke();
                logger.LogWarning("{Joke}", joke);

                await Task.Delay(TimeSpan.FromMinutes(1), stoppingToken);
            }
        }
        catch (OperationCanceledException)
        {
            // When the stopping token is canceled, for example, a call made
            // from services.msc,
            // we shouldn't exit with a non-zero exit code. In other words,
            // this is expected...
        }
        catch (Exception ex)
        {
            logger.LogError(ex, "{Message}", ex.Message);

            // Terminates this process and returns an exit code to the
            // operating system.
            // This is required to avoid the
            'BackgroundServiceExceptionBehavior', which
            // performs one of two scenarios:
            // 1. When set to "Ignore": will do nothing at all, errors cause
            // zombie services.
            // 2. When set to "StopHost": will cleanly stop the host, and
            log errors.
            //
            // In order for the Windows Service Management system to
            leverage configured
            // recovery options, we need to terminate the process with a
            non-zero exit code.
            Environment.Exit(1);
        }
    }
}
```

Verify service functionality

To see the app created as a Windows Service, open **Services**. Select the Windows key (or **Ctrl** + **Esc**), and search from "Services". From the **Services** app, you should be able to find your service by its name.

ⓘ Important

By default, regular (non-admin) users cannot manage Windows services. To verify that this app functions as expected, you'll need to use an Admin account.

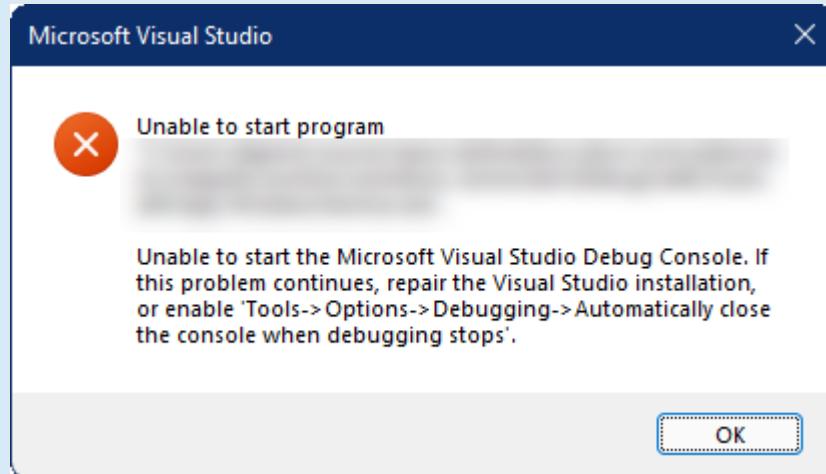

To verify that the service is functioning as expected, you need to:

- Start the service
- View the logs
- Stop the service

ⓘ Important

To debug the application, ensure that you're *not* attempting to debug the executable that is actively running within the Windows Services process.

Start the Windows Service

To start the Windows Service, use the `sc.exe start` command:

```
PowerShell
```

```
sc.exe start ".NET Joke Service"
```

You'll see output similar to the following:

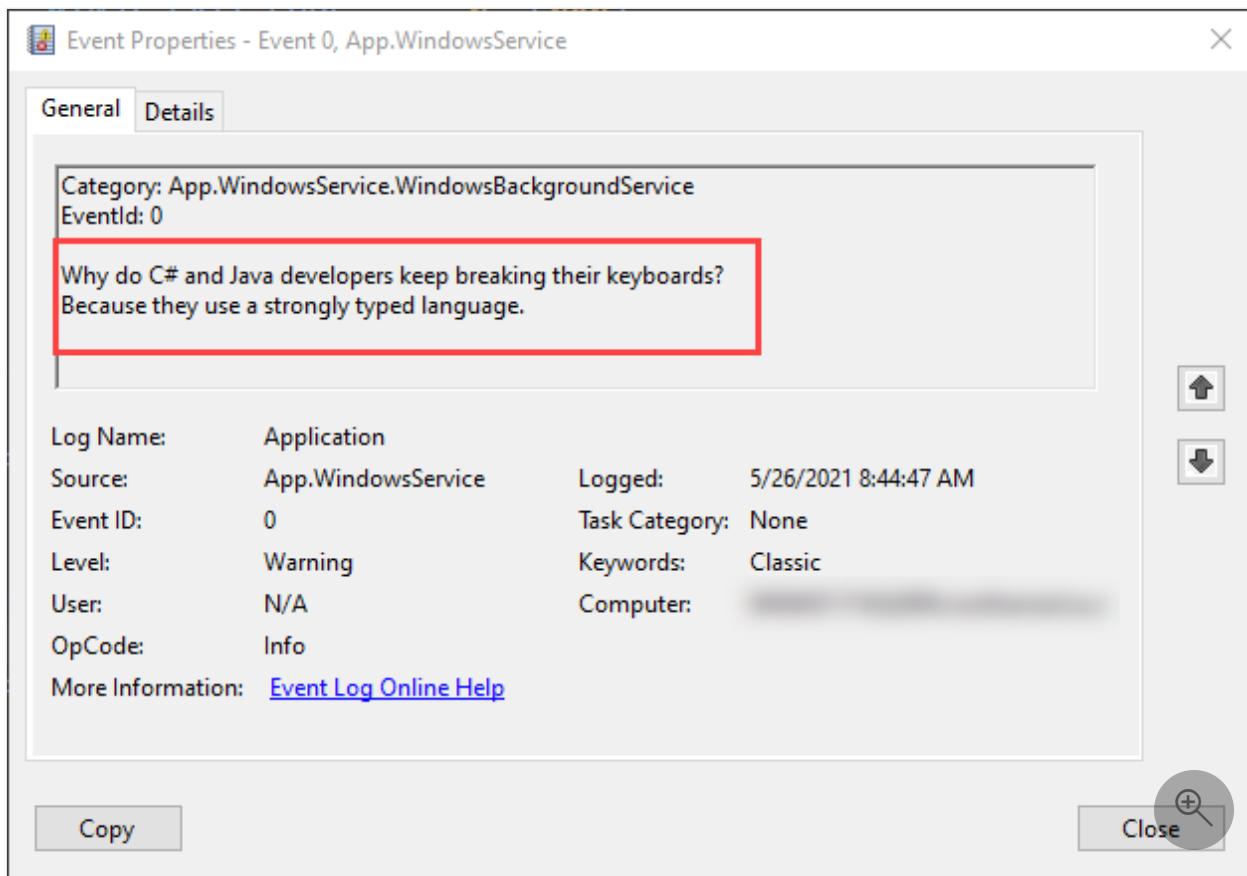

```
PowerShell
```

```
SERVICE_NAME: .NET Joke Service
  TYPE          : 10  WIN32_OWN_PROCESS
  STATE         : 2   START_PENDING
                  (NOT_STOPPABLE, NOT_PAUSABLE, IGNORES_SHUTDOWN)
  WIN32_EXIT_CODE    : 0  (0x0)
  SERVICE_EXIT_CODE  : 0  (0x0)
  CHECKPOINT       : 0x0
  WAIT_HINT        : 0x7d0
  PID              : 37636
  FLAGS
```

The service **Status** will transition out of `START_PENDING` to **Running**.

View logs

To view logs, open the **Event Viewer**. Select the Windows key (or `ctrl` + `Esc`), and search for `"Event Viewer"`. Select the **Event Viewer (Local) > Windows Logs > Application** node. You should see a **Warning** level entry with a **Source** matching the apps namespace. Double-click the entry, or right-click and select **Event Properties** to view the details.

After seeing logs in the **Event Log**, you should stop the service. It's designed to log a random joke once per minute. This is intentional behavior but is *not* practical for production services.

Stop the Windows Service

To stop the Windows Service, use the `sc.exe stop` command:

```
PowerShell  
  
sc.exe stop ".NET Joke Service"
```

You'll see output similar to the following:

```
PowerShell  
  
SERVICE_NAME: .NET Joke Service  
TYPE : 10 WIN32_OWN_PROCESS  
STATE : 3 STOP_PENDING  
        (STOPPABLE, NOT_PAUSABLE, ACCEPTS_SHUTDOWN)  
WIN32_EXIT_CODE : 0 (0x0)  
SERVICE_EXIT_CODE : 0 (0x0)  
CHECKPOINT : 0x0  
WAIT_HINT : 0x0
```

The service **Status** will transition from `STOP_PENDING` to **Stopped**.

Delete the Windows Service

To delete the Windows Service, use the native Windows Service Control Manager's (`sc.exe`) `delete` command. Run PowerShell as an Administrator.

Important

If the service is not in the **Stopped** state, it will not be immediately deleted. Ensure that the service is stopped before issuing the delete command.

PowerShell

```
sc.exe delete ".NET Joke Service"
```

You'll see an output message:

PowerShell

```
[SC] DeleteService SUCCESS
```

For more information, see [sc.exe delete](#).

Create a Windows Service installer

Article • 12/13/2023

When you create a .NET Windows Service (not to be mistaken with a .NET Framework Windows Service), you may want to create an installer for your service. Without an installer, users would have to know how to install and configure your service. An installer bundles your app's executables and exposes a customizable installation user experience. This tutorial is a continuation of the [Create a Windows Service](#) tutorial. It shows how to create an installer for your .NET Windows Service.

In this tutorial, you'll learn how to:

- ✓ Install the Visual Studio Installer Projects extension.
- ✓ Create a setup project.
- ✓ Update an existing .NET Worker project to support installation.
- ✓ Automate the installation and uninstallation with the Windows Service Control Manager.

Prerequisites

- You're expected to have completed the [Create a Windows Service](#) tutorial, or be prepared to clone the sample repo.
- The [.NET 8.0 SDK or later](#)
- A Windows OS
- A .NET integrated development environment (IDE)
 - Feel free to use [Visual Studio](#)
- An existing .NET Windows Service

Install tooling dependencies

Wix Toolset

Start by installing the Wix Toolset. The Wix Toolset is a set of tools that build Windows installation packages from XML source code.

.NET CLI

```
dotnet tool install --global wix
```

Next, install the [HeatWave for VS2022 extension](#). After installing, restart Visual Studio and you'll see new project templates available.

Get existing project

This tutorial is based on the app created as part of the [Create a Windows Service using BackgroundService](#) tutorial. You can either clone the sample repo or use the app you built in the previous tutorial.

Tip

All of the "Workers in .NET" example source code is available in the [Samples Browser](#) for download. For more information, see [Browse code samples: Workers in .NET](#).

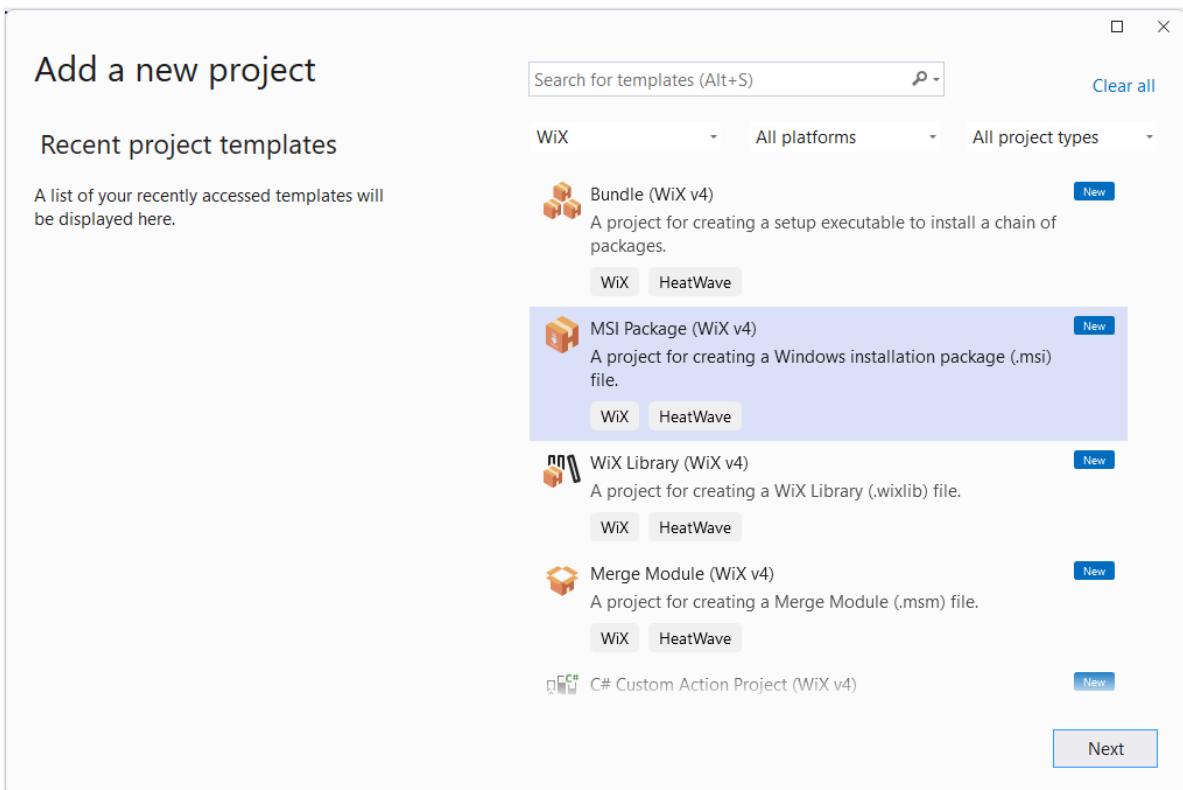

Wix Toolset

Open the solution in Visual Studio, and select `F5` to ensure that the app builds and runs as expected. Press `ctrl + C` to stop the app.

Add new setup project

Wix Toolset

To add a new Wix setup project, right-click on the solution in the [Solution Explorer](#) and select **Add > New Project**:

Select **MSI Package (WiX v4)** from the available templates, then select **Next**. Provide the desired **Name** and **Location**, then select **Create**.

Configure installer project

Wix Toolset

To configure the setup project, you first must add a reference to the `App.WindowsService` project. Right-click the setup project in the **Solution Explorer**, and then select **Add > Project Reference**.

The template includes example component and localization files. Delete these, files leaving only the `Package.wxs` file. Your project should now include a `ProjectReference` element, similar to the following:

XML

```
<Project Sdk="WixToolset.Sdk/4.0.0">
  <ItemGroup>
    <ProjectReference Include=".\\App.WindowsService.csproj" />
  </ItemGroup>
</Project>
```

After the project reference has been added, configure the `Package.wxs` file. Open the file in the editor, and then replace the contents with the following:

XML

```
<?xml version="1.0" encoding="UTF-8"?>

<!-- Define the variables in "$(var.*)" expressions -->
<?define Name = ".NET Joke Service" ?>
<?define Manufacturer = "Microsoft" ?>
<?define Version = "1.0.0.0" ?>
<?define UpgradeCode = "9ED3FF33-8718-444E-B44B-69A2344B7E98" ?>

<Wix xmlns="http://wixtoolset.org/schemas/v4/wxs">
    <Package Name="$(Name)"
        Manufacturer="$(Manufacturer)"
        Version="$(Version)"
        UpgradeCode="$(var.UpgradeCode)"
        Compressed="true">

        <!-- Allow upgrades and prevent downgrades -->
        <MajorUpgrade DowngradeErrorMessage="A later version of
[ProductName] is already installed. Setup will now exit." />

        <!-- Define the directory structure -->
        <Directory Id="TARGETDIR" Name="SourceDir">
            <Directory Id="ProgramFilesFolder">

                <!-- Create a folder inside program files -->
                <Directory Id="ROOTDIRECTORY"
Name="$(var.Manufacturer)">

                    <!-- Create a folder within the parent folder given
the name -->
                    <Directory Id="INSTALLFOLDER" Name="$(Name)" />
                </Directory>
            </Directory>
        </Directory>

        <!-- The files inside this DirectoryRef are linked to
            the App.WindowsService directory via INSTALLFOLDER -->
        <DirectoryRef Id="INSTALLFOLDER">

            <!-- Create a single component which is the
App.WindowsService.exe file -->
            <Component Id="ServiceExecutable" Bitness="always64">

                <!-- Copies the App.WindowsService.exe file using the
                    project reference preprocessor variables -->
                <File Id="App.WindowsService.exe"
Source="$(var.App.WindowsService.TargetDir)publish\App.WindowsService.ex
e"
                    KeyPath="true" />

                <!-- Remove all files from the INSTALLFOLDER on
uninstall -->
            
```

```

<RemoveFile Id="ALLFILES" Name="*.*" On="both" />

<ServiceInstall Id="ServiceInstaller"
    Type="ownProcess"
    Name="App.WindowsService"
    DisplayName="$(Name)"
    Description="A joke service that
periodically logs nerdy humor."
    Start="auto"
    ErrorControl="normal" />

<ServiceControl Id="StartService"
    Start="install"
    Stop="both"
    Remove="uninstall"
    Name="App.WindowsService"
    Wait="true" />
</Component>
</DirectoryRef>

<Feature Id="Service" Title="App.WindowsService Setup"
Level="1">
    <ComponentRef Id="ServiceExecutable" />
</Feature>

</Package>
</Wix>

```

When you build the project, the output is an MSI file that can be used to install and uninstall the service.

Test installation

Wix Toolset

To test the installer, publish the *App.WindowsService* project. Right-click the project in the **Solution Explorer**, and then select **Publish**. Once published with the profile you created in the previous tutorial, the executable will be in the publish directory. Next, you **Build** the setup project and run the installer.

You need to run the installation as an administrator. To do this, right-click the MSI file, and then select **Run as administrator**.

Once the service is installed, you can open **Services** to see the service running. To uninstall the service, use the **Windows Add or Remove Programs** feature to call the installer.

Implement the `IHostedService` interface

Article • 12/13/2023

When you need finite control beyond the provided [BackgroundService](#), you can implement your own [IHostedService](#). The [IHostedService](#) interface is the basis for all long running services in .NET. Custom implementations are registered with the [AddHostedService<THostedService>\(IServiceCollection\)](#) extension method.

In this tutorial, you learn how to:

- ✓ Implement the [IHostedService](#), and [IAsyncDisposable](#) interfaces.
- ✓ Create a timer-based service.
- ✓ Register the custom implementation with dependency injection and logging.

Tip

All of the "Workers in .NET" example source code is available in the [Samples Browser](#) for download. For more information, see [Browse code samples: Workers in .NET](#).

Prerequisites

- The [.NET 8.0 SDK or later](#)
- A .NET integrated development environment (IDE)
 - Feel free to use [Visual Studio](#)

Create a new project

To create a new Worker Service project with Visual Studio, you'd select **File > New > Project....** From the **Create a new project** dialog search for "Worker Service", and select Worker Service template. If you'd rather use the .NET CLI, open your favorite terminal in a working directory. Run the `dotnet new` command, and replace the `<Project.Name>` with your desired project name.

.NET CLI

```
dotnet new worker --name <Project.Name>
```

For more information on the .NET CLI new worker service project command, see [dotnet new worker](#).

💡 Tip

If you're using Visual Studio Code, you can run .NET CLI commands from the integrated terminal. For more information, see [Visual Studio Code: Integrated Terminal](#).

Create timer service

The timer-based background service makes use of the [System.Threading.Timer](#) class.

The timer triggers the `Dowork` method. The timer is disabled on `IHostLifetime.StopAsync(CancellationToken)` and disposed when the service container is disposed on `IAsyncDisposable.DisposeAsync()`:

Replace the contents of the `Worker` from the template with the following C# code, and rename the file to `TimerService.cs`:

C#

```
namespace App.TIMERHOSTEDSERVICE;

public sealed class TimerService(ILogger<TimerService> logger) : IHostedService, IAsyncDisposable
{
    private readonly Task _completedTask = Task.CompletedTask;
    private int _executionCount = 0;
    private Timer? _timer;

    public Task StartAsync(CancellationToken stoppingToken)
    {
        logger.LogInformation("{Service} is running.", nameof(TIMERHOSTEDSERVICE));
        _timer = new Timer(Dowork, null, TimeSpan.Zero,
TimeSpan.FromSeconds(5));

        return _completedTask;
    }

    private void Dowork(object? state)
    {
        int count = Interlocked.Increment(ref _executionCount);

        logger.LogInformation(
            "{Service} is working, execution count: {Count:#,0}",
            nameof(TIMERHOSTEDSERVICE),
```

```

        count);
    }

    public Task StopAsync(CancellationToken stoppingToken)
    {
        logger.LogInformation(
            "{Service} is stopping.", nameof(TimerHostedService));

        _timer?.Change(Timeout.Infinite, 0);

        return _completedTask;
    }

    public async ValueTask DisposeAsync()
    {
        if (_timer is IAsyncDisposable timer)
        {
            await timer.DisposeAsync();
        }

        _timer = null;
    }
}

```

ⓘ Important

The `Worker` was a subclass of `BackgroundService`. Now, the `TimerService` implements both the `IHostedService`, and `IAsyncDisposable` interfaces.

The `TimerService` is `sealed`, and cascades the `DisposeAsync` call from its `_timer` instance. For more information on the "cascading dispose pattern", see [Implement a `DisposeAsync` method](#).

When `StartAsync` is called, the timer is instantiated, thus starting the timer.

💡 Tip

The `Timer` doesn't wait for previous executions of `DoWork` to finish, so the approach shown might not be suitable for every scenario. `Interlocked.Increment` is used to increment the execution counter as an atomic operation, which ensures that multiple threads don't update `_executionCount` concurrently.

Replace the existing `Program` contents with the following C# code:

C#

```
using App.TimerHostedService;

HostApplicationBuilder builder = Host.CreateApplicationBuilder(args);
builder.Services.AddHostedService<TimerService>();

IHost host = builder.Build();
host.Run();
```

The service is registered in *(Program.cs)* with the `AddHostedService` extension method. This is the same extension method you use when registering [BackgroundService](#) subclasses, as they both implement the [IHostedService](#) interface.

For more information on registering services, see [Dependency injection in .NET](#).

Verify service functionality

To run the application from Visual Studio, select `F5` or select the **Debug > Start Debugging** menu option. If you're using the .NET CLI, run the `dotnet run` command from the working directory:

.NET CLI

```
dotnet run
```

For more information on the .NET CLI run command, see [dotnet run](#).

Let the application run for a bit to generate several execution count increments. You will see output similar to the following:

Output

```
info: App.TimerHostedService.TimerService[0]
      TimerHostedService is running.
info: Microsoft.Hosting.Lifetime[0]
      Application started. Press Ctrl+C to shut down.
info: Microsoft.Hosting.Lifetime[0]
      Hosting environment: Development
info: Microsoft.Hosting.Lifetime[0]
      Content root path: .\timer-service
info: App.TimerHostedService.TimerService[0]
      TimerHostedService is working, execution count: 1
info: App.TimerHostedService.TimerService[0]
      TimerHostedService is working, execution count: 2
info: App.TimerHostedService.TimerService[0]
      TimerHostedService is working, execution count: 3
info: App.TimerHostedService.TimerService[0]
```

```
TimerHostedService is working, execution count: 4
info: Microsoft.Hosting.Lifetime[0]
      Application is shutting down...
info: App.TimerHostedService.TimerService[0]
      TimerHostedService is stopping.
```

If running the application from within Visual Studio, select **Debug > Stop Debugging**.... Alternatively, select **Ctrl + C** from the console window to signal cancellation.

Deploy a Worker Service to Azure

Article • 12/13/2023

In this article, you'll learn how to deploy a .NET Worker Service to Azure. With your Worker running as an [Azure Container Instance \(ACI\)](#) from the [Azure Container Registry \(ACR\)](#), it can act as a microservice in the cloud. There are many use cases for long-running services, and the Worker Service exists for this reason.

In this tutorial, you learn how to:

- ✓ Create a worker service.
- ✓ Create container registry resource.
- ✓ Push an image to container registry.
- ✓ Deploy as container instance.
- ✓ Verify worker service functionality.

💡 Tip

All of the "Workers in .NET" example source code is available in the [Samples Browser](#) for download. For more information, see [Browse code samples: Workers in .NET](#).

Prerequisites

- The [.NET 5.0 SDK or later](#).
- Docker Desktop ([Windows](#) or [Mac](#)).
- An Azure account with an active subscription. [Create an account for free](#).
- Depending on your developer environment of choice:
 - [Visual Studio or Visual Studio Code](#).
 - [.NET CLI](#)
 - [Azure CLI](#).

Create a new project

To create a new Worker Service project with Visual Studio, select **File > New > Project...**. From the **Create a new project** dialog search for "Worker Service", and select Worker Service template. Enter the desired project name, select an appropriate location, and select **Next**. On the **Additional information** page, for the **Target Framework** select [.NET](#)

5.0, and check the **Enable Docker** option to enable docker support. Select the desired Docker OS.

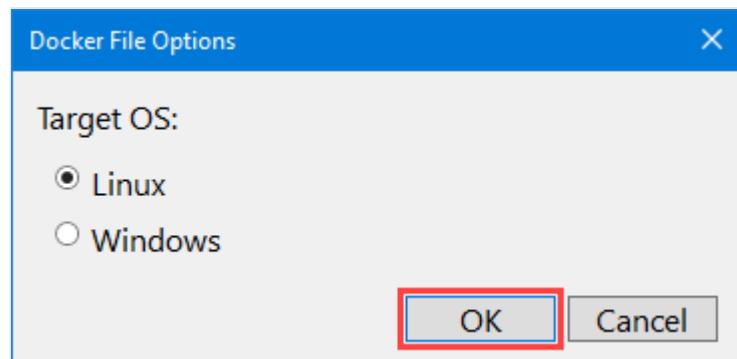

Build the application to ensure it restores the dependent packages, and compiles without error.

To build the application from Visual Studio, select **F6** or select the **Build > Build Solution** menu option.

Add Docker support

If you correctly selected the **Enable Docker** checkbox when creating a new Worker project, skip to the [Build the Docker image](#) step.

If you didn't select this option, no worries—you can still add it now. In Visual Studio, right-click on the *project node* in the **Solution Explorer**, and select **Add > Docker Support**. You'll be prompted to select a **Target OS**; select **OK** with the default OS selection.

Docker support requires a *Dockerfile*. This file is a set of comprehensive instructions, for building your .NET Worker Service as a Docker image. The *Dockerfile* is a file *without* a file extension. The following code is an example *Dockerfile*, and should exist at the root directory of the project file.

```
Dockerfile

FROM mcr.microsoft.com/dotnet/runtime:8.0 AS base
WORKDIR /app

# Creates a non-root user with an explicit UID and adds permission to access
# the /app folder
# For more info, please refer to https://aka.ms/vscode-docker-dotnet-
# configure-containers
RUN adduser -u 5678 --disabled-password --gecos "" appuser && chown -R
appuser /app
USER appuser
```

```
FROM mcr.microsoft.com/dotnet/sdk:8.0 AS build
WORKDIR /src
COPY ["App.CloudService.csproj", "./"]
RUN dotnet restore "App.CloudService.csproj"
COPY . .
WORKDIR "/src/."
RUN dotnet build "App.CloudService.csproj" -c Release -o /app/build

FROM build AS publish
RUN dotnet publish "App.CloudService.csproj" -c Release -o /app/publish

FROM base AS final
WORKDIR /app
COPY --from=publish /app/publish .
ENTRYPOINT ["dotnet", "App.CloudService.dll"]
```

Build the Docker image

To build the Docker image, the Docker Engine must be running.

ⓘ Important

When using Docker Desktop and Visual Studio, to avoid errors related to *volume sharing* — ensure that it is enabled.

1. On the **Settings** screen in Docker Desktop, select **Shared Drives**.
2. Select the drive(s) containing your project files.

For more information, see [Troubleshoot Visual Studio development with Docker](#).

Right-click on the *Dockerfile* in the **Solution Explorer**, and select **Build Docker Image**. The **Output** window displays, reporting the `docker build` command progress.

As the `docker build` command runs, it processes each line in the *Dockerfile* as an instruction step. This command builds the image and creates a local repository named `appcloudservice` that points to the image.

💡 Tip

The generated *Dockerfile* differs between development environments. For example, if you **Add Docker support** from Visual Studio you may experience issues if you attempt to **Build the Docker image** from Visual Studio Code—as the *Dockerfile* steps vary. It is best to choose a single *development environment* and use it throughout this tutorial.

Create container registry

An Azure Container Registry (ACR) resource allows you to build, store, and manage container images and artifacts in a private registry. To create a container registry, you need to [create a new resource](#) in the Azure portal.

1. Select the **Subscription**, and corresponding **Resource group** (or create a new one).
2. Enter a **Registry name**.
3. Select a **Location**.
4. Select an appropriate **SKU**, for example **Basic**.
5. Select **Review + create**.
6. After seeing **Validation passed**, select **Create**.

ⓘ Important

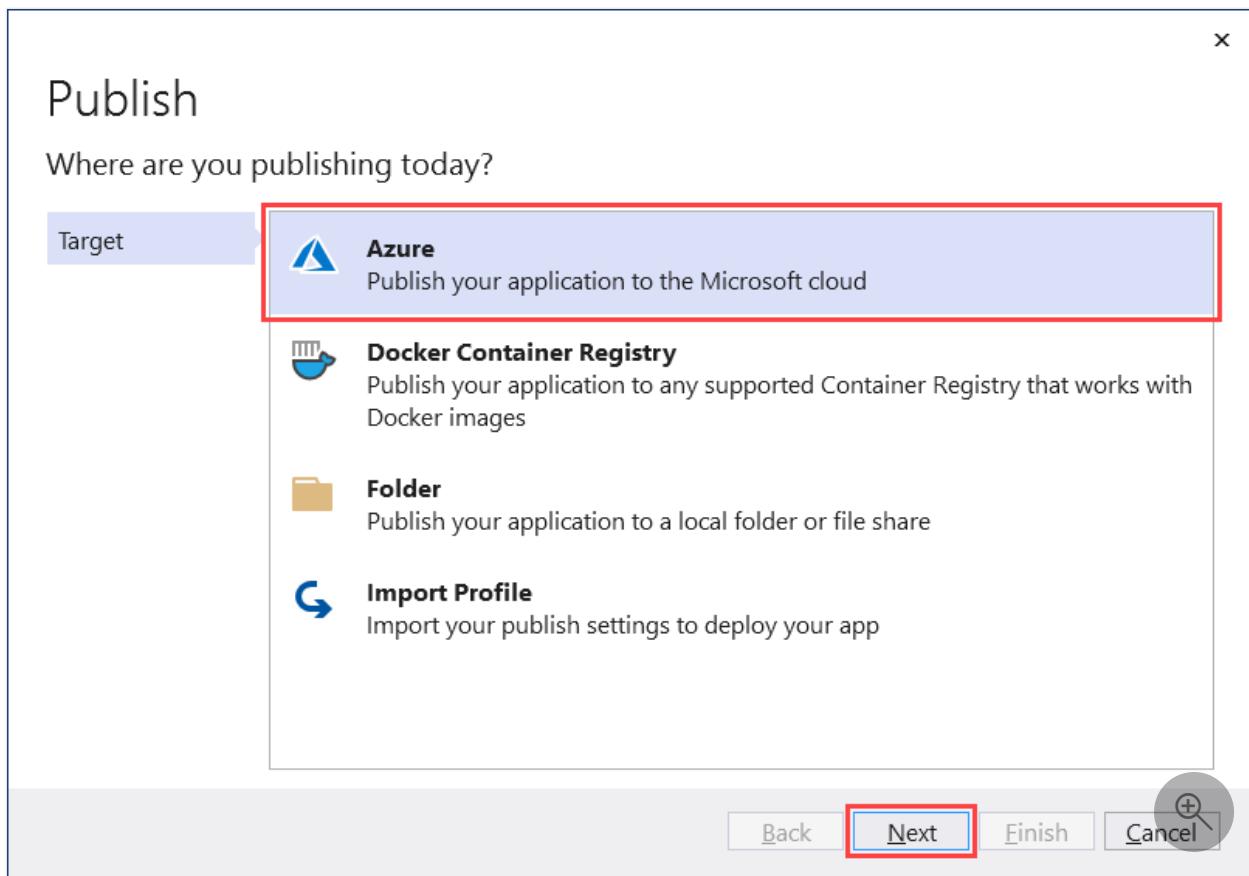

In order to use this container registry when creating a container instance, you must enable **Admin user**. Select **Access keys**, and enable **Admin user**.

For more information, see [Quickstart: Create an Azure container registry](#).

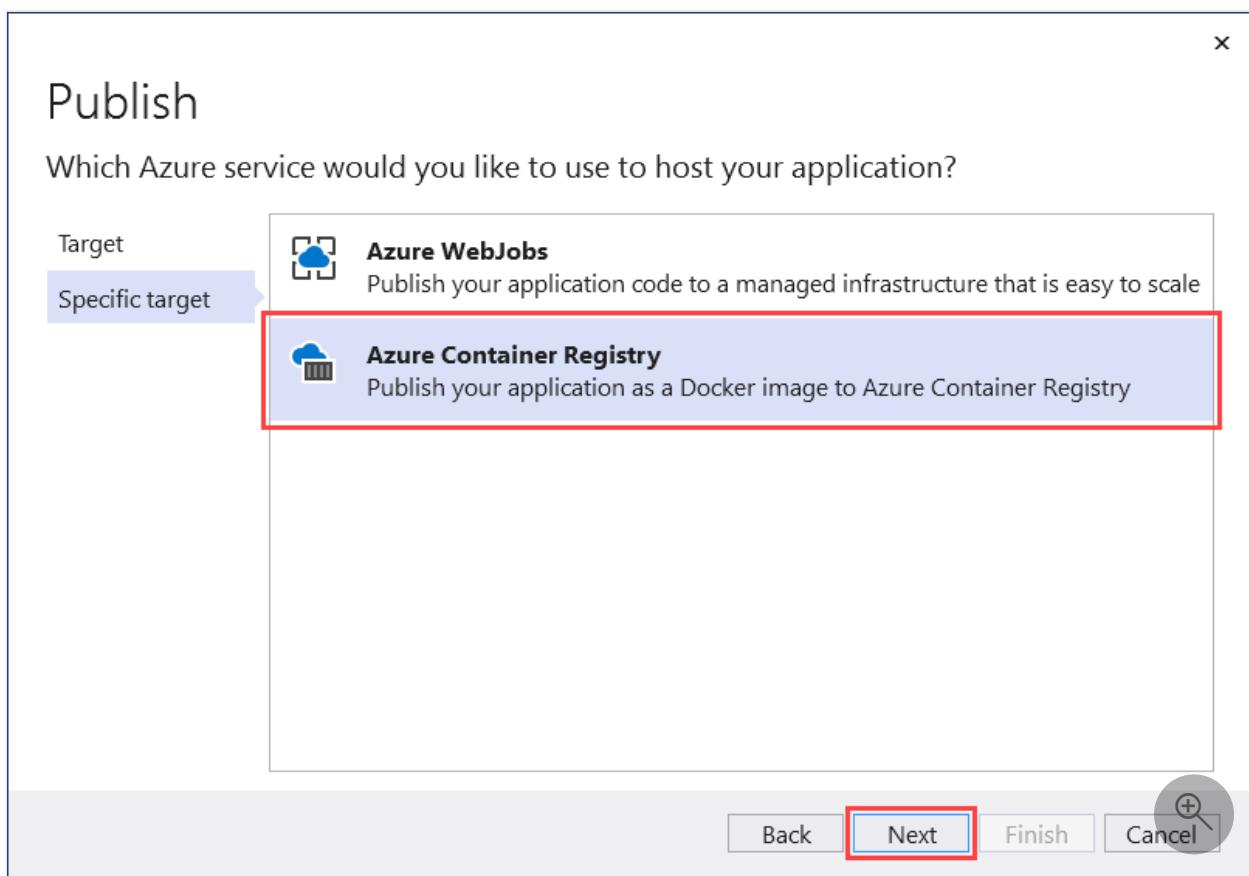

Push image to container registry

With the .NET Docker image built, and the container registry resource created, you can now push the image to container registry.

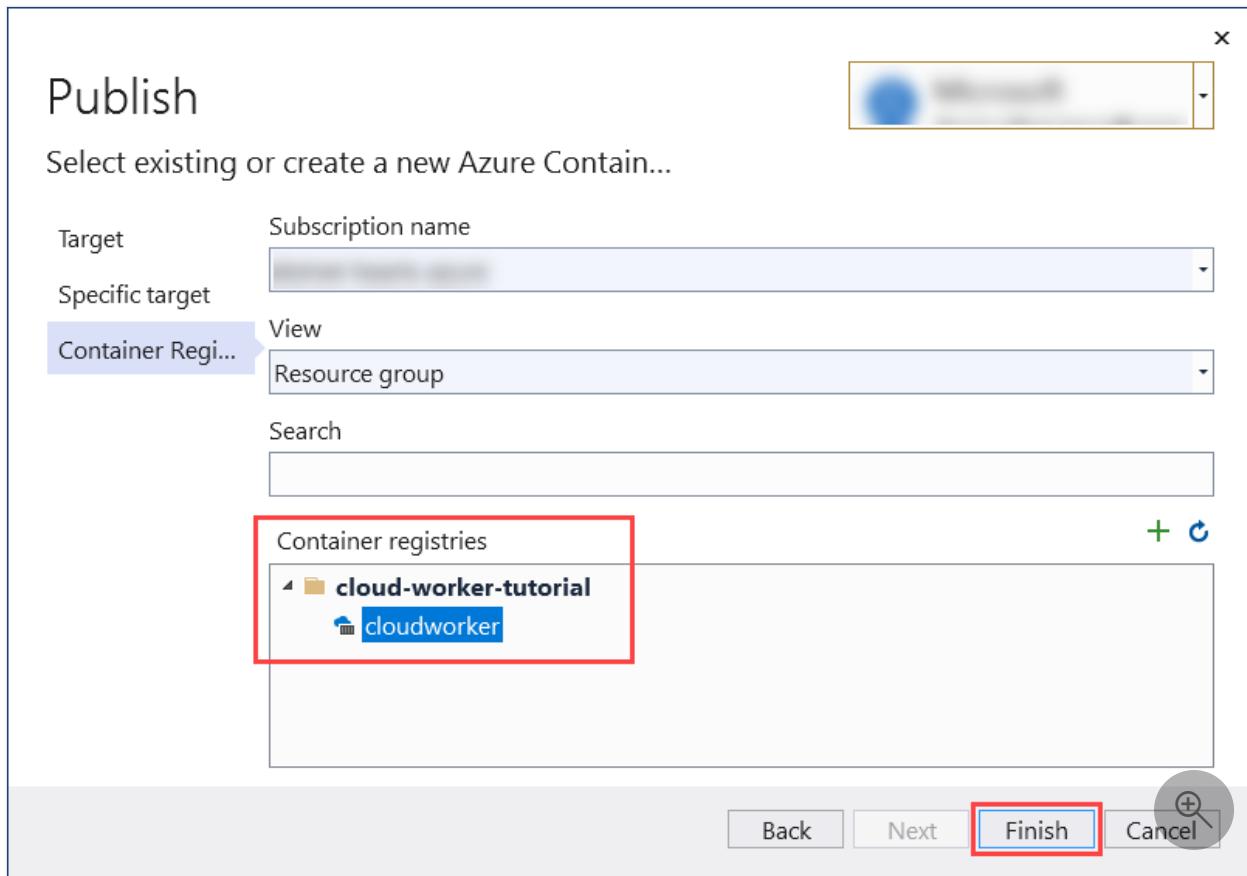

Right-click on the project in the **Solution Explorer**, and select **Publish**. The **Publish** dialog displays. For the **Target**, select **Azure** and then **Next**.

For the **Specific Target**, select **Azure Container Registry** and then **Next**.

Next, for the **Container Registry**, select the **Subscription name** that you used to create the ACR resource. From the **Container registries** selection area, select the container registry that you created, and then select **Finish**.

This creates a publish profile, which can be used to publish the image to container registry. Select the **Publish** button to push the image to the container registry, the **Output** window reports the publish progress—and when it completes successfully, you'll see a "Successfully published" message.

To verify that the image was successfully pushed to the container registry, navigate to the Azure portal. Open the container registry resource, under **Services**, select **Repositories**. You should see the image.

Deploy as container instance

To create a container instance, you also need to [create a new resource](#) in the Azure portal.

1. Select the same **Subscription**, and corresponding **Resource group** from the previous section.
2. Enter a **Container name**—`appcloudservice-container`.
3. Select a **Region** that corresponds to the previous **Location** selection.
4. For **Image source**, select **Azure Container Registry**.
5. Select the **Registry** by the name provided in the previous step.
6. Select the **Image** and **Image tag**.
7. Select **Review + create**.
8. Assuming **Validation passed**, select **Create**.

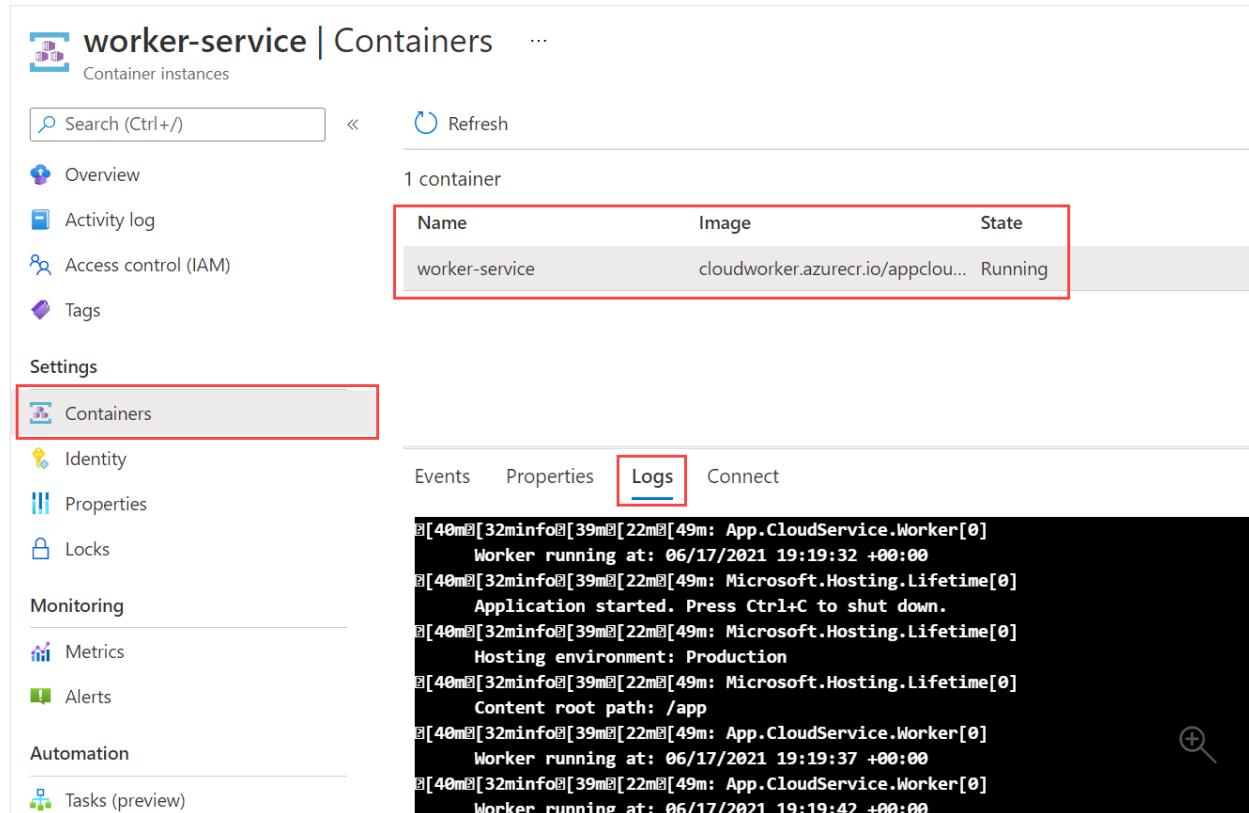

It may take a moment for the resources to be created, once created select the **Go to resource** button.

For more information, see [Quickstart: Create an Azure container instance](#).

Verify service functionality

Immediately after the container instance is created, it starts running.

To verify your worker service is functioning correctly, navigate to the Azure portal in the container instance resource, select the **Containers** option.

The screenshot shows the Azure portal interface for a container instance named "worker-service". The left sidebar has sections for Overview, Activity log, Access control (IAM), Tags, Settings (with Containers selected), Identity, Properties, Locks, Monitoring (Metrics and Alerts), Automation, and Tasks (preview). The main content area shows "1 container" and a table with columns Name, Image, and State. A single row is shown: Name is "worker-service", Image is "cloudworker.azurecr.io/appclou...", and State is "Running". Below the table is a "Logs" section with tabs for Events, Properties, Logs (selected), and Connect. The logs pane displays several lines of .NET worker service output:

```
[40m][32minfo@[39m@[22m@[49m: App.CloudService.Worker[0]
    Worker running at: 06/17/2021 19:19:32 +00:00
[40m][32minfo@[39m@[22m@[49m: Microsoft.Hosting.Lifetime[0]
    Application started. Press Ctrl+C to shut down.
[40m][32minfo@[39m@[22m@[49m: Microsoft.Hosting.Lifetime[0]
    Hosting environment: Production
[40m][32minfo@[39m@[22m@[49m: Microsoft.Hosting.Lifetime[0]
    Content root path: /app
[40m][32minfo@[39m@[22m@[49m: App.CloudService.Worker[0]
    Worker running at: 06/17/2021 19:19:37 +00:00
[40m][32minfo@[39m@[22m@[49m: App.CloudService.Worker[0]
    Worker running at: 06/17/2021 19:19:42 +00:00
```

You'll see the containers and their current **State**. In this case, it is **Running**. Select **Logs** to see the .NET worker service output.

Caching in .NET

Article • 12/11/2023

In this article, you'll learn about various caching mechanisms. Caching is the act of storing data in an intermediate-layer, making subsequent data retrievals faster.

Conceptually, caching is a performance optimization strategy and design consideration. Caching can significantly improve app performance by making infrequently changing (or expensive to retrieve) data more readily available. This article introduces the two primary types of caching, and provides sample source code for both:

- [Microsoft.Extensions.Caching.Memory](#)
- [Microsoft.Extensions.Caching.Distributed](#)

ⓘ Important

There are two `MemoryCache` classes within .NET, one in the `System.Runtime.Caching` namespace and the other in the `Microsoft.Extensions.Caching` namespace:

- [System.Runtime.Caching.MemoryCache](#)
- [Microsoft.Extensions.Caching.Memory.MemoryCache](#)

While this article focuses on caching, it doesn't include the [System.Runtime.Caching](#) NuGet package. All references to `MemoryCache` are within the `Microsoft.Extensions.Caching` namespace.

All of the `Microsoft.Extensions.*` packages come dependency injection (DI) ready, both the `IMemoryCache` and `IDistributedCache` interfaces can be used as services.

In-memory caching

In this section, you'll learn about the [Microsoft.Extensions.Caching.Memory](#) package. The current implementation of the `IMemoryCache` is a wrapper around the `ConcurrentDictionary<TKey,TValue>`, exposing a feature-rich API. Entries within the cache are represented by the `ICacheEntry`, and can be any `object`. The in-memory cache solution is great for apps that run on a single server, where all the cached data rents memory in the app's process.

💡 Tip

For multi-server caching scenarios, consider the [Distributed caching](#) approach as an alternative to in-memory caching.

In-memory caching API

The consumer of the cache has control over both sliding and absolute expirations:

- [ICacheEntry.AbsoluteExpiration](#)
- [ICacheEntry.AbsoluteExpirationRelativeToNow](#)
- [ICacheEntry.SlidingExpiration](#)

Setting an expiration will cause entries in the cache to be *evicted* if they're not accessed within the expiration time allotment. Consumers have additional options for controlling cache entries, through the [MemoryCacheEntryOptions](#). Each [ICacheEntry](#) is paired with [MemoryCacheEntryOptions](#) which exposes expiration eviction functionality with [IChangeToken](#), priority settings with [CacheItemPriority](#), and controlling the [ICacheEntry.Size](#). Consider the following extension methods:

- [MemoryCacheEntryExtensions.AddExpirationToken](#)
- [MemoryCacheEntryExtensions.RegisterPostEvictionCallback](#)
- [MemoryCacheEntryExtensions.SetSize](#)
- [MemoryCacheEntryExtensions.SetPriority](#)

In-memory cache example

To use the default [IMemoryCache](#) implementation, call the [AddMemoryCache](#) extension method to register all the required services with DI. In the following code sample, the generic host is used to expose DI functionality:

C#

```
using Microsoft.Extensions.Caching.Memory;
using Microsoft.Extensions.DependencyInjection;
using Microsoft.Extensions.Hosting;

HostApplicationBuilder builder = Host.CreateApplicationBuilder(args);
builder.Services.AddMemoryCache();
using IHost host = builder.Build();
```

Depending on your .NET workload, you may access the [IMemoryCache](#) differently; such as constructor injection. In this sample, you use the [IServiceProvider](#) instance on the [host](#) and call generic [GetRequiredService<T>\(IServiceProvider\)](#) extension method:

```
C#
```

```
IMemoryCache cache =  
    host.Services.GetRequiredService<IMemoryCache>();
```

With in-memory caching services registered, and resolved through DI — you're ready to start caching. This sample iterates through the letters in the English alphabet 'A' through 'Z'. The `record AlphabetLetter` type holds the reference to the letter, and generates a message.

```
C#
```

```
file record AlphabetLetter(char Letter)  
{  
    internal string Message =>  
        $"The '{Letter}' character is the {Letter - 64} letter in the  
        English alphabet.";  
}
```

The sample includes a helper function that iterates through the alphabet letters:

```
C#
```

```
static async ValueTask IterateAlphabetAsync(  
    Func<char, Task> asyncFunc)  
{  
    for (char letter = 'A'; letter <= 'Z'; ++letter)  
    {  
        await asyncFunc(letter);  
    }  
  
    Console.WriteLine();  
}
```

In the preceding C# code:

- The `Func<char, Task> asyncFunc` is awaited on each iteration, passing the current `letter`.
- After all letters have been processed, a blank line is written to the console.

To add items to the cache call one of the `Create`, or `Set` APIs:

```
C#
```

```
var addLettersToCacheTask = IterateAlphabetAsync(letter =>  
{  
    MemoryCacheEntryOptions options = new()
```

```

{
    AbsoluteExpirationRelativeToNow =
        TimeSpan.FromMilliseconds(MillisecondsAbsoluteExpiration)
};

_ = options.RegisterPostEvictionCallback(OnPostEviction);

AlphabetLetter alphabetLetter =
    cache.Set(
        letter, new AlphabetLetter(letter), options);

Console.WriteLine($"{alphabetLetter.Letter} was cached.");

return Task.Delay(
    TimeSpan.FromMilliseconds(MillisecondsDelayAfterAdd));
});

await addLettersToCacheTask;

```

In the preceding C# code:

- The variable `addLettersToCacheTask` delegates to `IterateAlphabetAsync` and is awaited.
- The `Func<char, Task> asyncFunc` is argued with a lambda.
- The `MemoryCacheEntryOptions` is instantiated with an absolute expiration relative to now.
- A post eviction callback is registered.
- An `AlphabetLetter` object is instantiated, and passed into `Set` along with `letter` and `options`.
- The letter is written to the console as being cached.
- Finally, a `Task.Delay` is returned.

For each letter in the alphabet, a cache entry is written with an expiration, and post eviction callback.

The post eviction callback writes the details of the value that was evicted to the console:

C#

```

static void OnPostEviction(
    object key, object? letter, EvictionReason reason, object? state)
{
    if (letter is AlphabetLetter alphabetLetter)
    {
        Console.WriteLine($"{alphabetLetter.Letter} was evicted for
{reason}.");
    }
}

```

Now that the cache is populated, another call to `IterateAlphabetAsync` is awaited, but this time you'll call `IMemoryCache.TryGetValue`:

```
C#  
  
var readLettersFromCacheTask = IterateAlphabetAsync(letter =>  
{  
    if (cache.TryGetValue(letter, out object? value) &&  
        value is AlphabetLetter alphabetLetter)  
    {  
        Console.WriteLine($"{letter} is still in cache.  
{alphabetLetter.Message}");  
    }  
  
    return Task.CompletedTask;  
});  
await readLettersFromCacheTask;
```

If the `cache` contains the `letter` key, and the `value` is an instance of an `AlphabetLetter` it's written to the console. When the `letter` key is not in the cache, it was evicted and its post eviction callback was invoked.

Additional extension methods

The `IMemoryCache` comes with many convenience-based extension methods, including an asynchronous `GetOrCreateAsync`:

- [CacheExtensions.Get](#)
- [CacheExtensions.GetOrCreate](#)
- [CacheExtensions.GetOrCreateAsync](#)
- [CacheExtensions.Set](#)
- [CacheExtensions.TryGetValue](#)

Put it all together

The entire sample app source code is a top-level program and requires two NuGet packages:

- [Microsoft.Extensions.Caching.Memory](#)
- [Microsoft.Extensions.Hosting](#)

```
C#  
  
using Microsoft.Extensions.Caching.Memory;  
using Microsoft.Extensions.DependencyInjection;
```

```
using Microsoft.Extensions.Hosting;

HostApplicationBuilder builder = Host.CreateApplicationBuilder(args);
builder.Services.AddMemoryCache();
using IHost host = builder.Build();

IMemoryCache cache =
    host.Services.GetRequiredService<IMemoryCache>();

const int MillisecondsDelayAfterAdd = 50;
const int MillisecondsAbsoluteExpiration = 750;

static void OnPostEviction(
    object key, object? letter, EvictionReason reason, object? state)
{
    if (letter is AlphabetLetter alphabetLetter)
    {
        Console.WriteLine($"'{alphabetLetter.Letter}' was evicted for
{reason}.");
    }
};

static async ValueTask IterateAlphabetAsync(
    Func<char, Task> asyncFunc)
{
    for (char letter = 'A'; letter <= 'Z'; ++letter)
    {
        await asyncFunc(letter);
    }

    Console.WriteLine();
}

var addLettersToCacheTask = IterateAlphabetAsync(letter =>
{
    MemoryCacheEntryOptions options = new()
    {
        AbsoluteExpirationRelativeToNow =
            TimeSpan.FromMilliseconds(MillisecondsAbsoluteExpiration)
    };

    _ = options.RegisterPostEvictionCallback(OnPostEviction);

    AlphabetLetter alphabetLetter =
        cache.Set(
            letter, new AlphabetLetter(letter), options);

    Console.WriteLine($"'{alphabetLetter.Letter}' was cached.");
}

    return Task.Delay(
        TimeSpan.FromMilliseconds(MillisecondsDelayAfterAdd));
});

await addLettersToCacheTask;

var readLettersFromCacheTask = IterateAlphabetAsync(letter =>
```

```
{  
    if (cache.TryGetValue(letter, out object? value) &&  
        value is AlphabetLetter alphabetLetter)  
    {  
        Console.WriteLine($"{letter} is still in cache.  
{alphabetLetter.Message}");  
    }  
  
    return Task.CompletedTask;  
});  
await readLettersFromCacheTask;  
  
await host.RunAsync();  
  
file record AlphabetLetter(char Letter)  
{  
    internal string Message =>  
        $"The '{Letter}' character is the {Letter - 64} letter in the  
English alphabet.";  
}
```

Feel free to adjust the `MillisecondsDelayAfterAdd` and `MillisecondsAbsoluteExpiration` values to observe the changes in behavior to the expiration and eviction of cached entries. The following is sample output from running this code, due to the non-deterministic nature of .NET events — there is no guarantee that your output will be identical.

Console

```
A was cached.  
B was cached.  
C was cached.  
D was cached.  
E was cached.  
F was cached.  
G was cached.  
H was cached.  
I was cached.  
J was cached.  
K was cached.  
L was cached.  
M was cached.  
N was cached.  
O was cached.  
P was cached.  
Q was cached.  
R was cached.  
S was cached.  
T was cached.  
U was cached.  
V was cached.  
W was cached.
```

```
X was cached.  
Y was cached.  
Z was cached.  
  
A was evicted for Expired.  
C was evicted for Expired.  
B was evicted for Expired.  
E was evicted for Expired.  
D was evicted for Expired.  
F was evicted for Expired.  
H was evicted for Expired.  
K was evicted for Expired.  
L was evicted for Expired.  
J was evicted for Expired.  
G was evicted for Expired.  
M was evicted for Expired.  
N was evicted for Expired.  
I was evicted for Expired.  
P was evicted for Expired.  
R was evicted for Expired.  
O was evicted for Expired.  
Q was evicted for Expired.  
S is still in cache. The 'S' character is the 19 letter in the English  
alphabet.  
T is still in cache. The 'T' character is the 20 letter in the English  
alphabet.  
U is still in cache. The 'U' character is the 21 letter in the English  
alphabet.  
V is still in cache. The 'V' character is the 22 letter in the English  
alphabet.  
W is still in cache. The 'W' character is the 23 letter in the English  
alphabet.  
X is still in cache. The 'X' character is the 24 letter in the English  
alphabet.  
Y is still in cache. The 'Y' character is the 25 letter in the English  
alphabet.  
Z is still in cache. The 'Z' character is the 26 letter in the English  
alphabet.
```

Since the absolute expiration

([MemoryCacheEntryOptions.AbsoluteExpirationRelativeToNow](#)) is set, all the cached items will eventually be evicted.

Worker Service caching

One common strategy for caching data, is updating the cache independently from the consuming data services. The *Worker Service* template is a great example, as the [BackgroundService](#) runs independent (or in the background) from the other application code. When an application starts running that hosts an implementation of the [IHostedService](#), the corresponding implementation (in this case the [BackgroundService](#)

or "worker") start running in the same process. These hosted services are registered with DI as singletons, through the `AddHostedService<THostedService>(IServiceCollection)` extension method. Other services can be registered with DI with any [service lifetime](#).

ⓘ Important

The service lifetime's are very important to understand. When you call `AddMemoryCache` to register all of the in-memory caching services, the services are registered as singletons.

Photo service scenario

Imagine you're developing a photo service that relies on third-party API accessible via HTTP. This photo data doesn't change very often, but there is a lot of it. Each photo is represented by a simple `record`:

C#

```
namespace CachingExamples.Memory;

public readonly record struct Photo(
    int AlbumId,
    int Id,
    string Title,
    string Url,
    string ThumbnailUrl);
```

In the following example, you'll see several services being registered with DI. Each service has a single responsibility.

C#

```
using CachingExamples.Memory;

HostApplicationBuilder builder = Host.CreateApplicationBuilder(args);

builder.Services.AddMemoryCache();
builder.Services.AddHttpClient<CacheWorker>();
builder.Services.AddHostedService<CacheWorker>();
builder.Services.AddScoped<PhotoService>();
builder.Services.AddSingleton(typeof(CacheSignal<>));

using IHost host = builder.Build();

await host.StartAsync();
```

In the preceding C# code:

- The generic host is created with [defaults](#).
- In-memory caching services are registered with [AddMemoryCache](#).
- An `HttpClient` instance is registered for the `CacheWorker` class with [AddHttpClient<TClient>\(IServiceCollection\)](#).
- The `CacheWorker` class is registered with [AddHostedService<THostedService>\(IServiceCollection\)](#).
- The `PhotoService` class is registered with [AddScoped<TService>\(IServiceCollection\)](#).
- The `CacheSignal<T>` class is registered with [AddSingleton](#).
- The `host` is instantiated from the builder, and started asynchronously.

The `PhotoService` is responsible for getting photos that match given criteria (or `filter`):

C#

```
using Microsoft.Extensions.Caching.Memory;

namespace CachingExamples.Memory;

public sealed class PhotoService(
    IMemoryCache cache,
    CacheSignal<Photo> cacheSignal,
    ILogger<PhotoService> logger)
{
    public async IAsyncEnumerable<Photo> GetPhotosAsync(Func<Photo, bool>?
filter = default)
    {
        try
        {
            await cacheSignal.WaitAsync();

            Photo[] photos =
                (await cache.GetOrCreateAsync(
                    "Photos", _ =>
                {
                    logger.LogWarning("This should never happen!");
                })
            )!;

            // If no filter is provided, use a pass-thru.
            filter ??= _ => true;

            foreach (Photo photo in photos)
            {
                if (!default(Photo).Equals(photo) && filter(photo))
                {
                    yield return photo;
                }
            }
        }
    }
}
```

```

        }
    }
    finally
    {
        cacheSignal.Release();
    }
}
}

```

In the preceding C# code:

- The constructor requires an `IMemoryCache`, `CacheSignal<Photo>`, and `ILogger`.
- The `GetPhotosAsync` method:
 - Defines a `Func<Photo, bool> filter` parameter, and returns an `IAsyncEnumerable<Photo>`.
 - Calls and waits for the `_cacheSignal.WaitAsync()` to release, this ensures that the cache is populated before accessing the cache.
 - Calls `_cache.GetOrCreateAsync()`, asynchronously getting all of the photos in the cache.
 - The `factory` argument logs a warning, and returns an empty photo array - this should never happen.
 - Each photo in the cache is iterated, filtered, and materialized with `yield return`.
 - Finally, the cache signal is reset.

Consumers of this service are free to call `GetPhotosAsync` method, and handle photos accordingly. No `HttpClient` is required as the cache contains the photos.

The asynchronous signal is based on an encapsulated `SemaphoreSlim` instance, within a generic-type constrained singleton. The `CacheSignal<T>` relies on an instance of `SemaphoreSlim`:

C#

```

namespace CachingExamples.Memory;

public sealed class CacheSignal<T>
{
    private readonly SemaphoreSlim _semaphore = new(1, 1);

    /// <summary>
    /// Exposes a <see cref="Task"/> that represents the asynchronous wait
    /// operation.
    /// When signaled (consumer calls <see cref="Release"/>), the
    /// <see cref="Task.Status"/> is set as <see
    /// cref="TaskStatus.RanToCompletion"/>.
}

```

```

    /// </summary>
    public Task WaitAsync() => _semaphore.WaitAsync();

    /// <summary>
    /// Exposes the ability to signal the release of the <see
    cref="WaitAsync"/>'s operation.
    /// Callers who were waiting, will be able to continue.
    /// </summary>
    public void Release() => _semaphore.Release();
}

```

In the preceding C# code, the decorator pattern is used to wrap an instance of the `SemaphoreSlim`. Since the `CacheSignal<T>` is registered as a singleton, it can be used across all service lifetimes with any generic type — in this case, the `Photo`. It is responsible for signaling the seeding of the cache.

The `CacheWorker` is a subclass of `BackgroundService`:

C#

```

using System.Net.Http.Json;
using Microsoft.Extensions.Caching.Memory;

namespace CachingExamples.Memory;

public sealed class CacheWorker(
    ILogger<CacheWorker> logger,
    HttpClient httpClient,
    CacheSignal<Photo> cacheSignal,
    IMemoryCache cache) : BackgroundService
{
    private readonly TimeSpan _updateInterval = TimeSpan.FromHours(3);

    private bool _isCacheInitialized = false;

    private const string Url =
"https://jsonplaceholder.typicode.com/photos";

    public override async Task StartAsync(CancellationToken cancellationToken)
    {
        await cacheSignal.WaitAsync();
        await base.StartAsync(cancellationToken);
    }

    protected override async Task ExecuteAsync(CancellationToken stoppingToken)
    {
        while (!stoppingToken.IsCancellationRequested)
        {
            logger.LogInformation("Updating cache.");
        }
    }
}

```

```

    try
    {
        Photo[]? photos =
            await httpClient.GetFromJsonAsync<Photo[]>(
                Url, stoppingToken);

        if (photos is { Length: > 0 })
        {
            cache.Set("Photos", photos);
            logger.LogInformation(
                "Cache updated with {Count:#,#} photos.",
                photos.Length);
        }
        else
        {
            logger.LogWarning(
                "Unable to fetch photos to update cache.");
        }
    }
    finally
    {
        if (!_isCacheInitialized)
        {
            cacheSignal.Release();
            _isCacheInitialized = true;
        }
    }

    try
    {
        logger.LogInformation(
            "Will attempt to update the cache in {Hours} hours from
now.",
            _updateInterval.Hours);

        await Task.Delay(_updateInterval, stoppingToken);
    }
    catch (OperationCanceledException)
    {
        logger.LogWarning("Cancellation acknowledged: shutting
down.");
        break;
    }
}
}
}

```

In the preceding C# code:

- The constructor requires an `ILogger`, `HttpClient`, and `IMemoryCache`.
- The `_updateInterval` is defined for three hours.
- The `ExecuteAsync` method:

- Loops while the app is running.
- Makes an HTTP request to "<https://jsonplaceholder.typicode.com/photos>", and maps the response as an array of `Photo` objects.
- The array of photos is placed in the `IMemoryCache` under the "Photos" key.
- The `_cacheSignal.Release()` is called, releasing any consumers who were waiting for the signal.
- The call to `Task.Delay` is awaited, given the update interval.
- After delaying for three hours, the cache is again updated.

Consumers in the same process could ask the `IMemoryCache` for the photos, but the `CacheWorker` is responsible for updating the cache.

Distributed caching

In some scenarios, a distributed cache is required — such is the case with multiple app servers. A distributed cache supports higher scale-out than the in-memory caching approach. Using a distributed cache offloads the cache memory to an external process, but does require extra network I/O and introduces a bit more latency (even if nominal).

The distributed caching abstractions are part of the [Microsoft.Extensions.Caching.Memory](#) NuGet package, and there is even an `AddDistributedMemoryCache` extension method.

⊗ Caution

The `AddDistributedMemoryCache` should only be used in development and/or testing scenarios, and is **not** a viable production implementation.

Consider any of the available implementations of the `IDistributedCache` from the following packages:

- [Microsoft.Extensions.Caching.SqlServer](#)
- [Microsoft.Extensions.Caching.StackExchangeRedis](#)
- [NCache.Microsoft.Extensions.Caching.OpenSource](#)

Distributed caching API

The distributed caching APIs are a bit more primitive than their in-memory caching API counterparts. The key-value pairs are a bit more basic. In-memory caching keys are based on an `object`, whereas the distributed keys are a `string`. With in-memory

caching, the value can be any strongly-typed generic, whereas values in distributed caching are persisted as `byte[]`. That's not to say that various implementations don't expose strongly-typed generic values but that would be an implementation detail.

Create values

To create values in the distributed cache, call one of the set APIs:

- [IDistributedCache.SetAsync](#)
- [IDistributedCache.Set](#)

Using the `AlphabetLetter` record from the in-memory cache example, you could serialize the object to JSON and then encode the `string` as a `byte[]`:

C#

```
DistributedCacheEntryOptions options = new()
{
    AbsoluteExpirationRelativeToNow =
        TimeSpan.FromMilliseconds(MillisecondsAbsoluteExpiration)
};

AlphabetLetter alphabetLetter = new(letter);
string json = JsonSerializer.Serialize(alphabetLetter);
byte[] bytes = Encoding.UTF8.GetBytes(json);

await cache.SetAsync(letter.ToString(), bytes, options);
```

Much like in-memory caching, cache entries can have options to help fine-tune their existence in the cache — in this case, the [DistributedCacheEntryOptions](#).

Create extension methods

There are several convenience-based extension methods for creating values, that help to avoid encoding `string` representations of objects into a `byte[]`:

- [DistributedCacheExtensions.SetStringAsync](#)
- [DistributedCacheExtensions.SetString](#)

Read values

To read values from the distributed cache, call one of the get APIs:

- [IDistributedCache.GetAsync](#)
- [IDistributedCache.Get](#)

C#

```
AlphabetLetter? alphabetLetter = null;
byte[]? bytes = await cache.GetAsync(letter.ToString());
if (bytes is { Length: > 0 })
{
    string json = Encoding.UTF8.GetString(bytes);
    alphabetLetter = JsonSerializer.Deserialize<AlphabetLetter>(json);
}
```

Once a cache entry is read out of the cache, you can get the UTF8 encoded `string` representation from the `byte[]`

Read extension methods

There are several convenience-based extension methods for reading values, that help to avoid decoding `byte[]` into `string` representations of objects:

- [DistributedCacheExtensions.GetStringAsync](#)
- [DistributedCacheExtensions.GetString](#)

Update values

There is no way to update the values in the distributed cache with a single API call, instead, values can have their sliding expirations reset with one of the refresh APIs:

- [IDistributedCache.RefreshAsync](#)
- [IDistributedCache.Refresh](#)

If the actual value needs to be updated, you'd have to delete the value and then re-add it.

Delete values

To delete values in the distributed cache, call one of the remove APIs:

- [IDistributedCache.RemoveAsync](#)
- [IDistributedCache.Remove](#)

💡 Tip

While there are synchronous versions of the aforementioned APIs, please consider the fact that implementations of distributed caches are reliant on network I/O. For

this reason, it is preferred more often than not to use the asynchronous APIs.

System.Threading.Channels library

Article • 06/27/2023

The [System.Threading.Channels](#) namespace provides a set of synchronization data structures for passing data between producers and consumers asynchronously. The library targets .NET Standard and works on all .NET implementations.

This library is available in the [System.Threading.Channels](#) NuGet package. However, if you're using .NET Core 3.0 or later, the package is included as part of the framework.

Producer/consumer conceptual programming model

Channels are an implementation of the producer/consumer conceptual programming model. In this programming model, producers asynchronously produce data, and consumers asynchronously consume that data. In other words, this model hands off data from one party to another. Try to think of channels as you would any other common generic collection type, such as a `List<T>`. The primary difference is that this collection manages synchronization and provides various consumption models through factory creation options. These options control the behavior of the channels, such as how many elements they're allowed to store and what happens if that limit is reached, or whether the channel is accessed by multiple producers or multiple consumers concurrently.

Bounding strategies

Depending on how a `Channel<T>` is created, its reader and writer behave differently.

To create a channel that specifies a maximum capacity, call [Channel.CreateBounded](#). To create a channel that is used by any number of readers and writers concurrently, call [Channel.CreateUnbounded](#). Each bounding strategy exposes various creator-defined options, either [BoundedChannelOptions](#) or [UnboundedChannelOptions](#) respectively.

ⓘ Note

Regardless of the bounding strategy, a channel will always throw a [ChannelClosedException](#) when it's used after it's been closed.

Unbounded channels

To create an unbounded channel, call one of the [Channel.CreateUnbounded](#) overloads:

C#

```
var channel = Channel.CreateUnbounded<T>();
```

When you create an unbounded channel, by default, the channel can be used by any number of readers and writers concurrently. Alternatively, you can specify nondefault behavior when creating an unbounded channel by providing an [UnboundedChannelOptions](#) instance. The channel's capacity is unbounded and all writes are performed synchronously. For more examples, see [Unbounded creation patterns](#).

Bounded channels

To create a bounded channel, call one of the [Channel.CreateBounded](#) overloads:

C#

```
var channel = Channel.CreateBounded<T>(7);
```

The preceding code creates a channel that has a maximum capacity of 7 items. When you create a bounded channel, the channel is bound to a maximum capacity. When the bound is reached, the default behavior is that the channel asynchronously blocks the producer until space becomes available. You can configure this behavior by specifying an option when you create the channel. Bounded channels can be created with any capacity value greater than zero. For other examples, see [Bounded creation patterns](#).

Full mode behavior

When using a bounded channel, you can specify the behavior the channel adheres to when the configured bound is reached. The following table lists the full mode behaviors for each [BoundedChannelFullMode](#) value:

| Value | Behavior |
|---|--|
| BoundedChannelFullMode.Wait | This is the default value. Calls to <code>WriteAsync</code> wait for space to be available in order to complete the write operation. Calls to <code>TryWrite</code> return <code>false</code> immediately. |
| BoundedChannelFullMode.DropNewest | Removes and ignores the newest item in the channel in |

| Value | Behavior |
|-----------------------------------|--|
| | order to make room for the item being written. |
| BoundedChannelFullMode.DropOldest | Removes and ignores the oldest item in the channel in order to make room for the item being written. |
| BoundedChannelFullMode.DropWrite | Drops the item being written. |

ⓘ Important

Whenever a [Channel<TWrite,TRead>.Writer](#) produces faster than a [Channel<TWrite,TRead>.Reader](#) can consume, the channel's writer experiences back pressure.

Producer APIs

The producer functionality is exposed on the [Channel<TWrite,TRead>.Writer](#). The producer APIs and expected behavior are detailed in the following table:

| API | Expected behavior |
|---|--|
| ChannelWriter<T>.Complete | Marks the channel as being complete, meaning no more items are written to it. |
| ChannelWriter<T>.TryComplete | Attempts to mark the channel as being completed, meaning no more data is written to it. |
| ChannelWriter<T>.TryWrite | Attempts to write the specified item to the channel. When used with an unbounded channel, this always returns <code>true</code> unless the channel's writer signals completion with either ChannelWriter<T>.Complete , or ChannelWriter<T>.TryComplete . |
| ChannelWriter<T>.WaitToWriteAsync | Returns a ValueTask<TResult> that completes when space is available to write an item. |
| ChannelWriter<T>.WriteAsync | Asynchronously writes an item to the channel. |

Consumer APIs

The consumer functionality is exposed on the [Channel<TWrite,TRead>.Reader](#). The consumer APIs and expected behavior are detailed in the following table:

| API | Expected behavior |
|---|--|
| <code>ChannelReader<T>.ReadAllAsync</code> | Creates an <code>IAsyncEnumerable<T></code> that enables reading all of the data from the channel. |
| <code>ChannelReader<T>.ReadAsync</code> | Asynchronously reads an item from the channel. |
| <code>ChannelReader<T>.TryPeek</code> | Attempts to peek at an item from the channel. |
| <code>ChannelReader<T>.TryRead</code> | Attempts to read an item from the channel. |
| <code>ChannelReader<T>.WaitToReadAsync</code> | Returns a <code>ValueTask<TResult></code> that completes when data is available to read. |

Common usage patterns

There are several usage patterns for channels. The API is designed to be simple, consistent, and as flexible as possible. All of the asynchronous methods return a `ValueTask` (or `ValueTask<bool>`) that represents a lightweight asynchronous operation that can avoid allocating if the operation completes synchronously and potentially even asynchronously. Additionally, the API is designed to be composable, in that the creator of a channel makes promises about its intended usage. When a channel is created with certain parameters, the internal implementation can operate more efficiently knowing these promises.

Creation patterns

Imagine that you're creating a producer/consumer solution for a global position system (GPS). You want to track the coordinates of a device over time. A sample coordinates object might look like this:

C#

```
/// <summary>
/// A representation of a device's coordinates,
/// which includes latitude and longitude.
/// </summary>
/// <param name="DeviceId">A unique device identifier.</param>
/// <param name="Latitude">The latitude of the device.</param>
/// <param name="Longitude">The longitude of the device.</param>
public readonly record struct Coordinates(
    Guid DeviceId,
    double Latitude,
    double Longitude);
```

Unbounded creation patterns

One common usage pattern is to create a default unbounded channel:

```
C#
```

```
var channel = Channel.CreateUnbounded<Coordinates>();
```

But instead, let's imagine that you want to create an unbounded channel with multiple producers and consumers:

```
C#
```

```
var channel = Channel.CreateUnbounded<Coordinates>(
    new UnboundedChannelOptions
    {
        SingleWriter = false,
        SingleReader = false,
        AllowSynchronousContinuations = true
    });

```

In this case, all writes are synchronous, even the `WriteAsync`. This is because an unbounded channel always has available room for a write effectively immediately. However, with `AllowSynchronousContinuations` set to `true`, the writes may end up doing work associated with a reader by executing their continuations. This doesn't affect the synchronicity of the operation.

Bounded creation patterns

With bounded channels, the configurability of the channel should be known to the consumer to help ensure proper consumption. That is, the consumer should know what behavior the channel exhibits when the configured bound is reached. Let's explore some of the common bounded creation patterns.

The simplest way to create a bounded channel is to specify a capacity:

```
C#
```

```
var channel = Channel.CreateBounded<Coordinates>(1);
```

The preceding code creates a bounded channel with a max capacity of `1`. Other options are available, some options are the same as an unbounded channel, while others are specific to bounded channels:

C#

```
var channel = Channel.CreateBounded<Coordinates>(
    new BoundedChannelOptions(1_000)
{
    SingleWriter = true,
    SingleReader = false,
    AllowSynchronousContinuations = false,
    FullMode = BoundedChannelFullMode.DropWrite
});
```

In the preceding code, the channel is created as a bounded channel that's limited to 1,000 items, with a single writer but many readers. Its full mode behavior is defined as `DropWrite`, which means that it drops the item being written if the channel is full.

To observe items that are dropped when using bounded channels, register an `itemDropped` callback:

C#

```
var channel = Channel.CreateBounded(
    new BoundedChannelOptions(10)
{
    AllowSynchronousContinuations = true,
    FullMode = BoundedChannelFullMode.DropOldest
},
static void (Coordinates dropped) =>
    Console.WriteLine($"Coordinates dropped: {dropped}"));
```

Whenever the channel is full and a new item is added, the `itemDropped` callback is invoked. In this example, the provided callback writes the item to the console, but you're free to take any other action you want.

Producer patterns

Imagine that the producer in this scenario is writing new coordinates to the channel. The producer can do this by calling `TryWrite`:

C#

```
static void ProduceWithWhileAndTryWrite(
    ChannelWriter<Coordinates> writer, Coordinates coordinates)
{
    while (coordinates is { Latitude: < 90, Longitude: < 180 })
    {
        var tempCoordinates = coordinates with
        {
```

```

        Latitude = coordinates.Latitude + .5,
        Longitude = coordinates.Longitude + 1
    };

    if (writer.TryWrite(item: tempCoordinates))
    {
        coordinates = tempCoordinates;
    }
}
}

```

The preceding producer code:

- Accepts the `channel<Coordinates>.Writer` (`ChannelWriter<Coordinates>`) as an argument, along with the initial `Coordinates`.
- Defines a conditional `while` loop that attempts to move the coordinates using `TryWrite`.

An alternative producer might use the `WriteAsync` method:

C#

```

static async ValueTask ProduceWithWhileWriteAsync(
    ChannelWriter<Coordinates> writer, Coordinates coordinates)
{
    while (coordinates is { Latitude: < 90, Longitude: < 180 })
    {
        await writer.WriteAsync(
            item: coordinates = coordinates with
            {
                Latitude = coordinates.Latitude + .5,
                Longitude = coordinates.Longitude + 1
            });
    }

    writer.Complete();
}

```

Again, the `ChannelWriter<Coordinates>.Writer` is used within a `while` loop. But this time, the `WriteAsync` method is called. The method will continue only after the coordinates have been written. When the `while` loop exits, a call to `Complete` is made, which signals that no more data is written to the channel.

Another producer pattern is to use the `WaitToWriteAsync` method, consider the following code:

C#

```

static async ValueTask ProduceWithWaitToWriteAsync(
    ChannelWriter<Coordinates> writer, Coordinates coordinates)
{
    while (coordinates is { Latitude: < 90, Longitude: < 180 } &&
        await writer.WaitToWriteAsync())
    {
        var tempCoordinates = coordinates with
        {
            Latitude = coordinates.Latitude + .5,
            Longitude = coordinates.Longitude + 1
        };

        if (writer.TryWrite(item: tempCoordinates))
        {
            coordinates = tempCoordinates;
        }

        await Task.Delay(TimeSpan.FromMilliseconds(10));
    }

    writer.Complete();
}

```

As part of the conditional `while`, the result of the `WaitToWriteAsync` call is used to determine whether to continue the loop.

Consumer patterns

There are several common channel consumer patterns. When a channel is never ending, meaning it produces data indefinitely, the consumer could use a `while (true)` loop, and read data as it becomes available:

C#

```

static async ValueTask ConsumeWithWhileAsync(
    ChannelReader<Coordinates> reader)
{
    while (true)
    {
        // May throw ChannelClosedException if
        // the parent channel's writer signals complete.
        Coordinates coordinates = await reader.ReadAsync();
        Console.WriteLine(coordinates);
    }
}

```

 Note

This code will throw an exception if the channel is closed.

An alternative consumer could avoid this concern by using a nested while loop, as shown in the following code:

C#

```
static async ValueTask ConsumeWithNestedWhileAsync(
    ChannelReader<Coordinates> reader)
{
    while (await reader.WaitToReadAsync())
    {
        while (reader.TryRead(out Coordinates coordinates))
        {
            Console.WriteLine(coordinates);
        }
    }
}
```

In the preceding code, the consumer waits to read data. Once the data is available, the consumer tries to read it. These loops continue to evaluate until the producer of the channel signals that it no longer has data to be read. With that said, when a producer is known to have a finite number of items it produces and it signals completion, the consumer can use `await foreach` semantics to iterate over the items:

C#

```
static async ValueTask ConsumeWithAwaitForeachAsync(
    ChannelReader<Coordinates> reader)
{
    await foreach (Coordinates coordinates in reader.ReadAllAsync())
    {
        Console.WriteLine(coordinates);
    }
}
```

The preceding code uses the `ReadAllAsync` method to read all of the coordinates from the channel.

System.MidpointRounding enum

Article • 01/08/2024

This article provides supplementary remarks to the reference documentation for this API.

Use the [MidpointRounding](#) enumeration with appropriate overloads of [Math.Round](#), [MathF.Round](#), and [Decimal.Round](#) to provide more control of the rounding process.

There are two overall rounding strategies—*round to nearest* and *directed rounding*—and each enumeration field participates in exactly one of these strategies.

Round to nearest

Fields:

- [AwayFromZero](#)
- [ToEven](#)

A round-to-nearest operation takes an original number with an implicit or specified precision; examines the next digit, which is at that precision plus one; and returns the nearest number with the same precision as the original number. For positive numbers, if the next digit is from 0 through 4, the nearest number is toward negative infinity. If the next digit is from 6 through 9, the nearest number is toward positive infinity. For negative numbers, if the next digit is from 0 through 4, the nearest number is toward positive infinity. If the next digit is from 6 through 9, the nearest number is toward negative infinity.

If the next digit is from 0 through 4 or 6 through 9, the [MidpointRounding.AwayFromZero](#) and [MidpointRounding.ToEven](#) do not affect the result of the rounding operation.

However, if the next digit is 5, which is the midpoint between two possible results, and all remaining digits are zero or there are no remaining digits, the nearest number is ambiguous. In this case, the round-to-nearest modes in [MidpointRounding](#) enable you to specify whether the rounding operation returns the nearest number away from zero or the nearest even number.

The following table demonstrates the results of rounding some negative and positive numbers in conjunction with round-to-nearest modes. The precision used to round the numbers is zero, which means the number after the decimal point affects the rounding operation. For example, for the number -2.5, the digit after the decimal point is 5. Because that digit is the midpoint, you can use a [MidpointRounding](#) value to determine

the result of rounding. If `AwayFromZero` is specified, -3 is returned because it is the nearest number away from zero with a precision of zero. If `ToEven` is specified, -2 is returned because it is the nearest even number with a precision of zero.

[+] Expand table

| Original number | AwayFromZero | ToEven |
|-----------------|--------------|--------|
| 3.5 | 4 | 4 |
| 2.8 | 3 | 3 |
| 2.5 | 3 | 2 |
| 2.1 | 2 | 2 |
| -2.1 | -2 | -2 |
| -2.5 | -3 | -2 |
| -2.8 | -3 | -3 |
| -3.5 | -4 | -4 |

Directed rounding

Fields:

- `ToNegativeInfinity`
- `ToPositiveInfinity`
- `ToZero`

A directed-rounding operation takes an original number with an implicit or specified precision and returns the next closest number in a specific direction with the same precision as the original number. Directed modes on `MidpointRounding` control toward which predefined number the rounding is performed.

The following table demonstrates the results of rounding some negative and positive numbers in conjunction with directed-rounding modes. The precision used to round the numbers is zero, which means the number before the decimal point is affected by the rounding operation.

[+] Expand table

| Original number | ToNegativeInfinity | ToPositiveInfinity | ToZero |
|-----------------|--------------------|--------------------|--------|
| 3.5 | 3 | 4 | 3 |
| 2.8 | 2 | 3 | 2 |
| 2.5 | 2 | 3 | 2 |
| 2.1 | 2 | 3 | 2 |
| -2.1 | -3 | -2 | -2 |
| -2.5 | -3 | -2 | -2 |
| -2.8 | -3 | -2 | -2 |
| -3.5 | -4 | -3 | -3 |

The Microsoft.Win32.Registry class

Article • 01/04/2024

This article provides supplementary remarks to the reference documentation for this API.

The [Registry](#) class provides the set of standard root keys found in the registry on machines running Windows. The registry is a storage facility for information about applications, users, and default system settings. Applications can use the registry for storing information that needs to be preserved after the application is closed, and access that same information when the application is reloaded. For example, you can store color preferences, screen locations, or the size of a window. You can control this data for each user by storing the information in a different location in the registry.

The base, or root, [RegistryKey](#) instances that are exposed by the [Registry](#) class delineate the basic storage mechanism for subkeys and values in the registry. All keys are read-only because the registry depends on their existence. The keys exposed by [Registry](#) are:

[+] Expand table

| Key | Description |
|---------------------------------|--|
| CurrentUser | Stores information about user preferences. |
| LocalMachine | Stores configuration information for the local machine. |
| ClassesRoot | Stores information about types (and classes) and their properties. |
| Users | Stores information about the default user configuration. |
| PerformanceData | Stores performance information for software components. |
| CurrentConfig | Stores non-user-specific hardware information. |
| DynData | Stores dynamic data. |

Once you've identified the root key under which you want to store/retrieve information from the registry, you can use the [RegistryKey](#) class to add or remove subkeys and manipulate the values for a given key.

Hardware devices can place information in the registry automatically using the Plug and Play interface. Software for installing device drivers can place information in the registry by writing to standard APIs.

Static methods for getting and setting values

The [Registry](#) class also contains `static GetValue` and `SetValue` methods for setting and retrieving values from registry keys. These methods open and close registry keys each time they're used. So when you access a large number of values, they don't perform as well as analogous methods in the [RegistryKey](#) class.

The [RegistryKey](#) class also provides methods that allow you to:

- Set Windows access control security for registry keys.
- Test the data type of a value before retrieving it.
- Delete keys.

System.Uri class

Article • 01/08/2024

This article provides supplementary remarks to the reference documentation for this API.

A URI is a compact representation of a resource available to your application on the intranet or internet. The [Uri](#) class defines the properties and methods for handling URIs, including parsing, comparing, and combining. The [Uri](#) class properties are read-only; to create a modifiable object, use the [UriBuilder](#) class.

Relative URLs (for example, "/new/index.htm") must be expanded with respect to a base URI so that they are absolute. The [MakeRelativeUri](#) method is provided to convert absolute URLs to relative URLs when necessary.

The [Uri](#) constructors do not escape URI strings if the string is a well-formed URI including a scheme identifier.

The [Uri](#) properties return a canonical data representation in escaped encoding, with all characters with Unicode values greater than 127 replaced with their hexadecimal equivalents. To put the URI in canonical form, the [Uri](#) constructor performs the following steps:

- Converts the URI scheme to lowercase.
- Converts the host name to lowercase.
- If the host name is an IPv6 address, the canonical IPv6 address is used. Scopeld and other optional IPv6 data are removed.
- Removes default and empty port numbers.
- Converts implicit file paths without the file:// scheme (for example, "C:\my\file") to explicit file paths with the file:// scheme.
- Escaped characters (also known as percent-encoded octets) that don't have a reserved purpose are decoded (also known as being unescaped). These unreserved characters include uppercase and lowercase letters (%41-%5A and %61-%7A), decimal digits (%30-%39), hyphen (%2D), period (%2E), underscore (%5F), and tilde (%7E).
- Canonicalizes the path for hierarchical URIs by compacting sequences such as ./, ../, and // (whether or not the sequence is escaped). Note that there are some schemes for which these sequences are not compacted.

- For hierarchical URIs, if the host is not terminated with a forward slash (/), one is added.
- By default, any reserved characters in the URI are escaped in accordance with RFC 2396. This behavior changes if International Resource Identifiers or International Domain Name parsing is enabled in which case reserved characters in the URI are escaped in accordance with RFC 3986 and RFC 3987.

As part of canonicalization in the constructor for some schemes, dot-segments and empty segments (./., /.../, and //) are compacted (in other words, they are removed). The schemes for which [Uri](#) compacts segments include http, https, tcp, net.pipe, and net.tcp. For some other schemes, these sequences are not compacted. The following code snippet shows how compacting looks in practice. The escaped sequences are unescaped, if necessary, and then compacted.

C#

```
var uri = new Uri("http://myUrl/../../"); // http scheme, unescaped
OR
var uri = new Uri("http://myUrl/%2E%2E/%2E%2E"); // http scheme, escaped
OR
var uri = new Uri("ftp://myUrl/../../"); // ftp scheme, unescaped
OR
var uri = new Uri("ftp://myUrl/%2E%2E/%2E%2E"); // ftp scheme, escaped

Console.WriteLine($"AbsoluteUri: {uri.AbsoluteUri}");
Console.WriteLine($"PathAndQuery: {uri.PathAndQuery}");
```

When this code executes, it returns output similar to the following text.

Output

```
AbsoluteUri: http://myurl/
PathAndQuery: /
```

You can transform the contents of the [Uri](#) class from an escape encoded URI reference to a readable URI reference by using the [ToString](#) method. Note that some reserved characters might still be escaped in the output of the [ToString](#) method. This is to support unambiguous reconstruction of a URI from the value returned by [ToString](#).

Some URIs include a fragment identifier or a query or both. A fragment identifier is any text that follows a number sign (#), not including the number sign; the fragment text is stored in the [Fragment](#) property. Query information is any text that follows a question mark (?) in the URI; the query text is stored in the [Query](#) property.

Note

The `URI` class supports the use of IP addresses in both quad-notation for IPv4 protocol and colon-hexadecimal for IPv6 protocol. Remember to enclose the IPv6 address in square brackets, as in `http://[::1]`.

International resource identifier support

Web addresses are typically expressed using uniform resource identifiers that consist of a very restricted set of characters:

- Upper and lower case ASCII letters from the English alphabet.
- Digits from 0 to 9.
- A small number of other ASCII symbols.

The specifications for URIs are documented in RFC 2396, RFC 2732, RFC 3986, and RFC 3987 published by the Internet Engineering Task Force (IETF).

With the growth of the Internet, there is a growing need to identify resources using languages other than English. Identifiers which facilitate this need and allow non-ASCII characters (characters in the Unicode/ISO 10646 character set) are known as International Resource Identifiers (IRIs). The specifications for IRIs are documented in RFC 3987 published by IETF. Using IRIs allows a URL to contain Unicode characters.

The existing `Uri` class was extended in .NET Framework v3.5, 3.0 SP1, and 2.0 SP1 to provide IRI support based on RFC 3987. Users of .NET Framework versions before version 4.5 will not see any change from .NET Framework 2.0 behavior unless they specifically enable IRI. This ensures application compatibility with prior versions of .NET Framework.

In .NET Framework 4.5 and later versions, IRI is always enabled and can't be changed using a configuration option. To enable support for IRI in .NET Framework versions prior to .NET Framework 4.5, set a configuration option in the `machine.config` or in the `app.config` file. Specify whether you want Internationalized Domain Name (IDN) parsing applied to the domain name and whether IRI parsing rules should be applied. For example:

XML

```
<configuration>
  <uri>
    <idn enabled="All" />
    <iriParsing enabled="true" />
```

```
</uri>  
</configuration>
```

Enabling IDN converts all Unicode labels in a domain name to their Punycode equivalents. Punycode names contain only ASCII characters and always start with the xn- prefix. The reason for this is to support existing DNS servers on the Internet, since most DNS servers only support ASCII characters (see RFC 3940).

Enabling IRI and IDN affects the value of the [Uri.DnsSafeHost](#) property. Enabling IRI and IDN can also change the behavior of the [Equals](#), [OriginalString](#), [GetComponents](#), and [IsWellFormedOriginalString](#) methods.

There are three possible values for IDN depending on the DNS servers that are used:

- idn enabled = All

This value will convert any Unicode domain names to their Punycode equivalents (IDN names).

- idn enabled = AllExceptIntranet

This value will convert all Unicode domain names not on the local Intranet to use the Punycode equivalents (IDN names). In this case to handle international names on the local Intranet, the DNS servers that are used for the Intranet should support Unicode name resolution.

- idn enabled = None

This value will not convert any Unicode domain names to use Punycode. This is the default value that's consistent with .NET Framework 2.0 behavior.

When IRI parsing is enabled (`iriParsing enabled = true`), normalization and character checking are done according to the latest IRI rules in RFC 3986 and RFC 3987. When IRI parsing is disabled, normalization and character checking are performed according to RFC 2396 and RFC 2732 (for IPv6 literals). In versions of .NET Framework before version 4.5, the default value is `false`. In .NET Framework 4.5+, .NET Core, and .NET 5+, the default value is `true`, and the enabled state of IRI parsing cannot be modified by settings in a `.config` file.

IRI and IDN processing in the [Uri](#) class can also be controlled using the [System.Configuration.IriParsingElement](#), [System.Configuration.IdnElement](#), and [System.Configuration.UriSection](#) configuration setting classes. The [System.Configuration.IriParsingElement](#) setting enables or disables IRI processing in the [Uri](#) class. The [System.Configuration.IdnElement](#) setting enables or disables IDN

processing in the [Uri](#) class. The [System.Configuration.IriParsingElement](#) setting also indirectly controls IDN. IRI processing must be enabled for IDN processing to be possible. If IRI processing is disabled, then IDN processing will be set to the default setting where .NET Framework 2.0 behavior is used for compatibility and IDN names are not used.

The configuration setting for the [System.Configuration.IriParsingElement](#) and [System.Configuration.IdnElement](#) are read once when the first [System.Uri](#) class is constructed. Changes to configuration settings after that time are ignored.

The [System.GenericUriParser](#) class has also been extended to allow creating a customizable parser that supports IRI and IDN. The behavior of a [System.GenericUriParser](#) object is specified by passing a bitwise combination of the values available in the [System.GenericUriParserOptions](#) enumeration to the [System.GenericUriParser](#) constructor. The [GenericUriParserOptions.IriParsing](#) type indicates the parser supports the parsing rules specified in RFC 3987 for International Resource Identifiers (IRI). Whether IRI is used is dictated by the configuration values previously discussed.

The [GenericUriParserOptions.Idn](#) type indicates that the parser supports Internationalized Domain Name (IDN) parsing of host names. In .NET 5 and later versions (including .NET Core) and .NET Framework 4.5+, IDN is always used. In previous versions, a configuration option determines whether IDN is used.

Implicit file path support

[Uri](#) can also be used to represent local file system paths. These paths can be represented *explicitly* in URIs that begin with the file:// scheme, and *implicitly* in URIs that do not have the file:// scheme. As a concrete example, the following two URIs are both valid, and represent the same file path:

C#

```
Uri uri1 = new Uri("C:/test/path/file.txt") // Implicit file path.  
Uri uri2 = new Uri("file:///C:/test/path/file.txt") // Explicit file path.
```

These implicit file paths are not compliant with the URI specification and so should be avoided when possible. When using .NET Core on Unix-based systems, implicit file paths can be especially problematic, because an absolute implicit file path is *indistinguishable* from a relative path. When such ambiguity is present, [Uri](#) default to interpreting the path as an absolute URI.

Security considerations

Because of security concerns, your application should use caution when accepting `Uri` instances from untrusted sources and with `dontEscape` set to `true` in the [constructor](#).

You can check a URL string for validity by calling the [IsWellFormedOriginalString](#) method.

When dealing with untrusted user input, confirm assumptions about the newly created `Uri` instance before trusting its properties. This can be done in the following way:

C#

```
string userInput = ...;

Uri baseUri = new Uri("https://myWebsite/files/");

if (!Uri.TryCreate(baseUri, userInput, out Uri newUri))
{
    // Fail: invalid input.
}

if (!baseUri.IsBaseOf(newUri))
{
    // Fail: the Uri base has been modified - the created Uri is not rooted
    // in the original directory.
}
```

This validation can be used in other cases, like when dealing with UNC paths, by simply changing the `baseUri`:

C#

```
Uri baseUri = new Uri(@"\\host\share\some\directory\name\");
```

Performance considerations

If you use a `Web.config` file that contains URLs to initialize your application, additional time is required to process the URLs if their scheme identifiers are nonstandard. In such a case, initialize the affected parts of your application when the URLs are needed, not at start time.

System.Type class

Article • 01/08/2024

This article provides supplementary remarks to the reference documentation for this API.

The [Type](#) class is the root of the [System.Reflection](#) functionality and is the primary way to access metadata. Use the members of [Type](#) to get information about a type declaration, about the members of a type (such as the constructors, methods, fields, properties, and events of a class), as well as the module and the assembly in which the class is deployed.

No permissions are required for code to use reflection to get information about types and their members, regardless of their access levels. No permissions are required for code to use reflection to access public members, or other members whose access levels would make them visible during normal compilation. However, in order for your code to use reflection to access members that would normally be inaccessible, such as private or internal methods, or protected fields of a type your class does not inherit, your code must have [ReflectionPermission](#). See [Security Considerations for Reflection](#).

`Type` is an abstract base class that allows multiple implementations. The system will always provide the derived class `RuntimeType`. In reflection, all classes beginning with the word Runtime are created only once per object in the system and support comparison operations.

ⓘ Note

In multithreading scenarios, do not lock `Type` objects in order to synchronize access to `static` data. Other code, over which you have no control, might also lock your class type. This might result in a deadlock. Instead, synchronize access to static data by locking a private `static` object.

ⓘ Note

A derived class can access protected members of the calling code's base classes. Also, access is allowed to assembly members of the calling code's assembly. As a rule, if you are allowed access in early-bound code, then you are also allowed access in late-bound code.

ⓘ Note

Interfaces that extend other interfaces do not inherit the methods defined in the extended interfaces.

What types does a Type object represent?

This class is thread safe; multiple threads can concurrently read from an instance of this type. An instance of the [Type](#) class can represent any of the following types:

- Classes
- Value types
- Arrays
- Interfaces
- Enumerations
- Delegates
- Constructed generic types and generic type definitions
- Type arguments and type parameters of constructed generic types, generic type definitions, and generic method definitions

Retrieve a Type object

The [Type](#) object associated with a particular type can be obtained in the following ways:

- The instance [Object.GetType](#) method returns a [Type](#) object that represents the type of an instance. Because all managed types derive from [Object](#), the [GetType](#) method can be called on an instance of any type.

The following example calls the [Object.GetType](#) method to determine the runtime type of each object in an object array.

C#

```
object[] values = { "word", true, 120, 136.34, 'a' };
foreach (var value in values)
    Console.WriteLine("{0} - type {1}", value,
                      value.GetType().Name);

// The example displays the following output:
//      word - type String
//      True - type Boolean
//      120 - type Int32
```

```
//      136.34 - type Double  
//      a - type Char
```

- The static [Type.GetType](#) methods return a [Type](#) object that represents a type specified by its fully qualified name.
- The [Module.GetTypes](#), [Module.GetType](#), and [Module.FindTypes](#) methods return [Type](#) objects that represent the types defined in a module. The first method can be used to obtain an array of [Type](#) objects for all the public and private types defined in a module. (You can obtain an instance of [Module](#) through the [Assembly.GetModule](#) or [Assembly.GetModules](#) method, or through the [Type.Module](#) property.)
- The [System.Reflection.Assembly](#) object contains a number of methods to retrieve the classes defined in an assembly, including [Assembly.GetType](#), [Assembly.GetTypes](#), and [Assembly.GetExportedTypes](#).
- The [FindInterfaces](#) method returns a filtered list of interface types supported by a type.
- The [GetElementType](#) method returns a [Type](#) object that represents the element.
- The [GetInterfaces](#) and [GetInterface](#) methods return [Type](#) objects representing the interface types supported by a type.
- The [GetTypeArray](#) method returns an array of [Type](#) objects representing the types specified by an arbitrary set of objects. The objects are specified with an array of type [Object](#).
- The [GetTypeFromProgID](#) and [GetTypeFromCLSID](#) methods are provided for COM interoperability. They return a [Type](#) object that represents the type specified by a [ProgID](#) or [CLSID](#).
- The [GetTypeFromHandle](#) method is provided for interoperability. It returns a [Type](#) object that represents the type specified by a class handle.
- The C# [typeof](#) operator, the C++ [typeid](#) operator, and the Visual Basic [GetType](#) operator obtain the [Type](#) object for a type.
- The [MakeGenericType](#) method returns a [Type](#) object representing a constructed generic type, which is an open constructed type if its [ContainsGenericParameters](#) property returns [true](#), and a closed constructed type otherwise. A generic type can be instantiated only if it is closed.

- The [MakeArrayType](#), [MakePointerType](#), and [MakeByRefType](#) methods return [Type](#) objects that represent, respectively, an array of a specified type, a pointer to a specified type, and the type of a reference parameter (`ref` in C#, 'byref' in F#, `ByRef` in Visual Basic).

Compare type objects for equality

A [Type](#) object that represents a type is unique; that is, two [Type](#) object references refer to the same object if and only if they represent the same type. This allows for comparison of [Type](#) objects using reference equality. The following example compares the [Type](#) objects that represent a number of integer values to determine whether they are of the same type.

C#

```
long number1 = 1635429;
int number2 = 16203;
double number3 = 1639.41;
long number4 = 193685412;

// Get the type of number1.
Type t = number1.GetType();

// Compare types of all objects with number1.
Console.WriteLine("Type of number1 and number2 are equal: {0}",
                  Object.ReferenceEquals(t, number2.GetType()));
Console.WriteLine("Type of number1 and number3 are equal: {0}",
                  Object.ReferenceEquals(t, number3.GetType()));
Console.WriteLine("Type of number1 and number4 are equal: {0}",
                  Object.ReferenceEquals(t, number4.GetType()));

// The example displays the following output:
//      Type of number1 and number2 are equal: False
//      Type of number1 and number3 are equal: False
//      Type of number1 and number4 are equal: True
```

System.Drawing.Drawing2D.Matrix class

Article • 01/08/2024

This article provides supplementary remarks to the reference documentation for this API.

The [Matrix](#) class encapsulates a 3-by-3 affine matrix that represents a geometric transform.

In GDI+, you can store an affine transformation in a [Matrix](#) object. Because the third column of a matrix that represents an affine transformation is always (0, 0, 1), you specify only the six numbers in the first two columns when you construct a [Matrix](#) object. The statement `Matrix myMatrix = new Matrix(0, 1, -1, 0, 3, 4)` constructs the matrix shown in the following figure.

The diagram shows a 3x3 matrix with dashed lines indicating its structure. The top-left 2x2 block is labeled 'Linear part' with an arrow. The bottom-right 2x2 block is labeled 'Translation part' with an arrow. The matrix elements are:

$$\begin{bmatrix} 0 & 1 & 0 \\ -1 & 0 & 0 \\ 3 & 4 & 1 \end{bmatrix}$$

ⓘ Note

In .NET 6 and later versions, the [System.Drawing.Common package](#), which includes this type, is only supported on Windows operating systems. Use of this type in cross-platform apps causes compile-time warnings and run-time exceptions. For more information, see [System.Drawing.Common only supported on Windows](#).

Composite transformations

A composite transformation is a sequence of transformations, one followed by the other. Consider the matrices and transformations in the following list:

expand Expand table

| Matrix | Transformation |
|----------|-------------------|
| Matrix A | Rotate 90 degrees |

| Matrix | Transformation |
|----------|---|
| Matrix B | Scale by a factor of 2 in the x direction |
| Matrix C | Translate 3 units in the y direction |

If you start with the point (2, 1) - represented by the matrix [2 1 1] - and multiply by A, then B, then C, the point (2, 1) will undergo the three transformations in the order listed.

$$[2 \ 1 \ 1]ABC = [-2 \ 5 \ 1]$$

Rather than store the three parts of the composite transformation in three separate matrices, you can multiply A, B, and C together to get a single 3×3 matrix that stores the entire composite transformation. Suppose $ABC = D$. Then a point multiplied by D gives the same result as a point multiplied by A, then B, then C.

$$[2 \ 1 \ 1]D = [-2 \ 5 \ 1]$$

The following illustration shows the matrices A, B, C, and D.

$$\begin{bmatrix} 0 & 1 & 0 \\ -1 & 0 & 0 \\ 0 & 0 & 1 \end{bmatrix} \begin{bmatrix} 2 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & 1 \end{bmatrix} \begin{bmatrix} 1 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 3 & 1 \end{bmatrix} = \begin{bmatrix} 0 & 1 & 0 \\ -2 & 0 & 0 \\ 0 & 3 & 1 \end{bmatrix}$$

A B C = D

The fact that the matrix of a composite transformation can be formed by multiplying the individual transformation matrices means that any sequence of affine transformations can be stored in a single [Matrix](#) object.

⊗ Caution

The order of a composite transformation is important. In general, rotate, then scale, then translate is not the same as scale, then rotate, then translate. Similarly, the order of matrix multiplication is important. In general, ABC is not the same as BAC.

The [Matrix](#) class provides several methods for building a composite transformation: [Multiply](#), [Rotate](#), [RotateAt](#), [Scale](#), [Shear](#), and [Translate](#). The following example creates the matrix of a composite transformation that first rotates 30 degrees, then scales by a factor of 2 in the y direction, and then translates 5 units in the x direction:

C#

```
Matrix myMatrix = new Matrix();
myMatrix.Rotate(30);
```

```
myMatrix.Scale(1, 2, MatrixOrder.Append);  
myMatrix.Translate(5, 0, MatrixOrder.Append);
```

System.Runtime.CompilerServices.InternalVisibleToAttribute class

Article • 01/08/2024

This article provides supplementary remarks to the reference documentation for this API.

The [InternalsVisibleToAttribute](#) attribute specifies that types that are ordinarily visible only within the current assembly are visible to a specified assembly.

Ordinarily, types and members with [internal scope in C#](#) or [Friend scope in Visual Basic](#) are visible only in the assembly in which they are defined. Types and members with [protected internal](#) scope ([Protected Friend](#) scope in Visual Basic) are visible only in their own assembly or to types that derive from their containing class. Types and members with [private protected](#) scope ([Private Protected](#) scope in Visual Basic) are visible in the containing class or in types that derive from their containing class within the current assembly.

The [InternalsVisibleToAttribute](#) attribute makes these types and members also visible to the types in a specified assembly, which is known as a friend assembly. This applies only to [internal](#) ([Friend](#) in Visual Basic), [protected internal](#) ([Protected Friend](#) in Visual Basic), and [private protected](#) ([Private Protected](#) in Visual Basic) members, but not [private](#) ones.

ⓘ Note

In the case of [private protected](#) ([Private Protected](#) in Visual Basic) members, the [InternalsVisibleToAttribute](#) attribute extends accessibility only to types that derive from the *containing class* of the member.

The attribute is applied at the assembly level. This means that it can be included at the beginning of a source code file, or it can be included in the AssemblyInfo file in a Visual Studio project. You can use the attribute to specify a single friend assembly that can access the internal types and members of the current assembly. You can define multiple friend assemblies in two ways. They can appear as individual assembly-level attributes, as the following example illustrates.

C#

```
[assembly:InternalsVisibleTo("Friend1a")]
[assembly:InternalsVisibleTo("Friend1b")]
```

They can also appear with separate [InternalsVisibleToAttribute](#) tags but a single `assembly` keyword, as the following example illustrates.

C#

```
[assembly:InternalsVisibleTo("Friend2a"),
    InternalsVisibleTo("Friend2b")]
```

The friend assembly is identified by the [InternalsVisibleToAttribute](#) constructor. Both the current assembly and the friend assembly must be unsigned, or both assemblies must be signed with a strong name.

If both assemblies are unsigned, the `assemblyName` argument consists of the name of the friend assembly, specified without a directory path or file name extension.

If both assemblies are signed with a strong name, the argument to the [InternalsVisibleToAttribute](#) constructor must consist of the name of the assembly without its directory path or file name extension, along with the full public key (and not its public key token). To get the full public key of a strong-named assembly, see the [Get the full public key](#) section later in this article. For more information about using [InternalsVisibleToAttribute](#) with strong-named assemblies, see the [InternalsVisibleToAttribute](#) constructor.

Do not include values for the [CultureInfo](#), [Version](#), or [ProcessorArchitecture](#) field in the argument; the Visual Basic, C#, and C++ compilers treat this as a compiler error. If you use a compiler that does not treat it as an error (such as the [IL Assembler \(ILAsm.exe\)](#)) and the assemblies are strong-named, a [MethodAccessException](#) exception is thrown the first time the specified friend assembly accesses the assembly that contains the [InternalsVisibleToAttribute](#) attribute.

For more information about how to use this attribute, see [Friend assemblies](#) and [C++ friend assemblies](#).

Get the full public key

You can use the [Strong Name Tool \(Sn.exe\)](#) to retrieve the full public key from a strong-named key (.snk) file. To do this, you perform the following steps:

1. Extract the public key from the strong-named key file to a separate file:

```
Sn -p <snk_file> <outfile>
```

2. Display the full public key to the console:

```
Sn -tp <outfile>
```

3. Copy and paste the full public key value into your source code.

Compile the friend assembly with C#

If you use the C# compiler to compile the friend assembly, you must explicitly specify the name of the output file (.exe or .dll) by using the **/out** compiler option. This is required because the compiler has not yet generated the name for the assembly it is building at the time it is binding to external references. The **/out** compiler option is optional for the Visual Basic compiler, and the corresponding **-out** or **-o** compiler option should not be used when compiling friend assemblies with the F# compiler.

Compile the friend assembly with C++

In C++, in order to make the internal members enabled by the [InternalsVisibleToAttribute](#) attribute accessible to a friend assembly, you must use the `as_friend` attribute in the C++ directive. For more information, see [Friend Assemblies \(C++\)](#).

System.Runtime.Versioning.ComponentGuaranteesAttribute class

Article • 01/08/2024

This article provides supplementary remarks to the reference documentation for this API.

The [ComponentGuaranteesAttribute](#) is used by developers of components and class libraries to indicate the level of compatibility that consumers of their libraries can expect across multiple versions. It indicates the level of guarantee that a future version of the library or component will not break an existing client. Clients can then use the [ComponentGuaranteesAttribute](#) as an aid in designing their own interfaces to ensure stability across versions.

ⓘ Note

The common language runtime (CLR) does not use this attribute in any way. Its value lies in formally documenting the intent of the component author. Compile-time tools can also use these declarations to detect compile-time errors that would otherwise break the declared guarantee.

Levels of compatibility

The [ComponentGuaranteesAttribute](#) supports the following levels of compatibility, which are represented by members of the [ComponentGuaranteesOptions](#) enumeration:

- No version-to-version compatibility ([ComponentGuaranteesOptions.None](#)). The client can expect that future versions will break the existing client. For more information, see the [No compatibility](#) section later in this article.
- Side-by-side version-to-version compatibility ([ComponentGuaranteesOptions.SideBySide](#)). The component has been tested to work when more than one version of the assembly is loaded in the same application domain. In general, future versions can break compatibility. However, when breaking changes are made, the old version is not modified but exists alongside the new version. Side-by-side execution is the expected way to make existing clients work when breaking changes are made. For more information, see the [Side-by-side compatibility](#) section later in this article.

- Stable version-to-version compatibility ([ComponentGuaranteesOptions.Stable](#)). Future versions should not break the client, and side-by-side execution should not be needed. However, if the client is inadvertently broken, it may be possible to use side-by-side execution to fix the problem. For more information, see the [Stable compatibility](#) section.
- Exchange version-to-version compatibility ([ComponentGuaranteesOptions.Exchange](#)). Extraordinary care is taken to ensure that future versions will not break the client. The client should use only these types in the signature of interfaces that are used for communication with other assemblies that are deployed independently of one another. Only one version of these types is expected to be in a given application domain, which means that if a client breaks, side-by-side execution cannot fix the compatibility problem. For more information, see the [Exchange type compatibility](#) section.

The following sections discuss each level of guarantee in greater detail.

No compatibility

Marking a component as [ComponentGuaranteesOptions.None](#) indicates that the provider makes no guarantees about compatibility. Clients should avoid taking any dependencies on the exposed interfaces. This level of compatibility is useful for types that are experimental or that are publicly exposed but are intended only for components that are always updated at the same time. [None](#) explicitly indicates that this component should not be used by external components.

Side-by-side compatibility

Marking a component as [ComponentGuaranteesOptions.SideBySide](#) indicates that the component has been tested to work when more than one version of the assembly is loaded into the same application domain. Breaking changes are allowed as long as they are made to the assembly that has the greater version number. Components that are bound to an old version of the assembly are expected to continue to bind to the old version, and other components can bind to the new version. It is also possible to update a component that is declared to be [SideBySide](#) by destructively modifying the old version.

Stable compatibility

Marking a type as [ComponentGuaranteesOptions.Stable](#) indicates that the type should remain stable across versions. However, it may also be possible for side-by-side versions

of a stable type to exist in the same application domain.

Stable types maintain a high binary compatibility bar. Because of this, providers should avoid making breaking changes to stable types. The following kinds of changes are acceptable:

- Adding private instance fields to, or removing fields from, a type, as long as this does not break the serialization format.
- Changing a non-serializable type to a serializable type. (However, a serializable type cannot be changed to a non-serializable type.)
- Throwing new, more derived exceptions from a method.
- Improving the performance of a method.
- Changing the range of return values, as long as the change does not adversely affect the majority of clients.
- Fixing serious bugs, if the business justification is high and the number of adversely affected clients is low.

Because new versions of stable components are not expected to break existing clients, generally only one version of a stable component is needed in an application domain. However, this is not a requirement, because stable types are not used as well-known exchange types that all components agree upon. Therefore, if a new version of a stable component does inadvertently break some component, and if other components need the new version, it may be possible to fix the problem by loading both the old and new component.

[Stable](#) provides a stronger version compatibility guarantee than [None](#). It is a common default for multi-version components.

[Stable](#) can be combined with [SideBySide](#), which states that the component will not break compatibility but is tested to work when more than one version is loaded in a given application domain.

After a type or method is marked as [Stable](#), it can be upgraded to [Exchange](#). However, it cannot be downgraded to [None](#).

Exchange type compatibility

Marking a type as [ComponentGuaranteesOptions.Exchange](#) provides a stronger version compatibility guarantee than [Stable](#), and should be applied to the most stable of all types. These types are intended to be used for interchange between independently built components across all component boundaries in both time (any version of the CLR or any version of a component or application) and space (cross-process, cross-CLR in one

process, cross-application domain in one CLR). If a breaking change is made to an exchange type, it is impossible to fix the issue by loading multiple versions of the type.

Exchange types should be changed only when a problem is very serious (such as a severe security issue) or the probability of breakage is very low (that is, if the behavior was already broken in a random way that code could not have conceivably taken a dependency on). You can make the following kinds of changes to an exchange type:

- Add inheritance of new interface definitions.
- Add new private methods that implement the methods of newly inherited interface definitions.
- Add new static fields.
- Add new static methods.
- Add new non-virtual instance methods.

The following are considered breaking changes and are not allowed for primitive types:

- Changing serialization formats. Version-tolerant serialization is required.
- Adding or removing private instance fields. This risks changing the serialization format of the type and breaking client code that uses reflection.
- Changing the serializability of a type. A non-serializable type may not be made serializable, and vice versa.
- Throwing different exceptions from a method.
- Changing the range of a method's return values, unless the member definition raises this possibility and clearly indicates how clients should handle unknown values.
- Fixing most bugs. Consumers of the type will rely on the existing behavior.

After a component, type, or member is marked with the [Exchange](#) guarantee, it cannot be changed to either [Stable](#) or [None](#).

Typically, exchange types are the basic types (such as [Int32](#) and [String](#) in .NET) and interfaces (such as [IList<T>](#), [IEnumerable<T>](#), and [IComparable<T>](#)) that are commonly used in public interfaces.

Exchange types may publicly expose only other types that are also marked with [Exchange](#) compatibility. In addition, exchange types cannot depend on the behavior of

Windows APIs that are prone to change.

Component guarantees

The following table indicates how a component's characteristics and usage affect its compatibility guarantee.

[+] Expand table

| Component characteristics | Exchange | Stable | Side-by-Side | None |
|--|----------|--------|--------------|------|
| Can be used in interfaces between components that version independently. | Y | N | N | N |
| Can be used (privately) by an assembly that versions independently. | Y | Y | Y | N |
| Can have multiple versions in a single application domain. | N | Y | Y | Y |
| Can make breaking changes | N | N | Y | Y |
| Tested to make certain multiple versions of the assembly can be loaded together. | N | N | Y | N |
| Can make breaking changes in place. | N | N | N | Y |
| Can make very safe non-breaking servicing changes in place. | Y | Y | Y | Y |

Apply the attribute

You can apply the [ComponentGuaranteesAttribute](#) to an assembly, a type, or a type member. Its application is hierarchical. That is, by default, the guarantee defined by the [Guarantees](#) property of the attribute at the assembly level defines the guarantee of all types in the assembly and all members in those types. Similarly, if the guarantee is applied to the type, by default it also applies to each member of the type.

This inherited guarantee can be overridden by applying the [ComponentGuaranteesAttribute](#) to individual types and type members. However, guarantees that override the default can only weaken the guarantee; they cannot strengthen it. For example, if an assembly is marked with the [None](#) guarantee, its types and members have no compatibility guarantee, and any other guarantee that is applied to types or members in the assembly is ignored.

Test the guarantee

The [Guarantees](#) property returns a member of the [ComponentGuaranteesOptions](#) enumeration, which is marked with the [FlagsAttribute](#) attribute. This means that you should test for the flag that you are interested in by masking away potentially unknown flags. For example, the following example tests whether a type is marked as [Stable](#).

C#

```
// Test whether guarantee is Stable.  
if ((guarantee & ComponentGuaranteesOptions.Stable) ==  
ComponentGuaranteesOptions.Stable)  
    Console.WriteLine("{0} is marked as {1}.", typ.Name, guarantee);
```

The following example tests whether a type is marked as [Stable](#) or [Exchange](#).

C#

```
// Test whether guarantee is Stable or Exchange.  
if ((guarantee & (ComponentGuaranteesOptions.Stable |  
ComponentGuaranteesOptions.Exchange)) > 0)  
    Console.WriteLine("{0} is marked as Stable or Exchange.", typ.Name,  
guarantee);
```

The following example tests whether a type is marked as [None](#) (that is, neither [Stable](#) nor [Exchange](#)).

C#

```
// Test whether there is no guarantee (neither Stable nor Exchange).  
if ((guarantee & (ComponentGuaranteesOptions.Stable |  
ComponentGuaranteesOptions.Exchange)) == 0)  
    Console.WriteLine("{0} has no compatibility guarantee.", typ.Name,  
guarantee);
```

System.Runtime.Loader.AssemblyLoadContext class

Article • 01/08/2024

This article provides supplementary remarks to the reference documentation for this API.

The [AssemblyLoadContext](#) represents a load context. Conceptually, a load context creates a scope for loading, resolving, and potentially unloading a set of assemblies.

The [AssemblyLoadContext](#) exists primarily to provide assembly loading isolation. It allows multiple versions of the same assembly to be loaded within a single process. It replaces the isolation mechanisms provided by multiple [AppDomain](#) instances in .NET Framework.

ⓘ Note

- [AssemblyLoadContext](#) does not provide any security features. All code has full permissions of the process.
- In .NET Core 2.0 - 2.2 only, [AssemblyLoadContext](#) is an abstract class. To create a concrete class in these versions, implement the [AssemblyLoadContext.Load\(AssemblyName\)](#) method.

Usage in the runtime

The runtime implements two assembly load contexts:

- [AssemblyLoadContext.Default](#) represents the runtime's default context, which is used for the application main assembly and its static dependencies.
- The [Assembly.LoadFile\(String\)](#) method isolates the assemblies it loads by instantiating the most basic [AssemblyLoadContext](#). It has a simplistic isolation scheme that loads each assembly in its own [AssemblyLoadContext](#) with no dependency resolution.

Application usage

An application can create its own [AssemblyLoadContext](#) to create a custom solution for advanced scenarios. The customization focuses on defining dependency resolution

mechanisms.

The [AssemblyLoadContext](#) provides two extension points to implement managed assembly resolution:

1. The [AssemblyLoadContext.Load\(AssemblyName\)](#) method provides the first chance for the [AssemblyLoadContext](#) to resolve, load, and return the assembly. If the [AssemblyLoadContext.Load\(AssemblyName\)](#) method returns `null`, the loader tries to load the assembly into the [AssemblyLoadContext.Default](#).
2. If the [AssemblyLoadContext.Default](#) is unable to resolve the assembly, the original [AssemblyLoadContext](#) gets a second chance to resolve the assembly. The runtime raises the [Resolving](#) event.

Additionally, the [AssemblyLoadContext.LoadUnmanagedDll\(String\)](#) virtual method allows customization of the default unmanaged assembly resolution. The default implementation returns `null`, which causes the runtime search to use its default search policy. The default search policy is sufficient for most scenarios.

Technical challenges

- It's not possible to load multiple versions of the runtime in a single process.

✖ Caution

Loading multiple copies or different versions of framework assemblies can lead to unexpected and hard-to-diagnose behavior.

💡 Tip

Use process boundaries with remoting or interprocess communication to solve this isolation problem.

- The timing of assembly loading can make testing and debugging difficult. Assemblies are typically loaded without their dependencies immediately being resolved. The dependencies are loaded as they are needed:
 - When code branches into a dependent assembly.
 - When code loads resources.
 - When code explicitly loads assemblies.
- The implementation of [AssemblyLoadContext.Load\(AssemblyName\)](#) can add new dependencies that may need to be isolated to allow different versions to exist. The

most natural implementation would place these dependencies in the default context. Careful design can isolate the new dependencies.

- The same assembly is loaded multiple times into different contexts.
 - This can lead to confusing error messages, for example "Unable to cast object of type 'Sample.Plugin' to type 'Sample.Plugin'".
 - Marshaling across isolation boundaries is non-trivial. A typical solution is to use an interface defined in an assembly that's only loaded into the default load context.

Common Language Runtime (CLR) overview

Article • 04/25/2023

.NET provides a run-time environment called the common language runtime that runs the code and provides services that make the development process easier.

Compilers and tools expose the common language runtime's functionality and enable you to write code that benefits from the managed execution environment. Code that you develop with a language compiler that targets the runtime is called managed code. Managed code benefits from features such as cross-language integration, cross-language exception handling, enhanced security, versioning and deployment support, a simplified model for component interaction, and debugging and profiling services.

ⓘ Note

Compilers and tools can produce output that the common language runtime can consume because the type system, the format of metadata, and the run-time environment (the virtual execution system) are all defined by a public standard, the ECMA Common Language Infrastructure specification. For more information, see [ECMA C# and Common Language Infrastructure Specifications](#).

To enable the runtime to provide services to managed code, language compilers must emit metadata that describes the types, members, and references in your code. Metadata is stored with the code; every loadable common language runtime portable executable (PE) file contains metadata. The runtime uses metadata to locate and load classes, lay out instances in memory, resolve method invocations, generate native code, enforce security, and set run-time context boundaries.

The runtime automatically handles object layout and manages references to objects, releasing them when they're no longer being used. Objects whose lifetimes are managed in this way are called managed data. Garbage collection eliminates memory leaks and some other common programming errors. If your code is managed, you can use managed, unmanaged, or both managed and unmanaged data in your .NET application. Because language compilers supply their own types, such as primitive types, you might not always know or need to know whether your data is being managed.

The common language runtime makes it easy to design components and applications whose objects interact across languages. Objects written in different languages can communicate with each other, and their behaviors can be tightly integrated. For

example, you can define a class and then use a different language to derive a class from your original class or call a method on the original class. You can also pass an instance of a class to a method of a class written in a different language. This cross-language integration is possible because language compilers and tools that target the runtime use a common type system defined by the runtime. They follow the runtime's rules for defining new types and for creating, using, persisting, and binding to types.

As part of their metadata, all managed components carry information about the components and resources they were built against. The runtime uses this information to ensure that your component or application has the specified versions of everything it needs, which makes your code less likely to break because of some unmet dependency. Registration information and state data are no longer stored in the registry, where they can be difficult to establish and maintain. Instead, information about the types you define and their dependencies is stored with the code as metadata. This way, the task of component replication and removal is less complicated.

Language compilers and tools expose the runtime's functionality in ways that are intended to be useful and intuitive to developers. Some features of the runtime might be more noticeable in one environment than in another. How you experience the runtime depends on which language compilers or tools you use. For example, if you're a Visual Basic developer, you might notice that with the common language runtime, the Visual Basic language has more object-oriented features than before. The runtime provides the following benefits:

- Performance improvements.
- The ability to easily use components developed in other languages.
- Extensible types provided by a class library.
- Language features such as inheritance, interfaces, and overloading for object-oriented programming.
- Support for explicit free threading that allows creation of multithreaded and scalable applications.
- Support for structured exception handling.
- Support for custom attributes.
- Garbage collection.
- Use of delegates instead of function pointers for increased type safety and security. For more information about delegates, see [Common Type System](#).

CLR versions

.NET Core and .NET 5+ releases have a single product version, that is, there's no separate CLR version. For a list of .NET Core versions, see [Download .NET Core](#).

However, the .NET Framework version number doesn't necessarily correspond to the version number of the CLR it includes. For a list of .NET Framework versions and their corresponding CLR versions, see [.NET Framework versions and dependencies](#).

Managed Execution Process

Article • 09/15/2021

The managed execution process includes the following steps, which are discussed in detail later in this topic:

1. Choosing a compiler.

To obtain the benefits provided by the common language runtime, you must use one or more language compilers that target the runtime.

2. Compiling your code to MSIL.

Compiling translates your source code into Microsoft intermediate language (MSIL) and generates the required metadata.

3. Compiling MSIL to native code.

At execution time, a just-in-time (JIT) compiler translates the MSIL into native code.

During this compilation, code must pass a verification process that examines the MSIL and metadata to find out whether the code can be determined to be type safe.

4. Running code.

The common language runtime provides the infrastructure that enables execution to take place and services that can be used during execution.

Choosing a Compiler

To obtain the benefits provided by the common language runtime (CLR), you must use one or more language compilers that target the runtime, such as Visual Basic, C#, Visual C++, F#, or one of many third-party compilers such as an Eiffel, Perl, or COBOL compiler.

Because it is a multilanguage execution environment, the runtime supports a wide variety of data types and language features. The language compiler you use determines which runtime features are available, and you design your code using those features.

Your compiler, not the runtime, establishes the syntax your code must use. If your component must be completely usable by components written in other languages, your component's exported types must expose only language features that are included in the Common Language Specification (CLS). You can use the [CLSCompliantAttribute](#) attribute to ensure that your code is CLS-compliant. For more information, see [Language independence and language-independent components](#).

[Back to top](#)

Compiling to MSIL

When compiling to managed code, the compiler translates your source code into Microsoft intermediate language (MSIL), which is a CPU-independent set of instructions that can be efficiently converted to native code. MSIL includes instructions for loading, storing, initializing, and calling methods on objects, as well as instructions for arithmetic and logical operations, control flow, direct memory access, exception handling, and other operations. Before code can be run, MSIL must be converted to CPU-specific code, usually by a [just-in-time \(JIT\) compiler](#). Because the common language runtime supplies one or more JIT compilers for each computer architecture it supports, the same set of MSIL can be JIT-compiled and run on any supported architecture.

When a compiler produces MSIL, it also produces metadata. Metadata describes the types in your code, including the definition of each type, the signatures of each type's members, the members that your code references, and other data that the runtime uses at execution time. The MSIL and metadata are contained in a portable executable (PE) file that is based on and that extends the published Microsoft PE and common object file format (COFF) used historically for executable content. This file format, which accommodates MSIL or native code as well as metadata, enables the operating system to recognize common language runtime images. The presence of metadata in the file together with MSIL enables your code to describe itself, which means that there is no need for type libraries or Interface Definition Language (IDL). The runtime locates and extracts the metadata from the file as needed during execution.

[Back to top](#)

Compiling MSIL to Native Code

Before you can run Microsoft intermediate language (MSIL), it must be compiled against the common language runtime to native code for the target machine architecture. .NET provides two ways to perform this conversion:

- A .NET just-in-time (JIT) compiler.
- [Ngen.exe \(Native Image Generator\)](#).

Compilation by the JIT Compiler

JIT compilation converts MSIL to native code on demand at application run time, when the contents of an assembly are loaded and executed. Because the common language runtime supplies a JIT compiler for each supported CPU architecture, developers can build a set of MSIL assemblies that can be JIT-compiled and run on different computers with different machine architectures. However, if your managed code calls platform-specific native APIs or a platform-specific class library, it will run only on that operating system.

JIT compilation takes into account the possibility that some code might never be called during execution. Instead of using time and memory to convert all the MSIL in a PE file to native code, it converts the MSIL as needed during execution and stores the resulting native code in memory so that it is accessible for subsequent calls in the context of that process. The loader creates and attaches a stub to each method in a type when the type is loaded and initialized. When a method is called for the first time, the stub passes control to the JIT compiler, which converts the MSIL for that method into native code and modifies the stub to point directly to the generated native code. Therefore, subsequent calls to the JIT-compiled method go directly to the native code.

Install-Time Code Generation Using NGen.exe

Because the JIT compiler converts an assembly's MSIL to native code when individual methods defined in that assembly are called, it affects performance adversely at run time. In most cases, that diminished performance is acceptable. More importantly, the code generated by the JIT compiler is bound to the process that triggered the compilation. It cannot be shared across multiple processes. To allow the generated code to be shared across multiple invocations of an application or across multiple processes that share a set of assemblies, the common language runtime supports an ahead-of-time compilation mode. This ahead-of-time compilation mode uses the [Ngen.exe \(Native Image Generator\)](#) to convert MSIL assemblies to native code much like the JIT compiler does. However, the operation of Ngen.exe differs from that of the JIT compiler in three ways:

- It performs the conversion from MSIL to native code before running the application instead of while the application is running.
- It compiles an entire assembly at a time, instead of one method at a time.
- It persists the generated code in the Native Image Cache as a file on disk.

Code Verification

As part of its compilation to native code, the MSIL code must pass a verification process unless an administrator has established a security policy that allows the code to bypass verification. Verification examines MSIL and metadata to find out whether the code is type safe, which means that it accesses only the memory locations it is authorized to access. Type safety helps isolate objects from each other and helps protect them from inadvertent or malicious corruption. It also provides assurance that security restrictions on code can be reliably enforced.

The runtime relies on the fact that the following statements are true for code that is verifiably type safe:

- A reference to a type is strictly compatible with the type being referenced.
- Only appropriately defined operations are invoked on an object.
- Identities are what they claim to be.

During the verification process, MSIL code is examined in an attempt to confirm that the code can access memory locations and call methods only through properly defined types. For example, code cannot allow an object's fields to be accessed in a manner that allows memory locations to be overrun. Additionally, verification inspects code to determine whether the MSIL has been correctly generated, because incorrect MSIL can lead to a violation of the type safety rules. The verification process passes a well-defined set of type-safe code, and it passes only code that is type safe. However, some type-safe code might not pass verification because of some limitations of the verification process, and some languages, by design, do not produce verifiably type-safe code. If type-safe code is required by the security policy but the code does not pass verification, an exception is thrown when the code is run.

[Back to top](#)

Running Code

The common language runtime provides the infrastructure that enables managed execution to take place and services that can be used during execution. Before a method can be run, it must be compiled to processor-specific code. Each method for which MSIL has been generated is JIT-compiled when it is called for the first time, and then run. The next time the method is run, the existing JIT-compiled native code is run. The process of JIT-compiling and then running the code is repeated until execution is complete.

During execution, managed code receives services such as garbage collection, security, interoperability with unmanaged code, cross-language debugging support, and

enhanced deployment and versioning support.

In Microsoft Windows Vista, the operating system loader checks for managed modules by examining a bit in the COFF header. The bit being set denotes a managed module. If the loader detects managed modules, it loads mscoree.dll, and `_CorValidateImage` and `_CorImageUnloading` notify the loader when the managed module images are loaded and unloaded. `_CorValidateImage` performs the following actions:

1. Ensures that the code is valid managed code.
2. Changes the entry point in the image to an entry point in the runtime.

On 64-bit Windows, `_CorValidateImage` modifies the image that is in memory by transforming it from PE32 to PE32+ format.

Assemblies in .NET

Article • 03/15/2023

Assemblies are the fundamental units of deployment, version control, reuse, activation scoping, and security permissions for .NET-based applications. An assembly is a collection of types and resources that are built to work together and form a logical unit of functionality. Assemblies take the form of executable (.exe) or dynamic link library (.dll) files, and are the building blocks of .NET applications. They provide the common language runtime with the information it needs to be aware of type implementations.

In .NET and .NET Framework, you can build an assembly from one or more source code files. In .NET Framework, assemblies can contain one or more modules. This way, larger projects can be planned so that several developers can work on separate source code files or modules, which are combined to create a single assembly. For more information about modules, see [How to: Build a multifile assembly](#).

Assemblies have the following properties:

- Assemblies are implemented as *.exe* or *.dll* files.
- For libraries that target .NET Framework, you can share assemblies between applications by putting them in the [global assembly cache \(GAC\)](#). You must strong-name assemblies before you can include them in the GAC. For more information, see [Strong-named assemblies](#).
- Assemblies are only loaded into memory if they're required. If they aren't used, they aren't loaded. Therefore, assemblies can be an efficient way to manage resources in larger projects.
- You can programmatically obtain information about an assembly by using reflection. For more information, see [Reflection \(C#\)](#) or [Reflection \(Visual Basic\)](#).
- You can load an assembly just to inspect it by using the [MetadataLoadContext](#) class on .NET and .NET Framework. [MetadataLoadContext](#) replaces the [Assembly.ReflectionOnlyLoad](#) methods.

Assemblies in the common language runtime

Assemblies provide the common language runtime with the information it needs to be aware of type implementations. To the runtime, a type doesn't exist outside the context of an assembly.

An assembly defines the following information:

- **Code** that the common language runtime executes. Each assembly can have only one entry point: `DllMain`, `WinMain`, or `Main`.
- The **security boundary**. An assembly is the unit at which permissions are requested and granted. For more information about security boundaries in assemblies, see [Assembly security considerations](#).
- The **type boundary**. Every type's identity includes the name of the assembly in which it resides. A type called `MyType` that's loaded in the scope of one assembly isn't the same as a type called `MyType` that's loaded in the scope of another assembly.
- The **reference-scope boundary**: The [assembly manifest](#) has metadata that's used for resolving types and satisfying resource requests. The manifest specifies the types and resources to expose outside the assembly and enumerates other assemblies on which it depends. Microsoft intermediate language (MSIL) code in a portable executable (PE) file won't be executed unless it has an associated [assembly manifest](#).
- The **version boundary**. The assembly is the smallest versionable unit in the common language runtime. All types and resources in the same assembly are versioned as a unit. The [assembly manifest](#) describes the version dependencies you specify for any dependent assemblies. For more information about versioning, see [Assembly versioning](#).
- The **deployment unit**: When an application starts, only the assemblies that the application initially calls must be present. Other assemblies, such as assemblies containing localization resources or utility classes, can be retrieved on demand. This process allows apps to be simple and thin when first downloaded. For more information about deploying assemblies, see [Deploy applications](#).
- A **side-by-side execution unit**: For more information about running multiple versions of an assembly, see [Assemblies and side-by-side execution](#).

Create an assembly

Assemblies can be static or dynamic. Static assemblies are stored on a disk in portable executable (PE) files. Static assemblies can include interfaces, classes, and resources like bitmaps, JPEG files, and other resource files. You can also create dynamic assemblies, which are run directly from memory and aren't saved to disk before execution. You can save dynamic assemblies to disk after they've been executed.

There are several ways to create assemblies. You can use development tools, such as Visual Studio that can create `.dll` or `.exe` files. You can use tools in the Windows SDK to create assemblies with modules from other development environments. You can also use common language runtime APIs, such as [System.Reflection.Emit](#), to create dynamic assemblies.

Compile assemblies by building them in Visual Studio, building them with .NET Core command-line interface tools, or building .NET Framework assemblies with a command-line compiler. For more information about building assemblies using .NET CLI, see [.NET CLI overview](#).

 **Note**

To build an assembly in Visual Studio, on the **Build** menu, select **Build**.

Assembly manifest

Every assembly has an *assembly manifest* file. Similar to a table of contents, the assembly manifest contains:

- The assembly's identity (its name and version).
- A file table describing all the other files that make up the assembly, such as other assemblies you created that your `.exe` or `.dll` file relies on, bitmap files, or Readme files.
- An *assembly reference list*, which is a list of all external dependencies, such as `.dlls` or other files. Assembly references contain references to both global and private objects. Global objects are available to all other applications. In .NET Core, global objects are coupled with a particular .NET Core runtime. In .NET Framework, global objects reside in the global assembly cache (GAC). `System.IO.dll` is an example of an assembly in the GAC. Private objects must be in a directory level at or below the directory in which your app is installed.

Assemblies contain information about content, versioning, and dependencies. So the applications that use them don't need to rely on external sources, such as the registry on Windows systems, to function properly. Assemblies reduce `.dll` conflicts and make your applications more reliable and easier to deploy. In many cases, you can install a .NET-based application simply by copying its files to the target computer. For more information, see [Assembly manifest](#).

Add a reference to an assembly

To use an assembly in an application, you must add a reference to it. When an assembly is referenced, all the accessible types, properties, methods, and other members of its namespaces are available to your application as if their code were part of your source file.

ⓘ Note

Most assemblies from the .NET Class Library are referenced automatically. If a system assembly isn't automatically referenced, add a reference in one of the following ways:

- For .NET and .NET Core, add a reference to the NuGet package that contains the assembly. Either use the NuGet Package Manager in Visual Studio or add a `<PackageReference>` element for the assembly to the `.csproj` or `.vbproj` project.
- For .NET Framework, add a reference to the assembly by using the **Add Reference** dialog in Visual Studio or the `-reference` command line option for the **C#** or **Visual Basic** compilers.

In C#, you can use two versions of the same assembly in a single application. For more information, see [extern alias](#).

Assembly contents

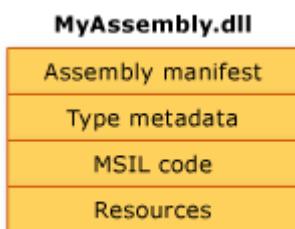

Article • 09/15/2021

In general, a static assembly can consist of four elements:

- The [assembly manifest](#), which contains assembly metadata.
- Type metadata.
- Microsoft intermediate language (MSIL) code that implements the types. It is generated by the compiler from one or more source code files.
- A set of [resources](#).

Only the assembly manifest is required, but either types or resources are needed to give the assembly any meaningful functionality.

The following illustration shows these elements grouped into a single physical file:

As you design your source code, you make explicit decisions about how to partition the functionality of your application into one or more files. When designing .NET code, you'll make similar decisions about how to partition the functionality into one or more assemblies.

Assembly manifest

Article • 09/15/2021

Every assembly, whether static or dynamic, contains a collection of data that describes how the elements in the assembly relate to each other. The assembly manifest contains this assembly metadata. An assembly manifest contains all the metadata needed to specify the assembly's version requirements and security identity, and all metadata needed to define the scope of the assembly and resolve references to resources and classes. The assembly manifest can be stored in either a PE file (an .exe or .dll) with Microsoft intermediate language (MSIL) code or in a standalone PE file that contains only assembly manifest information.

The following illustration shows the different ways the manifest can be stored.

For an assembly with one associated file, the manifest is incorporated into the PE file to form a single-file assembly. You can create a multifile assembly with a standalone manifest file or with the manifest incorporated into one of the PE files in the assembly.

Each assembly's manifest performs the following functions:

- Enumerates the files that make up the assembly.
- Governs how references to the assembly's types and resources map to the files that contain their declarations and implementations.
- Enumerates other assemblies on which the assembly depends.
- Provides a level of indirection between consumers of the assembly and the assembly's implementation details.
- Renders the assembly self-describing.

Assembly manifest contents

The following table shows the information contained in the assembly manifest. The first four items: assembly name, version number, culture, and strong name information make up the assembly's identity.

| Information | Description |
|--------------------------------------|---|
| Assembly name | A text string specifying the assembly's name. |
| Version number | A major and minor version number, and a revision and build number. The common language runtime uses these numbers to enforce version policy. |
| Culture | Information on the culture or language the assembly supports. This information should be used only to designate an assembly as a satellite assembly containing culture- or language-specific information. (An assembly with culture information is automatically assumed to be a satellite assembly.) |
| Strong name information | The public key from the publisher if the assembly has been given a strong name. |
| List of all files in the assembly | A hash of each file contained in the assembly and a file name. Note that all files that make up the assembly must be in the same directory as the file containing the assembly manifest. |
| Type reference information | Information used by the runtime to map a type reference to the file that contains its declaration and implementation. This is used for types that are exported from the assembly. |
| Information on referenced assemblies | A list of other assemblies that are statically referenced by the assembly. Each reference includes the dependent assembly's name, assembly metadata (version, culture, operating system, and so on), and public key, if the assembly is strong named. |

You can add or change some information in the assembly manifest by using assembly attributes in your code. You can change version information and informational attributes, including Trademark, Copyright, Product, Company, and Informational Version. For a complete list of assembly attributes, see [Set assembly attributes](#).

Assembly security considerations

Article • 03/30/2023

When you build an assembly, you can specify a set of permissions that the assembly requires to run. Whether certain permissions are granted or not granted to an assembly is based on evidence.

There are two distinct ways evidence is used:

- The input evidence is merged with the evidence gathered by the loader to create a final set of evidence used for policy resolution. The methods that use this semantic include `Assembly.Load`, `Assembly.LoadFrom`, and `Activator.CreateInstance`.
- The input evidence is used unaltered as the final set of evidence used for policy resolution. The methods that use this semantic include `Assembly.Load(byte[])` and `AppDomain.DefineDynamicAssembly()`.

Optional permissions can be granted by the [security policy](#) set on the computer where the assembly will run. If you want your code to handle all potential security exceptions, you can do one of the following:

- Insert a permission request for all the permissions your code must have, and handle up front the load-time failure that occurs if the permissions are not granted.
- Do not use a permission request to obtain permissions your code might need, but be prepared to handle security exceptions if permissions are not granted.

(!) Note

Security is a complex area, and you have many options to choose from. For more information, see [Key Security Concepts](#).

At load time, the assembly's evidence is used as input to security policy. Security policy is established by the enterprise and the computer's administrator as well as by user policy settings, and determines the set of permissions that's granted to all managed code when executed. Security policy can be established for the publisher of the assembly (if it has a signing tool generated signature), for the Web site and zone (which was an Internet Explorer concept) that the assembly was downloaded from, or for the assembly's strong name. For example, a computer's administrator can establish security policy that allows all code downloaded from a Web site and signed by a given software

company to access a database on a computer, but does not grant access to write to the computer's disk.

Strong-named assemblies and signing tools

⚠ Warning

Do not rely on strong names for security. They provide a unique identity only.

You can sign an assembly in two different but complementary ways: with a strong name or by using [SignTool.exe \(Sign Tool\)](#). Signing an assembly with a strong name adds public key encryption to the file containing the assembly manifest. Strong name signing helps to verify name uniqueness, prevent name spoofing, and provide callers with some identity when a reference is resolved.

No level of trust is associated with a strong name, which makes [SignTool.exe \(Sign Tool\)](#) important. The two signing tools require a publisher to prove its identity to a third-party authority and obtain a certificate. This certificate is then embedded in your file and can be used by an administrator to decide whether to trust the code's authenticity.

You can give both a strong name and a digital signature created using [SignTool.exe \(Sign Tool\)](#) to an assembly, or you can use either alone. The two signing tools can sign only one file at a time; for a multifile assembly, you sign the file that contains the assembly manifest. A strong name is stored in the file containing the assembly manifest, but a signature created using [SignTool.exe \(Sign Tool\)](#) is stored in a reserved slot in the portable executable (PE) file containing the assembly manifest. Signing of an assembly using [SignTool.exe \(Sign Tool\)](#) can be used (with or without a strong name) when you already have a trust hierarchy that relies on [SignTool.exe \(Sign Tool\)](#) generated signatures, or when your policy uses only the key portion and does not check a chain of trust.

ⓘ Note

When using both a strong name and a signing tool signature on an assembly, the strong name must be assigned first.

The common language runtime also performs a hash verification; the assembly manifest contains a list of all files that make up the assembly, including a hash of each file as it existed when the manifest was built. As each file is loaded, its contents are hashed and

compared with the hash value stored in the manifest. If the two hashes do not match, the assembly fails to load.

Strong naming and signing using [SignTool.exe \(Sign Tool\)](#) guarantee integrity through digital signatures and certificates. All the technologies mentioned, that is, hash verification, strong naming, and signing using [SignTool.exe \(Sign Tool\)](#), work together to ensure that the assembly has not been altered in any way.

Assembly versioning

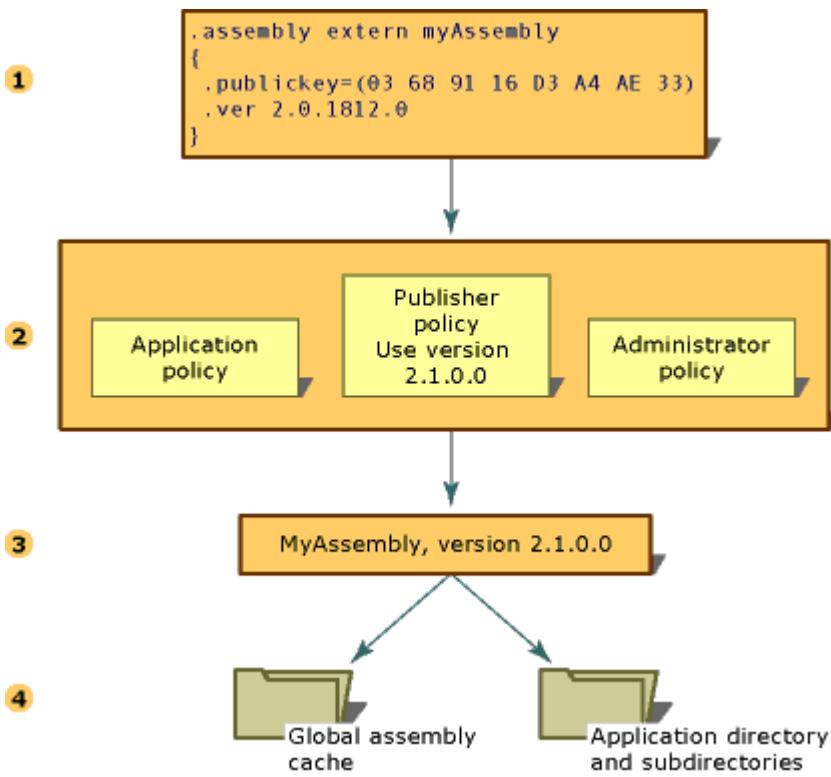

Article • 10/01/2021

All versioning of assemblies that use the common language runtime is done at the assembly level. The specific version of an assembly and the versions of dependent assemblies are recorded in the assembly's manifest. The default version policy for the runtime is that applications run only with the versions they were built and tested with, unless overridden by explicit version policy in configuration files (the application configuration file, the publisher policy file, and the computer's administrator configuration file).

The runtime performs several steps to resolve an assembly binding request:

1. Checks the original assembly reference to determine the version of the assembly to be bound.
2. Checks for all applicable configuration files to apply version policy.
3. Determines the correct assembly from the original assembly reference and any redirection specified in the configuration files, and determines the version that should be bound to the calling assembly.
4. Checks the global assembly cache, codebases specified in configuration files, and then checks the application's directory and subdirectories using the probing rules explained in [How the runtime locates assemblies](#).

The following illustration shows these steps:

For more information about configuring applications, see [Configure apps](#). For more information about binding policy, see [How the runtime locates assemblies](#).

Version information

Each assembly has two distinct ways of expressing version information:

- The assembly's version number, which, together with the assembly name and culture information, is part of the assembly's identity. This number is used by the runtime to enforce version policy and plays a key part in the type resolution process at run time.
- An informational version, which is a string that represents additional version information included for informational purposes only.

Assembly version number

Each assembly has a version number as part of its identity. As such, two assemblies that differ by version number are considered by the runtime to be completely different assemblies. This version number is physically represented as a four-part string with the following format:

<major version>. <minor version>. <build number>. <revision>

For example, version 1.5.1254.0 indicates 1 as the major version, 5 as the minor version, 1254 as the build number, and 0 as the revision number.

The version number is stored in the assembly manifest along with other identity information, including the assembly name and public key, as well as information on relationships and identities of other assemblies connected with the application.

When an assembly is built, the development tool records dependency information for each assembly that is referenced in the assembly manifest. The runtime uses these version numbers, in conjunction with configuration information set by an administrator, an application, or a publisher, to load the proper version of a referenced assembly.

The runtime distinguishes between regular and strong-named assemblies for the purposes of versioning. Version checking only occurs with strong-named assemblies.

For information about specifying version binding policies, see [Configure apps](#). For information about how the runtime uses version information to find a particular assembly, see [How the runtime locates assemblies](#).

Assembly informational version

The informational version is a string that attaches additional version information to an assembly for informational purposes only; this information is not used at run time. The text-based informational version corresponds to the product's marketing literature, packaging, or product name and is not used by the runtime. For example, an informational version could be "Common Language Runtime version 1.0" or "NET Control SP 2". On the Version tab of the file properties dialog in Microsoft Windows, this information appears in the item "Product Version".

ⓘ Note

Although you can specify any text, a warning message appears on compilation if the string is not in the format used by the assembly version number, or if it is in that format but contains wildcards. This warning is harmless.

The informational version is represented using the custom attribute [System.Reflection.AssemblyInformationalVersionAttribute](#). For more information about the informational version attribute, see [Set assembly attributes](#).

System.Version class

Article • 01/08/2024

This article provides supplementary remarks to the reference documentation for this API.

The [Version class](#) represents the version number of an assembly, operating system, or the common language runtime. Version numbers consist of two to four components: major, minor, build, and revision. The major and minor components are required; the build and revision components are optional, but the build component is required if the revision component is defined. All defined components must be integers greater than or equal to 0. The format of the version number is as follows (optional components are shown in square brackets):

major.minor[.build[.revision]]

The components are used by convention as follows:

- *Major*: Assemblies with the same name but different major versions are not interchangeable. A higher version number might indicate a major rewrite of a product where backward compatibility cannot be assumed.
- *Minor*: If the name and major version number on two assemblies are the same, but the minor version number is different, this indicates significant enhancement with the intention of backward compatibility. This higher minor version number might indicate a point release of a product or a fully backward-compatible new version of a product.
- *Build*: A difference in build number represents a recompilation of the same source. Different build numbers might be used when the processor, platform, or compiler changes.
- *Revision*: Assemblies with the same name, major, and minor version numbers but different revisions are intended to be fully interchangeable. A higher revision number might be used in a build that fixes a security hole in a previously released assembly.

Subsequent versions of an assembly that differ only by build or revision numbers are considered to be Hotfix updates of the prior version.

 **Important**

The value of [Version](#) properties that have not been explicitly assigned a value is undefined (-1).

The [MajorRevision](#) and [MinorRevision](#) properties enable you to identify a temporary version of your application that, for example, corrects a problem until you can release a permanent solution. Furthermore, the Windows NT operating system uses the [MajorRevision](#) property to encode the service pack number.

Assign version information to assemblies

Ordinarily, the [Version](#) class is not used to assign a version number to an assembly. Instead, the [AssemblyVersionAttribute](#) class is used to define an assembly's version, as illustrated by the example in this article.

Retrieve version information

[Version](#) objects are most frequently used to store version information about some system or application component (such as the operating system), the common language runtime, the current application's executable, or a particular assembly. The following examples illustrate some of the most common scenarios:

- Retrieving the operating system version. The following example uses the [OperatingSystem.Version](#) property to retrieve the version number of the operating system.

C#

```
// Get the operating system version.  
OperatingSystem os = Environment.OSVersion;  
Version ver = os.Version;  
Console.WriteLine("Operating System: {0} ({1})", os.VersionString,  
ver.ToString());
```

- Retrieving the version of the common language runtime. The following example uses the [Environment.Version](#) property to retrieve version information about the common language runtime.

C#

```
// Get the common language runtime version.  
Version ver = Environment.Version;  
Console.WriteLine("CLR Version {0}", ver.ToString());
```

- Retrieving the current application's assembly version. The following example uses the [Assembly.GetEntryAssembly](#) method to obtain a reference to an [Assembly](#) object that represents the application executable and then retrieves its assembly version number.

C#

```
using System;
using System.Reflection;

public class Example4
{
    public static void Main()
    {
        // Get the version of the executing assembly (that is, this
        // assembly).
        Assembly assem = Assembly.GetEntryAssembly();
        AssemblyName assemName = assem.GetName();
        Version ver = assemName.Version;
        Console.WriteLine("Application {0}, Version {1}", assemName.Name,
        ver.ToString());
    }
}
```

- Retrieving the current assembly's assembly version. The following example uses the [Type.Assembly](#) property to obtain a reference to an [Assembly](#) object that represents the assembly that contains the application entry point, and then retrieves its version information.

C#

```
using System;
using System.Reflection;

public class Example3
{
    public static void Main()
    {
        // Get the version of the current assembly.
        Assembly assem = typeof(Example).Assembly;
        AssemblyName assemName = assem.GetName();
        Version ver = assemName.Version;
        Console.WriteLine("{0}, Version {1}", assemName.Name,
        ver.ToString());
    }
}
```

- Retrieving the version of a specific assembly. The following example uses the [Assembly.ReflectionOnlyLoadFrom](#) method to obtain a reference to an [Assembly](#)

object that has a particular file name, and then retrieves its version information. Note that several other methods also exist to instantiate an [Assembly](#) object by file name or by strong name.

C#

```
using System;
using System.Reflection;

public class Example5
{
    public static void Main()
    {
        // Get the version of a specific assembly.
        string filename = @".\StringLibrary.dll";
        Assembly assem = Assembly.ReflectionOnlyLoadFrom(filename);
        AssemblyName assemName = assem.GetName();
        Version ver = assemName.Version;
        Console.WriteLine("{0}, Version {1}", assemName.Name,
ver.ToString());
    }
}
```

- Retrieving the Publish Version of a ClickOnce application. The following example uses the [ApplicationDeployment.CurrentVersion](#) property to display an application's Publish Version. Note that its successful execution requires the example's application identity to be set. This is handled automatically by the Visual Studio Publish Wizard.

C#

```
using System;
using System.Deployment.Application;

public class Example
{
    public static void Main()
    {
        Version ver =
ApplicationDeployment.CurrentDeployment.CurrentVersion;
        Console.WriteLine("ClickOnce Publish Version: {0}", ver);
    }
}
```

 **Important**

The Publish Version of an application for ClickOnce deployment is completely independent of its assembly version.

Compare version objects

You can use the [CompareTo](#) method to determine whether one [Version](#) object is earlier than, the same as, or later than a second [Version](#) object. The following example indicates that Version 2.1 is later than Version 2.0.

C#

```
Version v1 = new Version(2, 0);
Version v2 = new Version("2.1");
Console.WriteLine("Version {0} is ", v1);
switch(v1.CompareTo(v2))
{
    case 0:
        Console.WriteLine("the same as");
        break;
    case 1:
        Console.WriteLine("later than");
        break;
    case -1:
        Console.WriteLine("earlier than");
        break;
}
Console.WriteLine(" Version {0}.", v2);
// The example displays the following output:
//      Version 2.0 is earlier than Version 2.1.
```

For two versions to be equal, the major, minor, build, and revision numbers of the first [Version](#) object must be identical to those of the second [Version](#) object. If the build or revision number of a [Version](#) object is undefined, that [Version](#) object is considered to be earlier than a [Version](#) object whose build or revision number is equal to zero. The following example illustrates this by comparing three [Version](#) objects that have undefined version components.

C#

```
using System;

enum VersionTime {Earlier = -1, Same = 0, Later = 1};

public class Example2
{
    public static void Main()
    {
```

```
Version v1 = new Version(1, 1);
Version v1a = new Version("1.1.0");
ShowRelationship(v1, v1a);

Version v1b = new Version(1, 1, 0, 0);
ShowRelationship(v1b, v1a);
}

private static void ShowRelationship(Version v1, Version v2)
{
    Console.WriteLine("Relationship of {0} to {1}: {2}",
                      v1, v2, (VersionTime) v1.CompareTo(v2));
}
}

// The example displays the following output:
//      Relationship of 1.1 to 1.1.0: Earlier
//      Relationship of 1.1.0.0 to 1.1.0: Later
```

Assemblies and side-by-side execution

Article • 09/15/2021

Side-by-side execution is the ability to store and execute multiple versions of an application or component on the same computer. This means that you can have multiple versions of the runtime, and multiple versions of applications and components that use a version of the runtime, on the same computer at the same time. Side-by-side execution gives you more control over what versions of a component an application binds to, and more control over what version of the runtime an application uses.

Support for side-by-side storage and execution of different versions of the same assembly is an integral part of strong naming and is built into the infrastructure of the runtime. Because the strong-named assembly's version number is part of its identity, the runtime can store multiple versions of the same assembly in the global assembly cache and load those assemblies at run time.

Although the runtime provides you with the ability to create side-by-side applications, side-by-side execution is not automatic. For more information on creating applications for side-by-side execution, see [Guidelines for creating components for side-by-side execution](#).

.NET assembly file format

Article • 09/15/2021

.NET defines a binary file format, *assembly*, that is used to fully describe and contain .NET programs. Assemblies are used for the programs themselves as well as any dependent libraries. A .NET program can be executed as one or more assemblies, with no other required artifacts, beyond the appropriate .NET implementation. Native dependencies, including operating system APIs, are a separate concern and are not contained within the .NET assembly format, although they are sometimes described with this format (for example, WinRT).

Each CLI component carries the metadata for declarations, implementations, and references specific to that component. Therefore, the component-specific metadata is referred to as component metadata, and the resulting component is said to be self-describing – from ECMA 335 I.9.1, Components and assemblies.

The format is fully specified and standardized as [ECMA 335](#). All .NET compilers and runtimes use this format. The presence of a documented and infrequently updated binary format has been a major benefit (arguably a requirement) for interoperability. The format was last updated in a substantive way in 2005 (.NET Framework 2.0) to accommodate generics and processor architecture.

The format is CPU- and OS-agnostic. It has been used as part of .NET implementations that target many chips and CPUs. While the format itself has Windows heritage, it is implementable on any operating system. Its arguably most significant choice for OS interoperability is that most values are stored in little-endian format. It doesn't have a specific affinity to machine pointer size (for example, 32-bit, 64-bit).

The .NET assembly format is also very descriptive about the structure of a given program or library. It describes the internal components of an assembly, specifically assembly references and types defined and their internal structure. Tools or APIs can read and process this information for display or to make programmatic decisions.

Format

The .NET binary format is based on the Windows [PE file](#) format. In fact, .NET class libraries are conformant Windows PEs, and appear on first glance to be Windows dynamic link libraries (DLLs) or application executables (EXEs). This is a very useful characteristic on Windows, where they can masquerade as native executable binaries and get some of the same treatment (for example, OS load, PE tools).

PE Headers

CLI Header

CLI Data : metadata, IL method bodies, fix-ups

Native Image Sections

Assembly Headers from ECMA 335 II.25.1, Structure of the runtime file format.

Process the assemblies

It is possible to write tools or APIs to process assemblies. Assembly information enables making programmatic decisions at run time, re-writing assemblies, providing API IntelliSense in an editor and generating documentation. [System.Reflection](#), [System.Reflection.MetadataLoadContext](#), and [Mono.Cecil](#) ↗ are good examples of tools that are frequently used for this purpose.

How to use and debug assembly unloadability in .NET

Article • 11/13/2023

.NET (Core) introduced the ability to load and later unload a set of assemblies. In .NET Framework, custom app domains were used for this purpose, but .NET (Core) only supports a single default app domain.

Unloadability is supported through [AssemblyLoadContext](#). You can load a set of assemblies into a collectible `AssemblyLoadContext`, execute methods in them or just inspect them using reflection, and finally unload the `AssemblyLoadContext`. That unloads the assemblies loaded into the `AssemblyLoadContext`.

There's one noteworthy difference between the unloading using `AssemblyLoadContext` and using AppDomains. With AppDomains, the unloading is forced. At unload time, all threads running in the target AppDomain are aborted, managed COM objects created in the target AppDomain are destroyed, and so on. With `AssemblyLoadContext`, the unload is "cooperative". Calling the [AssemblyLoadContext.Unload](#) method just initiates the unloading. The unloading finishes after:

- No threads have methods from the assemblies loaded into the `AssemblyLoadContext` on their call stacks.
- None of the types from the assemblies loaded into the `AssemblyLoadContext`, instances of those types, and the assemblies themselves are referenced by:
 - References outside of the `AssemblyLoadContext`, except for weak references ([WeakReference](#) or [WeakReference<T>](#)).
 - Strong garbage collector (GC) handles ([GCHandleType.Normal](#) or [GCHandleType.Pinned](#)) from both inside and outside of the `AssemblyLoadContext`.

Use collectible `AssemblyLoadContext`

This section contains a detailed step-by-step tutorial that shows a simple way to load a .NET (Core) application into a collectible `AssemblyLoadContext`, execute its entry point, and then unload it. You can find a complete sample at [https://github.com/dotnet/samples/tree/main/core/tutorials/Unloading ↗](https://github.com/dotnet/samples/tree/main/core/tutorials/Unloading).

Create a collectible `AssemblyLoadContext`

Derive your class from the [AssemblyLoadContext](#) and override its [AssemblyLoadContext.Load](#) method. That method resolves references to all assemblies that are dependencies of assemblies loaded into that [AssemblyLoadContext](#).

The following code is an example of the simplest custom [AssemblyLoadContext](#):

```
C#  
  
class TestAssemblyLoadContext : AssemblyLoadContext  
{  
    public TestAssemblyLoadContext() : base(isCollectible: true)  
    {  
    }  
  
    protected override Assembly? Load(AssemblyName name)  
    {  
        return null;  
    }  
}
```

As you can see, the `Load` method returns `null`. That means that all the dependency assemblies are loaded into the default context, and the new context contains only the assemblies explicitly loaded into it.

If you want to load some or all of the dependencies into the [AssemblyLoadContext](#) too, you can use the [AssemblyDependencyResolver](#) in the `Load` method. The [AssemblyDependencyResolver](#) resolves the assembly names to absolute assembly file paths. The resolver uses the `.deps.json` file and assembly files in the directory of the main assembly loaded into the context.

```
C#  
  
using System.Reflection;  
using System.Runtime.Loader;  
  
namespace complex  
{  
    class TestAssemblyLoadContext : AssemblyLoadContext  
    {  
        private AssemblyDependencyResolver _resolver;  
  
        public TestAssemblyLoadContext(string mainAssemblyToLoadPath) :  
base(isCollectible: true)  
        {  
            _resolver = new  
AssemblyDependencyResolver(mainAssemblyToLoadPath);  
        }  
  
        protected override Assembly? Load(AssemblyName name)
```

```
        {
            string? assemblyPath = _resolver.ResolveAssemblyToPath(name);
            if (assemblyPath != null)
            {
                return LoadFromAssemblyPath(assemblyPath);
            }

            return null;
        }
    }
}
```

Use a custom collectible AssemblyLoadContext

This section assumes the simpler version of the `TestAssemblyLoadContext` is being used.

You can create an instance of the custom `AssemblyLoadContext` and load an assembly into it as follows:

C#

```
var alc = new TestAssemblyLoadContext();
Assembly a = alc.LoadFromAssemblyPath(assemblyPath);
```

For each of the assemblies referenced by the loaded assembly, the `TestAssemblyLoadContext.Load` method is called so that the `TestAssemblyLoadContext` can decide where to get the assembly from. In this case, it returns `null` to indicate that it should be loaded into the default context from locations that the runtime uses to load assemblies by default.

Now that an assembly was loaded, you can execute a method from it. Run the `Main` method:

C#

```
var args = new object[1] {new string[] {"Hello"}};
_ = a.EntryPoint?.Invoke(null, args);
```

After the `Main` method returns, you can initiate unloading by either calling the `Unload` method on the custom `AssemblyLoadContext` or removing the reference you have to the `AssemblyLoadContext`:

C#

```
alc.Unload();
```

This is sufficient to unload the test assembly. Next, you'll put all of this into a separate noninlineable method to ensure that the `TestAssemblyLoadContext`, `Assembly`, and `MethodInfo` (the `Assembly.EntryPoint`) can't be kept alive by stack slot references (real- or JIT-introduced locals). That could keep the `TestAssemblyLoadContext` alive and prevent the unload.

Also, return a weak reference to the `AssemblyLoadContext` so that you can use it later to detect unload completion.

C#

```
[MethodImpl(MethodImplOptions.NoInlining)]
static void ExecuteAndUnload(string assemblyPath, out WeakReference
alcWeakRef)
{
    var alc = new TestAssemblyLoadContext();
    Assembly a = alc.LoadFromAssemblyPath(assemblyPath);

    alcWeakRef = new WeakReference(alc, trackResurrection: true);

    var args = new object[1] {new string[] {"Hello"}};
    _ = a.EntryPoint?.Invoke(null, args);

    alc.Unload();
}
```

Now you can run this function to load, execute, and unload the assembly.

C#

```
WeakReference testAlcWeakRef;
ExecuteAndUnload("absolute/path/to/your/assembly", out testAlcWeakRef);
```

However, the unload doesn't complete immediately. As previously mentioned, it relies on the garbage collector to collect all the objects from the test assembly. In many cases, it isn't necessary to wait for the unload completion. However, there are cases where it's useful to know that the unload has finished. For example, you might want to delete the assembly file that was loaded into the custom `AssemblyLoadContext` from disk. In such a case, the following code snippet can be used. It triggers garbage collection and waits for pending finalizers in a loop until the weak reference to the custom `AssemblyLoadContext` is set to `null`, indicating the target object was collected. In most cases, just one pass through the loop is required. However, for more complex cases where objects created

by the code running in the `AssemblyLoadContext` have finalizers, more passes might be needed.

C#

```
for (int i = 0; testAlcWeakRef.IsAlive && (i < 10); i++)
{
    GC.Collect();
    GC.WaitForPendingFinalizers();
}
```

The Unloading event

In some cases, it might be necessary for the code loaded into a custom `AssemblyLoadContext` to perform some cleanup when the unloading is initiated. For example, it might need to stop threads or clean up strong GC handles. The `Unloading` event can be used in such cases. You can hook a handler that performs the necessary cleanup to this event.

Troubleshoot unloadability issues

Due to the cooperative nature of the unloading, it's easy to forget about references that might be keeping the stuff in a collectible `AssemblyLoadContext` alive and preventing unload. Here's a summary of entities (some of them nonobvious) that can hold the references:

- Regular references held from outside of the collectible `AssemblyLoadContext` that are stored in a stack slot or a processor register (method locals, either explicitly created by the user code or implicitly by the just-in-time (JIT) compiler), a static variable, or a strong (pinning) GC handle, and transitively pointing to:
 - An assembly loaded into the collectible `AssemblyLoadContext`.
 - A type from such an assembly.
 - An instance of a type from such an assembly.
- Threads running code from an assembly loaded into the collectible `AssemblyLoadContext`.
- Instances of custom, noncollectible `AssemblyLoadContext` types created inside of the collectible `AssemblyLoadContext`.
- Pending `RegisteredWaitHandle` instances with callbacks set to methods in the custom `AssemblyLoadContext`.

Tip

Object references that are stored in stack slots or processor registers and that could prevent unloading of an `AssemblyLoadContext` can occur in the following situations:

- When function call results are passed directly to another function, even though there is no user-created local variable.
- When the JIT compiler keeps a reference to an object that was available at some point in a method.

Debug unloading issues

Debugging issues with unloading can be tedious. You can get into situations where you don't know what can be holding an `AssemblyLoadContext` alive, but the unload fails. The best tool to help with that is WinDbg (or LLDB on Unix) with the SOS plugin. You need to find what's keeping a `LoaderAllocator` that belongs to the specific `AssemblyLoadContext` alive. The SOS plugin lets you look at GC heap objects, their hierarchies, and roots.

To load the SOS plugin into the debugger, enter one of the following commands in the debugger command line.

In WinDbg (if it's not already loaded):

```
Console  
.loadby sos coreclr
```

In LLDB:

```
Console  
plugin load /path/to/libssosplugin.so
```

Now you'll debug an example program that has problems with unloading. The source code is available in the [Example source code](#) section. When you run it under WinDbg, the program breaks into the debugger right after attempting to check for the unload success. You can then start looking for the culprits.

 **Tip**

If you debug using LLDB on Unix, the SOS commands in the following examples don't have the ! in front of them.

Console

```
!dumpheap -type LoaderAllocator
```

This command dumps all objects with a type name containing `LoaderAllocator` that are in the GC heap. Here's an example:

Console

| Address | MT | Size |
|------------------|------------------|------|
| 000002b78000ce40 | 00007ffadc93a288 | 48 |
| 000002b78000ceb0 | 00007ffadc93a218 | 24 |

Statistics:

| MT | Count | TotalSize | Class | Name |
|--|-------|-----------|-----------------------------------|------|
| 00007ffadc93a218 | 1 | 24 | | |
| System.Reflection.LoaderAllocatorScout | | | | |
| 00007ffadc93a288 | 1 | 48 | System.Reflection.LoaderAllocator | |
| Total | 2 | objects | | |

In the "Statistics:" part, check the `MT` (`MethodTable`) that belongs to the `System.Reflection.LoaderAllocator`, which is the object you care about. Then, in the list at the beginning, find the entry with `MT` that matches that one, and get the address of the object itself. In this case, it's "000002b78000ce40".

Now that you know the address of the `LoaderAllocator` object, you can use another command to find its GC roots:

Console

```
!gcroot 0x000002b78000ce40
```

This command dumps the chain of object references that lead to the `LoaderAllocator` instance. The list starts with the root, which is the entity that keeps the `LoaderAllocator` alive and thus is the core of the problem. The root can be a stack slot, a processor register, a GC handle, or a static variable.

Here's an example of the output of the `gcroot` command:

Console

```

Thread 4ac:
  000000cf9499dd20 00007ffa7d0236bc example.Program.Main(System.String[])
[E:\unloadability\example\Program.cs @ 70]
  rbp-20: 000000cf9499dd90
    -> 000002b78000d328 System.Reflection.RuntimeMethodInfo
    -> 000002b78000d1f8 System.RuntimeType+RuntimeTypeCache
    -> 000002b78000d1d0 System.RuntimeType
    -> 000002b78000ce40 System.Reflection.LoaderAllocator

HandleTable:
  000002b7f8a81198 (strong handle)
  -> 000002b78000d948 test.Test
  -> 000002b78000ce40 System.Reflection.LoaderAllocator

  000002b7f8a815f8 (pinned handle)
  -> 000002b790001038 System.Object[]
  -> 000002b78000d390 example.TestInfo
  -> 000002b78000d328 System.Reflection.RuntimeMethodInfo
  -> 000002b78000d1f8 System.RuntimeType+RuntimeTypeCache
  -> 000002b78000d1d0 System.RuntimeType
  -> 000002b78000ce40 System.Reflection.LoaderAllocator

Found 3 roots.

```

The next step is to figure out where the root is located so you can fix it. The easiest case is when the root is a stack slot or a processor register. In that case, the `gcroot` shows the name of the function whose frame contains the root and the thread executing that function. The difficult case is when the root is a static variable or a GC handle.

In the previous example, the first root is a local of type `System.Reflection.RuntimeMethodInfo` stored in the frame of the function `example.Program.Main(System.String[])` at address `rbp-20` (`rbp` is the processor register `rbp` and `-20` is a hexadecimal offset from that register).

The second root is a normal (strong) `GCHandle` that holds a reference to an instance of the `test.Test` class.

The third root is a pinned `GCHandle`. This one is actually a static variable, but unfortunately, there's no way to tell. Statics for reference types are stored in a managed object array in internal runtime structures.

Another case that can prevent unloading of an `AssemblyLoadContext` is when a thread has a frame of a method from an assembly loaded into the `AssemblyLoadContext` on its stack. You can check that by dumping managed call stacks of all threads:

Console

```
~*e !clrstack
```

The command means "apply to all threads the `!clrstack` command". The following is the output of that command for the example. Unfortunately, LLDB on Unix doesn't have any way to apply a command to all threads, so you must manually switch threads and repeat the `clrstack` command. Ignore all threads where the debugger says "Unable to walk the managed stack".

Console

```
OS Thread Id: 0x6ba8 (0)

OS Thread Id: 0x60bc (7)
    Child SP          IP Call Site
0000001fc727f158 00007ffb5437fce4 [HelperMethodFrame: 0000001fc727f158]
System.Threading.Thread.SleepInternal(Int32)
```

```
0000001fc727f260 00007ffb37ea7c2b System.Threading.Thread.Sleep(Int32)
0000001fc727f290 00007ffa865005b3 test.Program.ThreadProc()
[E:\unloadability\test\Program.cs @ 17]
0000001fc727f2c0 00007ffb37ea6a5b
System.Threading.Thread.ThreadMain_ThreadStart()
0000001fc727f2f0 00007ffadbc4cbe3
System.Threading.ExecutionContext.RunInternal(System.Threading.ExecutionCont
ext, System.Threading.ContextCallback, System.Object)
0000001fc727f568 00007ffae5fdc1e3 [GCFrame: 0000001fc727f568]
0000001fc727f7f0 00007ffae5fdc1e3 [DebuggerU2MCatchHandlerFrame:
0000001fc727f7f0]
```

As you can see, the last thread has `test.Program.ThreadProc()`. This is a function from the assembly loaded into the `AssemblyLoadContext`, and so it keeps the `AssemblyLoadContext` alive.

Example source code

The following code that contains unloadability issues is used in the previous debugging example.

Main testing program

```
C#  
  
using System;
using System.Reflection;
using System.Runtime.CompilerServices;
using System.Runtime.Loader;  
  
namespace example
{
    class TestAssemblyLoadContext : AssemblyLoadContext
    {
        public TestAssemblyLoadContext() : base(true)
        {
        }
        protected override Assembly? Load(AssemblyName name)
        {
            return null;
        }
    }

    class TestInfo
    {
        public TestInfo(MethodInfo? mi)
        {
            _entryPoint = mi;
        }
    }
}
```

```
        MethodInfo? _entryPoint;
    }

    class Program
    {
        static TestInfo? entryPoint;

        [MethodImpl(MethodImplOptions.NoInlining)]
        static int ExecuteAndUnload(string assemblyPath, out WeakReference testAlcWeakRef, out MethodInfo? testEntryPoint)
        {
            var alc = new TestAssemblyLoadContext();
            testAlcWeakRef = new WeakReference(alc);

            Assembly a = alc.LoadFromAssemblyPath(assemblyPath);
            if (a == null)
            {
                testEntryPoint = null;
                Console.WriteLine("Loading the test assembly failed");
                return -1;
            }

            var args = new object[1] {new string[] {"Hello"}};

            // Issue preventing unloading #1 - we keep MethodInfo of a
method
            // for an assembly loaded into the TestAssemblyLoadContext in a
static variable.
            entryPoint = new TestInfo(a.EntryPoint);
            testEntryPoint = a.EntryPoint;

            var oResult = a.EntryPoint?.Invoke(null, args);
            alc.Unload();
            return (oResult is int result) ? result : -1;
        }

        static void Main(string[] args)
        {
            WeakReference testAlcWeakRef;
            // Issue preventing unloading #2 - we keep MethodInfo of a
method for an assembly loaded into the TestAssemblyLoadContext in a local
variable
            MethodInfo? testEntryPoint;
            int result = ExecuteAndUnload(@"absolute/path/to/test.dll", out
testAlcWeakRef, out testEntryPoint);

            for (int i = 0; testAlcWeakRef.IsAlive && (i < 10); i++)
            {
                GC.Collect();
                GC.WaitForPendingFinalizers();
            }

            System.Diagnostics.Debugger.Break();
        }
    }
}
```

```
        Console.WriteLine($"Test completed, result={result}, entryPoint:  
{testEntryPoint} unload success: {!testAlcWeakRef.IsAlive}");  
    }  
}  
}
```

Program loaded into the TestAssemblyLoadContext

The following code represents the *test.dll* passed to the `ExecuteAndUnload` method in the main testing program.

C#

```
using System;  
using System.Runtime.InteropServices;  
using System.Threading;  
  
namespace test  
{  
    class Test  
    {  
    }  
  
    class Program  
    {  
        public static void ThreadProc()  
        {  
            // Issue preventing unloading #4 - a thread running method  
            // inside of the TestAssemblyLoadContext at the unload time  
            Thread.Sleep(Timeout.Infinite);  
        }  
  
        static GCHandle handle;  
        static int Main(string[] args)  
        {  
            // Issue preventing unloading #3 - normal GC handle  
            handle = GCHandle.Alloc(new Test());  
            Thread t = new Thread(new ThreadStart(ThreadProc));  
            t.IsBackground = true;  
            t.Start();  
            Console.WriteLine($"Hello from the test: args[0] = {args[0]}");  
  
            return 1;  
        }  
    }  
}
```

Reference assemblies

Article • 09/15/2021

Reference assemblies are a special type of assembly that contain only the minimum amount of metadata required to represent the library's public API surface. They include declarations for all members that are significant when referencing an assembly in build tools, but exclude all member implementations and declarations of private members that have no observable impact on their API contract. In contrast, regular assemblies are called *implementation assemblies*.

Reference assemblies can't be loaded for execution, but they can be passed as compiler input in the same way as implementation assemblies. Reference assemblies are usually distributed with the Software Development Kit (SDK) of a particular platform or library.

Using a reference assembly enables developers to build programs that target a specific library version without having the full implementation assembly for that version.

Suppose, you have only the latest version of some library on your machine, but you want to build a program that targets an earlier version of that library. If you compile directly against the implementation assembly, you might inadvertently use API members that aren't available in the earlier version. You'll only find this mistake when testing the program on the target machine. If you compile against the reference assembly for the earlier version, you'll immediately get a compile-time error.

A reference assembly can also represent a contract, that is, a set of APIs that don't correspond to the concrete implementation assembly. Such reference assemblies, called the *contract assembly*, can be used to target multiple platforms that support the same set of APIs. For example, .NET Standard provides the contract assembly, *netstandard.dll*, that represents the set of common APIs shared between different .NET platforms. The implementations of these APIs are contained in different assemblies on different platforms, such as *mscorlib.dll* on .NET Framework or *System.Private.CoreLib.dll* on .NET Core. A library that targets .NET Standard can run on all platforms that support .NET Standard.

Using reference assemblies

To use certain APIs from your project, you must add references to their assemblies. You can add references to either implementation assemblies or to reference assemblies. It's recommended you use reference assemblies whenever they're available. Doing so ensures that you're using only the supported API members in the target version, meant

to be used by API designers. Using the reference assembly ensures you're not taking a dependency on implementation details.

Reference assemblies for the .NET Framework libraries are distributed with targeting packs. You can obtain them by downloading a standalone installer or by selecting a component in Visual Studio installer. For more information, see [Install the .NET Framework for developers](#). For .NET Core and .NET Standard, reference assemblies are automatically downloaded as necessary (via NuGet) and referenced. For .NET Core 3.0 and higher, the reference assemblies for the core framework are in the [Microsoft.NETCore.App.Ref](#) package (the [Microsoft.NETCore.App](#) package is used instead for versions before 3.0).

When you add references to .NET Framework assemblies in Visual Studio using the [Add reference](#) dialog, you select an assembly from the list, and Visual Studio automatically finds reference assemblies that correspond to the target framework version selected in your project. The same applies to adding references directly into MSBuild project using the [Reference](#) project item: you only need to specify the assembly name, not the full file path. When you add references to these assemblies in the command line by using the `-reference` compiler option ([in C#](#) and in [Visual Basic](#)) or by using the [Compilation.AddReferences](#) method in the Roslyn API, you must manually specify reference assembly files for the correct target platform version. .NET Framework reference assembly files are located in the `%ProgramFiles(x86)%\Reference Assemblies\Microsoft\Framework\.NETFramework` directory. For .NET Core, you can force publish operation to copy reference assemblies for your target platform into the `publish/refs` subdirectory of your output directory by setting the `PreserveCompilationContext` project property to `true`. Then you can pass these reference assembly files to the compiler. Using `DependencyContext` from [Microsoft.Extensions.DependencyModel](#) package can help locate their paths.

Because they contain no implementation, reference assemblies can't be loaded for execution. Trying to do so results in a [System.BadImageFormatException](#). If you want to examine the contents of a reference assembly, you can load it into the reflection-only context in .NET Framework (using the [Assembly.ReflectionOnlyLoad](#) method) or into the [MetadataLoadContext](#) in .NET Core.

Generating reference assemblies

Generating reference assemblies for your libraries can be useful when your library consumers need to build their programs against many different versions of the library. Distributing implementation assemblies for all these versions might be impractical

because of their large size. Reference assemblies are smaller in size, and distributing them as a part of your library's SDK reduces download size and saves disk space.

IDEs and build tools also can take advantage of reference assemblies to reduce build times in case of large solutions consisting of multiple class libraries. Usually, in incremental build scenarios a project is rebuilt when any of its input files are changed, including the assemblies it depends on. The implementation assembly changes whenever the programmer changes the implementation of any member. The reference assembly only changes when its public API is affected. So, using the reference assembly as an input file instead of the implementation assembly allows skipping the build of the dependent project in some cases.

You can generate reference assemblies:

- In an MSBuild project, by using the [ProduceReferenceAssembly](#) project property.
- When compiling program from command line, by specifying `-refonly` ([C# / Visual Basic](#)) or `-refout` ([C# / Visual Basic](#)) compiler options.
- When using the Roslyn API, by setting `EmitOptions.EmitMetadataOnly` to `true` and `EmitOptions.IncludePrivateMembers` to `false` in an object passed to the `Compilation.Emit` method.

If you want to distribute reference assemblies with NuGet packages, you must include them in the `ref\` subdirectory under the package directory instead of in the `lib\` subdirectory used for implementation assemblies.

Reference assemblies structure

Reference assemblies are an expansion of the related concept, *metadata-only assemblies*. Metadata-only assemblies have their method bodies replaced with a single `throw null` body, but include all members except anonymous types. The reason for using `throw null` bodies (as opposed to no bodies) is so that `PEVerify` can run and pass (thus validating the completeness of the metadata).

Reference assemblies further remove metadata (private members) from metadata-only assemblies:

- A reference assembly only has references for what it needs in the API surface. The real assembly may have additional references related to specific implementations. For instance, the reference assembly for `class C { private void M() { dynamic d = 1; ... } }` doesn't reference any types required for `dynamic`.
- Private function-members (methods, properties, and events) are removed in cases where their removal doesn't observably impact compilation. If there are no

`InternalsVisibleTo` attributes, internal function members are also removed.

The metadata in reference assemblies continues to keep the following information:

- All types, including private and nested types.
- All attributes, even internal ones.
- All virtual methods.
- Explicit interface implementations.
- Explicitly implemented properties and events, because their accessors are virtual.
- All fields of structures.

Reference assemblies include an assembly-level `ReferenceAssembly` attribute. This attribute may be specified in source; then the compiler won't need to synthesize it. Because of this attribute, runtimes will refuse to load reference assemblies for execution (but they can be loaded in reflection-only mode).

Exact reference assembly structure details depend on the compiler version. Newer versions may choose to exclude more metadata if it's determined as not affecting the public API surface.

Note

Information in this section is applicable only to reference assemblies generated by Roslyn compilers starting from C# version 7.1 or Visual Basic version 15.3. The structure of reference assemblies for .NET Framework and .NET Core libraries can differ in some details, because they use their own mechanism of generating reference assemblies. For example, they might have totally empty method bodies instead of the `throw null` body. But the general principle still applies: they don't have usable method implementations and contain metadata only for members that have an observable impact from a public API perspective.

Resolve assembly loads

Article • 09/15/2021

.NET provides the [AppDomain.AssemblyResolve](#) event for applications that require greater control over assembly loading. By handling this event, your application can load an assembly into the load context from outside the normal probing paths, select which of several assembly versions to load, emit a dynamic assembly and return it, and so on. This topic provides guidance for handling the [AssemblyResolve](#) event.

ⓘ Note

For resolving assembly loads in the reflection-only context, use the [AppDomain.ReflectionOnlyAssemblyResolve](#) event instead.

How the AssemblyResolve event works

When you register a handler for the [AssemblyResolve](#) event, the handler is invoked whenever the runtime fails to bind to an assembly by name. For example, calling the following methods from user code can cause the [AssemblyResolve](#) event to be raised:

- An [AppDomain.Load](#) method overload or [Assembly.Load](#) method overload whose first argument is a string that represents the display name of the assembly to load (that is, the string returned by the [Assembly.FullName](#) property).
- An [AppDomain.Load](#) method overload or [Assembly.Load](#) method overload whose first argument is an [AssemblyName](#) object that identifies the assembly to load.
- An [Assembly.LoadWithPartialName](#) method overload.
- An [AppDomain.CreateInstance](#) or [AppDomain.CreateInstanceAndUnwrap](#) method overload that instantiates an object in another application domain.

What the event handler does

The handler for the [AssemblyResolve](#) event receives the display name of the assembly to be loaded, in the [ResolveEventArgs.Name](#) property. If the handler does not recognize the assembly name, it returns `null` (C#), `Nothing` (Visual Basic), or `nullptr` (Visual C++).

If the handler recognizes the assembly name, it can load and return an assembly that satisfies the request. The following list describes some sample scenarios.

- If the handler knows the location of a version of the assembly, it can load the assembly by using the [Assembly.LoadFrom](#) or [Assembly.LoadFile](#) method, and can return the loaded assembly if successful.
- If the handler has access to a database of assemblies stored as byte arrays, it can load a byte array by using one of the [Assembly.Load](#) method overloads that take a byte array.
- The handler can generate a dynamic assembly and return it.

 **Note**

The handler must load the assembly into the load-from context, into the load context, or without context. If the handler loads the assembly into the reflection-only context by using the [Assembly.ReflectionOnlyLoad](#) or the [Assembly.ReflectionOnlyLoadFrom](#) method, the load attempt that raised the [AssemblyResolve](#) event fails.

It is the responsibility of the event handler to return a suitable assembly. The handler can parse the display name of the requested assembly by passing the [ResolveEventArgs.Name](#) property value to the [AssemblyName\(String\)](#) constructor. Beginning with the .NET Framework 4, the handler can use the [ResolveEventArgs.RequestingAssembly](#) property to determine whether the current request is a dependency of another assembly. This information can help identify an assembly that will satisfy the dependency.

The event handler can return a different version of the assembly than the version that was requested.

In most cases, the assembly that is returned by the handler appears in the load context, regardless of the context the handler loads it into. For example, if the handler uses the [Assembly.LoadFrom](#) method to load an assembly into the load-from context, the assembly appears in the load context when the handler returns it. However, in the following case the assembly appears without context when the handler returns it:

- The handler loads an assembly without context.
- The [ResolveEventArgs.RequestingAssembly](#) property is not null.
- The requesting assembly (that is, the assembly that is returned by the [ResolveEventArgs.RequestingAssembly](#) property) was loaded without context.

For information about contexts, see the [Assembly.LoadFrom\(String\)](#) method overload.

Multiple versions of the same assembly can be loaded into the same application domain. This practice is not recommended, because it can lead to type assignment problems. See [Best practices for assembly loading](#).

What the event handler should not do

The primary rule for handling the [AssemblyResolve](#) event is that you should not try to return an assembly you do not recognize. When you write the handler, you should know which assemblies might cause the event to be raised. Your handler should return null for other assemblies.

Important

Beginning with the .NET Framework 4, the [AssemblyResolve](#) event is raised for satellite assemblies. This change affects an event handler that was written for an earlier version of the .NET Framework, if the handler tries to resolve all assembly load requests. Event handlers that ignore assemblies they do not recognize are not affected by this change: They return `null`, and normal fallback mechanisms are followed.

When loading an assembly, the event handler must not use any of the [AppDomain.Load](#) or [Assembly.Load](#) method overloads that can cause the [AssemblyResolve](#) event to be raised recursively, because this can lead to a stack overflow. (See the list provided earlier in this topic.) This happens even if you provide exception handling for the load request, because no exception is thrown until all event handlers have returned. Thus, the following code results in a stack overflow if `MyAssembly` is not found:

C#

```
using System;
using System.Reflection;

class BadExample
{
    static void Main()
    {
        AppDomain ad = AppDomain.CreateDomain("Test");
        ad.AssemblyResolve += MyHandler;

        try
        {
            object obj = ad.CreateInstanceAndUnwrap(
                "MyAssembly, version=1.2.3.4, culture=neutral,
                publicKeyToken=null",
```

```

        "MyType");
    }
    catch (Exception ex)
    {
        Console.WriteLine(ex.Message);
    }
}

static Assembly MyHandler(object source, ResolveEventArgs e)
{
    Console.WriteLine("Resolving {0}", e.Name);
    // DO NOT DO THIS: This causes a StackOverflowException
    return Assembly.Load(e.Name);
}
}

/* This example produces output similar to the following:

Resolving MyAssembly, Version=1.2.3.4, Culture=neutral, PublicKeyToken=null
Resolving MyAssembly, Version=1.2.3.4, Culture=neutral, PublicKeyToken=null
...
Resolving MyAssembly, Version=1.2.3.4, Culture=neutral, PublicKeyToken=null
Resolving MyAssembly, Version=1.2.3.4, Culture=neutral, PublicKeyToken=null

Process is terminated due to StackOverflowException.
*/

```

The correct way to handle AssemblyResolve

When resolving assemblies from the `AssemblyResolve` event handler, a `StackOverflowException` will eventually be thrown if the handler uses the `Assembly.Load` or `AppDomain.Load` method calls. Instead, use `LoadFile` or `LoadFrom` methods, as they do not raise the `AssemblyResolve` event.

Imagine that `MyAssembly.dll` is located near the executing assembly, in a known location, it can be resolved using `Assembly.LoadFile` given the path to the assembly.

C#

```

using System;
using System.IO;
using System.Reflection;

class CorrectExample
{
    static void Main()
    {
        AppDomain ad = AppDomain.CreateDomain("Test");
        ad.AssemblyResolve += MyHandler;
    }
}

static Assembly MyHandler(object source, ResolveEventArgs e)
{
    Console.WriteLine("Resolving {0}", e.Name);
    // DO NOT DO THIS: This causes a StackOverflowException
    return Assembly.Load(e.Name);
}

```

```
try
{
    object obj = ad.CreateInstanceAndUnwrap(
        "MyAssembly", version=1.2.3.4, culture=neutral,
publicKeyToken=null",
        "MyType");
}
catch (Exception ex)
{
    Console.WriteLine(ex.Message);
}
}

static Assembly MyHandler(object source, ResolveEventArgs e)
{
    Console.WriteLine("Resolving {0}", e.Name);

    var path = Path.GetFullPath("../..\\MyAssembly.dll");
    return Assembly.LoadFile(path);
}
}
```

Create assemblies

Article • 09/15/2021

You can create single-file or multifile assemblies using an IDE, such as Visual Studio, or the compilers and tools provided by the Windows SDK. The simplest assembly is a single file that has a simple name and is loaded into a single application domain. This assembly cannot be referenced by other assemblies outside the application directory and does not undergo version checking. To uninstall the application made up of the assembly, you simply delete the directory where it resides. For many developers, an assembly with these features is all that is needed to deploy an application.

You can create a multifile assembly from several code modules and resource files. You can also create an assembly that can be shared by multiple applications. A shared assembly must have a strong name and can be deployed in the global assembly cache.

You have several options when grouping code modules and resources into assemblies, depending on the following factors:

- **Versioning**

Group modules that should have the same version information.

- **Deployment**

Group code modules and resources that support your model of deployment.

- **Reuse**

Group modules if they can be logically used together for some purpose. For example, an assembly consisting of types and classes used infrequently for program maintenance can be put in the same assembly. In addition, types that you intend to share with multiple applications should be grouped into an assembly and the assembly should be signed with a strong name.

- **Security**

Group modules containing types that require the same security permissions.

- **Scoping**

Group modules containing types whose visibility should be restricted to the same assembly.

There are special considerations when making common language runtime assemblies available to unmanaged COM applications. For more information about working with unmanaged code, see [Expose .NET Framework components to COM](#).

Assembly names

Article • 09/15/2021

An assembly's name is stored in metadata and has a significant impact on the assembly's scope and use by an application. A strong-named assembly has a fully qualified name that includes the assembly's name, culture, public key, version number, and, optionally, processor architecture. Use the [FullName](#) property to obtain the fully qualified name, frequently referred to as the display name, for loaded assemblies.

The runtime uses the name information to locate the assembly and differentiate it from other assemblies with the same name. For example, a strong-named assembly called `myTypes` could have the following fully qualified name:

```
myTypes, Version=1.0.1234.0, Culture=en-US,  
PublicKeyToken=b77a5c561934e089c, ProcessorArchitecture=msil
```

In this example, the fully qualified name indicates that the `myTypes` assembly has a strong name with a public key token, has the culture value for United States English, and has a version number of 1.0.1234.0. Its processor architecture is `msil`, which means that it will be just-in-time (JIT)-compiled to 32-bit code or 64-bit code depending on the operating system and processor.

Tip

The `ProcessorArchitecture` information allows processor-specific versions of assemblies. You can create versions of an assembly whose identity differs only by processor architecture, for example 32-bit and 64-bit processor-specific versions. Processor architecture is not required for strong names. For more information, see [AssemblyName.ProcessorArchitecture](#).

Code that requests types in an assembly must use a fully qualified assembly name. This is called fully qualified binding. Partial binding, which specifies only an assembly name, is not permitted when referencing assemblies in .NET Framework.

All assembly references to assemblies that make up .NET Framework must also contain the fully qualified name of the assembly. For example, a reference to the `System.Data` .NET Framework assembly for version 1.0 would include:

```
System.data, version=1.0.3300.0, Culture=neutral,  
PublicKeyToken=b77a5c561934e089
```

The version corresponds to the version number of all .NET Framework assemblies that shipped with .NET Framework version 1.0. For .NET Framework assemblies, the culture value is always neutral, and the public key is the same as shown in the above example.

For example, to add an assembly reference in a configuration file to set up a trace listener, you would include the fully qualified name of the system .NET Framework assembly:

XML

```
<add name="myListener" type="System.Diagnostics.TextWriterTraceListener,  
System, Version=1.0.3300.0, Culture=neutral,  
PublicKeyToken=b77a5c561934e089" initializeData="c:\myListener.log" />
```

ⓘ Note

The runtime treats assembly names as case-insensitive when binding to an assembly, but preserves whatever case is used in an assembly name. Several tools in the Windows SDK handle assembly names as case-sensitive. For best results, manage assembly names as though they were case-sensitive.

Name application components

The runtime does not consider the file name when determining an assembly's identity. The assembly identity, which consists of the assembly name, version, culture, and strong name, must be clear to the runtime.

For example, if you have an assembly called *myAssembly.exe* that references an assembly called *myAssembly.dll*, binding occurs correctly if you execute *myAssembly.exe*. However, if another application executes *myAssembly.exe* using the method [AppDomain.ExecuteAssembly](#), the runtime determines that `myAssembly` is already loaded when *myAssembly.exe* requests binding to `myAssembly`. In this case, *myAssembly.dll* is never loaded. Because *myAssembly.exe* does not contain the requested type, a [TypeLoadException](#) occurs.

To avoid this problem, make sure the assemblies that make up your application do not have the same assembly name or place assemblies with the same name in different directories.

Note

In .NET Framework, if you put a strong-named assembly in the global assembly cache, the assembly's file name must match the assembly name, not including the file name extension, such as `.exe` or `.dll`. For example, if the file name of an assembly is `myAssembly.dll`, the assembly name must be `myAssembly`. Private assemblies deployed only in the root application directory can have an assembly name that is different from the file name.

How to: Find an assembly's fully qualified name

Article • 09/15/2021

To discover the fully qualified name of a .NET Framework assembly in the global assembly cache, use the Global Assembly Cache tool ([Gacutil.exe](#)). See [How to: View the contents of the global assembly cache](#).

For .NET Core assemblies, and for .NET Framework assemblies that aren't in the global assembly cache, you can get the fully qualified assembly name in a number of ways:

- You can use code to output the information to the console or to a variable, or you can use the [Ildasm.exe \(IL Disassembler\)](#) to examine the assembly's metadata, which contains the fully qualified name.
- If the assembly is already loaded by the application, you can retrieve the value of the [Assembly.FullName](#) property to get the fully qualified name. You can use the [Assembly](#) property of a [Type](#) defined in that assembly to retrieve a reference to the [Assembly](#) object. The example provides an illustration.
- If you know the assembly's file system path, you can call the `static` (C#) or `shared` (Visual Basic) [AssemblyName.GetAssemblyName](#) method to get the fully qualified assembly name. The following is a simple example.

C#

```
using System;
using System.Reflection;

public class Example
{
    public static void Main()
    {

        Console.WriteLine(AssemblyName.GetAssemblyName(@".\UtilityLibrary.dll"))
    }
}

// The example displays output like the following:
// UtilityLibrary, Version=1.1.0.0, Culture=neutral,
// PublicKeyToken=null
```

- You can use the [Ildasm.exe \(IL Disassembler\)](#) to examine the assembly's metadata, which contains the fully qualified name.

For more information about setting assembly attributes such as version, culture, and assembly name, see [Set assembly attributes](#). For more information about giving an assembly a strong name, see [Create and use strong-named assemblies](#).

Example

The following example shows how to display the fully qualified name of an assembly containing a specified class to the console. It uses the [Type.Assembly](#) property to retrieve a reference to an assembly from a type that's defined in that assembly.

C#

```
using System;
using System.Reflection;

class asmname
{
    public static void Main()
    {
        Type t = typeof(System.Data.DataSet);
        string s = t.Assembly.FullName.ToString();
        Console.WriteLine("The fully qualified assembly name " +
            "containing the specified class is {0}.", s);
    }
}
```

Assembly location

Article • 09/15/2021

An assembly's location determines whether the common language runtime can locate it when referenced, and can also determine whether the assembly can be shared with other assemblies. You can deploy an assembly in the following locations:

- The application's directory or subdirectories.

This is the most common location for deploying an assembly. The subdirectories of an application's root directory can be based on language or culture. If an assembly has information in the culture attribute, it must be in a subdirectory under the application directory with that culture's name.

- The global assembly cache.

This is a machine-wide code cache that is installed wherever the common language runtime is installed. In most cases, if you intend to share an assembly with multiple applications, you should deploy it into the global assembly cache.

- On an HTTP server.

An assembly deployed on an HTTP server must have a strong name; you point to the assembly in the codebase section of the application's configuration file.

Set assembly attributes

Article • 01/18/2023

Assembly attributes are values that provide information about an assembly. They're usually set in an `AssemblyInfo.cs` file. The attributes are divided into the following sets of information:

- Assembly identity attributes
- Informational attributes
- Assembly manifest attributes
- Strong name attributes

Tip

This article is scoped to adding assembly attributes from code. For information on adding assembly attributes to projects (not in code), see [MSBuild reference for .NET SDK projects: Assembly attribute properties](#).

Assembly identity attributes

Three attributes, together with a strong name (if applicable), determine the identity of an assembly: name, version, and culture. These attributes form the full name of the assembly and are required when referencing the assembly in code. You can use attributes to set an assembly's version and culture. The compiler or the [Assembly Linker \(Al.exe\)](#) sets the name value when the assembly is created, based on the file containing the assembly manifest.

The following table describes the version and culture attributes.

| Assembly identity attribute | Description |
|--|--|
| AssemblyCultureAttribute | Enumerated field indicating the culture that the assembly supports. An assembly can also specify culture independence, indicating that it contains the resources for the default culture. Note: The runtime treats any assembly that does not have the culture attribute set to null as a satellite assembly. Such assemblies are subject to satellite assembly binding rules. For more information, see How the runtime locates assemblies . |
| AssemblyFlagsAttribute | Value that sets assembly attributes, such as whether the assembly can be run side by side. |

| Assembly identity attribute | Description |
|--|---|
| AssemblyVersionAttribute | Numeric value in the format <i>major.minor.build.revision</i> (for example, 2.4.0.0). The common language runtime uses this value to perform binding operations in strong-named assemblies. Note: If the AssemblyInformationalVersionAttribute attribute is not applied to an assembly, the version number specified by the AssemblyVersionAttribute attribute is used by the Application.ProductVersion , Application.UserAppDataPath , and Application.UserAppDataRegistry properties. |

The following code example shows how to apply the version and culture attributes to an assembly.

C#

```
// Set version number for the assembly.
[assembly:AssemblyVersionAttribute("4.3.2.1")]
// Set culture as German.
[assembly:AssemblyCultureAttribute("de")]
```

Informational attributes

You can use informational attributes to provide additional company or product information for an assembly. The following table describes the informational attributes you can apply to an assembly.

| Informational attribute | Description |
|---|--|
| AssemblyCompanyAttribute | String value specifying a company name. |
| AssemblyCopyrightAttribute | String value specifying copyright information. |
| AssemblyFileVersionAttribute | String value specifying the Win32 file version number. This normally defaults to the assembly version. |
| AssemblyInformationalVersionAttribute | String value specifying version information that is not used by the common language runtime, such as a full product version number. Note: If this attribute is applied to an assembly, the string it specifies can be obtained at run time by using the Application.ProductVersion property. The string is also used in the path and registry key provided by the Application.UserAppDataPath and Application.UserAppDataRegistry properties. |

| Informational attribute | Description |
|--|--|
| AssemblyProductAttribute | String value specifying product information. |
| AssemblyTrademarkAttribute | String value specifying trademark information. |

These attributes can appear on the Windows Properties page of the assembly, or they can be overridden using the `/win32res` compiler option to specify your Win32 resource file.

Assembly manifest attributes

You can use assembly manifest attributes to provide information in the assembly manifest, including title, description, the default alias, and configuration. The following table describes the assembly manifest attributes.

| Assembly manifest attribute | Description |
|--|---|
| AssemblyConfigurationAttribute | String value indicating the configuration of the assembly, such as Retail or Debug. The runtime does not use this value. |
| AssemblyDefaultAliasAttribute | String value specifying a default alias to be used by referencing assemblies. This value provides a friendly name when the name of the assembly itself is not friendly (such as a GUID value). This value can also be used as a short form of the full assembly name. |
| AssemblyDescriptionAttribute | String value specifying a short description that summarizes the nature and purpose of the assembly. |
| AssemblyTitleAttribute | String value specifying a friendly name for the assembly. For example, an assembly named <code>comdlg</code> might have the title Microsoft Common Dialog Control. |

Strong name attributes

You can use strong name attributes to set a strong name for an assembly. The following table describes the strong name attributes.

| Strong name attribute | Description |
|--|---|
| AssemblyDelaySignAttribute | Boolean value indicating that delay signing is being used. |
| AssemblyKeyFileAttribute | String value indicating the name of the file that contains either the public key (if using delay signing) or both the public and private keys passed as a parameter to the constructor of this attribute. |

| Strong name attribute | Description |
|--|--|
| | Note that the file name is relative to the output file path (the <code>.exe</code> or <code>.dll</code>), not the source file path. |
| AssemblyKeyNameAttribute | Indicates the key container that contains the key pair passed as a parameter to the constructor of this attribute. |

The following code example shows the attributes to apply when using delay signing to create a strong-named assembly with a public key file called `myKey.snk`.

C#

```
[assembly:AssemblyKeyFileAttribute("myKey.snk")]
[assembly:AssemblyDelaySignAttribute(true)]
```

Strong-named assemblies

Article • 09/15/2021

Strong-naming an assembly creates a unique identity for the assembly, and can prevent assembly conflicts.

What makes a strong-named assembly?

A strong named assembly is generated by using the private key that corresponds to the public key distributed with the assembly, and the assembly itself. The assembly includes the assembly manifest, which contains the names and hashes of all the files that make up the assembly. Assemblies that have the same strong name should be identical.

You can strong-name assemblies by using Visual Studio or a command-line tool. For more information, see [How to: Sign an assembly with a strong name](#) or [Sn.exe \(Strong Name tool\)](#).

When a strong-named assembly is created, it contains the simple text name of the assembly, the version number, optional culture information, a digital signature, and the public key that corresponds to the private key used for signing.

⚠ Warning

Do not rely on strong names for security. They provide a unique identity only.

Why strong-name your assemblies?

For .NET Framework, strong-named assemblies are useful in the following scenarios:

- You want to enable your assemblies to be referenced by strong-named assemblies, or you want to give `friend` access to your assemblies from other strong-named assemblies.
- An app needs access to different versions of the same assembly. This means you need different versions of an assembly to load side by side in the same app domain without conflict. For example, if different extensions of an API exist in assemblies that have the same simple name, strong-naming provides a unique identity for each version of the assembly.

- You do not want to negatively affect performance of apps using your assembly, so you want the assembly to be domain neutral. This requires strong-naming because a domain-neutral assembly must be installed in the global assembly cache.
- You want to centralize servicing for your app by applying publisher policy, which means the assembly must be installed in the global assembly cache.

For .NET Core and .NET 5+, strong-named assemblies do not provide material benefits. The runtime never validates the strong-name signature, nor does it use the strong-name for assembly binding.

If you are an open-source developer and you want the identity benefits of a strong-named assembly for better compatibility with .NET Framework, consider checking in the private key associated with an assembly to your source control system.

Create and use strong-named assemblies

Article • 09/15/2021

A strong name consists of the assembly's identity—its simple text name, version number, and culture information (if provided)—plus a public key and a digital signature. It is generated from an assembly file using the corresponding private key. (The assembly file contains the assembly manifest, which contains the names and hashes of all the files that make up the assembly.)

⚠ Warning

Do not rely on strong names for security. They provide a unique identity only.

A strong-named assembly can only use types from other strong-named assemblies. Otherwise, the integrity of the strong-named assembly would be compromised.

ⓘ Note

Although .NET Core supports strong-named assemblies, and all assemblies in the .NET Core library are signed, the majority of third-party assemblies do not need strong names. For more information, see [Strong Name Signing](#) on GitHub.

Strong name scenario

The following scenario outlines the process of signing an assembly with a strong name and later referencing it by that name.

1. Assembly A is created with a strong name using one of the following methods:

- Using a development environment that supports creating strong names, such as Visual Studio.
- Creating a cryptographic key pair using the [Strong Name tool \(Sn.exe\)](#) and assigning that key pair to the assembly using either a command-line compiler or the [Assembly Linker \(Al.exe\)](#). The Windows SDK provides both Sn.exe and Al.exe.

2. The development environment or tool signs the hash of the file containing the assembly's manifest with the developer's private key. This digital signature is stored in the portable executable (PE) file that contains Assembly A's manifest.
3. Assembly B is a consumer of Assembly A. The reference section of Assembly B's manifest includes a token that represents Assembly A's public key. A token is a portion of the full public key and is used rather than the key itself to save space.
4. The common language runtime verifies the strong name signature when the assembly is placed in the global assembly cache. When binding by strong name at run time, the common language runtime compares the key stored in Assembly B's manifest with the key used to generate the strong name for Assembly A. If the .NET security checks pass and the bind succeeds, Assembly B has a guarantee that Assembly A's bits have not been tampered with and that these bits actually come from the developers of Assembly A.

 **Note**

This scenario doesn't address trust issues. Assemblies can carry full Microsoft Authenticode signatures in addition to a strong name. Authenticode signatures include a certificate that establishes trust. It's important to note that strong names don't require code to be signed in this way. Strong names only provide a unique identity.

Bypass signature verification of trusted assemblies

Starting with the .NET Framework 3.5 Service Pack 1, strong-name signatures are not validated when an assembly is loaded into a full-trust application domain, such as the default application domain for the `MyComputer` zone. This is referred to as the strong-name bypass feature. In a full-trust environment, demands for [StrongNameIdentityPermission](#) always succeed for signed, full-trust assemblies, regardless of their signature. The strong-name bypass feature avoids the unnecessary overhead of strong-name signature verification of full-trust assemblies in this situation, allowing the assemblies to load faster.

The bypass feature applies to any assembly that is signed with a strong name and that has the following characteristics:

- Fully trusted without [StrongName](#) evidence (for example, has `MyComputer` zone evidence).
- Loaded into a fully trusted [AppDomain](#).
- Loaded from a location under the [ApplicationBase](#) property of that [AppDomain](#).
- Not delay-signed.

This feature can be disabled for individual applications or for a computer. See [How to: Disable the strong-name bypass feature](#).

How to: Create a public-private key pair

Article • 09/15/2021

To sign an assembly with a strong name, you must have a public/private key pair. This public and private cryptographic key pair is used during compilation to create a strong-named assembly. You can create a key pair using the [Strong Name tool \(Sn.exe\)](#). Key pair files usually have an *.snk* extension.

ⓘ Note

In Visual Studio, the C# and Visual Basic project property pages include a **Signing** tab that enables you to select existing key files or to generate new key files without using *Sn.exe*. In Visual C++, you can specify the location of an existing key file in the **Advanced** property page in the **Linker** section of the **Configuration Properties** section of the **Property Pages** window. The use of the **AssemblyKeyFileAttribute** attribute to identify key file pairs was made obsolete beginning with Visual Studio 2005.

Create a key pair

To create a key pair, at a command prompt, type the following command:

```
sn -k <file name>
```

In this command, *file name* is the name of the output file containing the key pair.

The following example creates a key pair called *sgKey.snk*.

```
Windows Command Prompt
```

```
sn -k sgKey.snk
```

If you intend to delay sign an assembly and you control the whole key pair (which is unlikely outside test scenarios), you can use the following commands to generate a key pair and then extract the public key from it into a separate file. First, create the key pair:

```
Windows Command Prompt
```

```
sn -k keypair.snk
```

Next, extract the public key from the key pair and copy it to a separate file:

```
Windows Command Prompt
```

```
sn -p keypair.snk public.snk
```

Once you create the key pair, you must put the file where the strong name signing tools can find it.

When signing an assembly with a strong name, the [Assembly Linker \(Al.exe\)](#) looks for the key file relative to the current directory and to the output directory. When using command-line compilers, you can simply copy the key to the current directory containing your code modules.

If you are using an earlier version of Visual Studio that does not have a **Signing** tab in the project properties, the recommended key file location is the project directory with the file attribute specified as follows:

```
C#
```

```
[assembly:AssemblyKeyFileAttribute("keyfile.snk")]
```

How to: Sign an assembly with a strong name

Article • 08/31/2022

ⓘ Note

Although .NET Core supports strong-named assemblies, and all assemblies in the .NET Core library are signed, the majority of third-party assemblies do not need strong names. For more information, see [Strong Name Signing](#) on GitHub.

There are a number of ways to sign an assembly with a strong name:

- By using the [Build > Strong naming](#) page in the [project designer](#) for a project in Visual Studio. This is the easiest and most convenient way to sign an assembly with a strong name.
- By using the [Assembly Linker \(Al.exe\)](#) to link a .NET Framework code module (a *.netmodule* file) with a key file.
- By using assembly attributes to insert the strong name information into your code. You can use either the [AssemblyKeyFileAttribute](#) or the [AssemblyKeyNameAttribute](#) attribute, depending on where the key file to be used is located.
- By using compiler options.

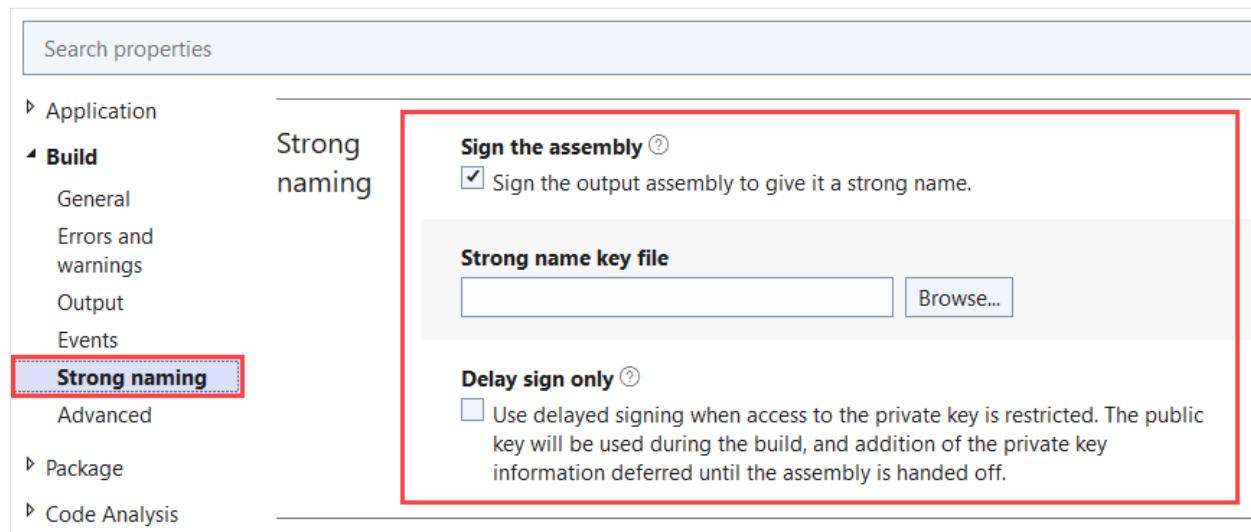

You must have a cryptographic key pair to sign an assembly with a strong name. For more information about creating a key pair, see [How to: Create a public-private key pair](#).

Create and sign an assembly with a strong name by using Visual Studio

1. In **Solution Explorer**, open the shortcut menu for the project, and then choose **Properties**.
2. Under the **Build** tab you'll find a **Strong naming** node.
3. Select the **Sign the assembly** checkbox, which expands the options.
4. Select the **Browse** button to choose a **Strong name key file** path.

ⓘ Note

In order to **delay sign** an assembly, choose a public key file.

Create and sign an assembly with a strong name by using the Assembly Linker

Open [Visual Studio Developer Command Prompt](#) or [Visual Studio Developer PowerShell](#), and enter the following command:

```
al /out:<assemblyName> <moduleName> /keyfile:<keyfileName>
```

Where:

- *assemblyName* is the name of the strongly signed assembly (a *.dll* or *.exe* file) that Assembly Linker will emit.
- *moduleName* is the name of a .NET Framework code module (a *.netmodule* file) that includes one or more types. You can create a *.netmodule* file by compiling your code with the `/target:module` switch in C# or Visual Basic.
- *keyfileName* is the name of the container or file that contains the key pair. Assembly Linker interprets a relative path in relation to the current directory.

The following example signs the assembly *MyAssembly.dll* with a strong name by using the key file *sgKey.snk*.

```
Console  
al /out:MyAssembly.dll MyModule.netmodule /keyfile:sgKey.snk
```

For more information about this tool, see [Assembly Linker](#).

Sign an assembly with a strong name by using attributes

1. Add the [System.Reflection.AssemblyKeyFileAttribute](#) or [AssemblyKeyNameAttribute](#) attribute to your source code file, and specify the name of the file or container that contains the key pair to use when signing the assembly with a strong name.

2. Compile the source code file normally.

 **Note**

The C# and Visual Basic compilers issue compiler warnings (CS1699 and BC41008, respectively) when they encounter the [AssemblyKeyFileAttribute](#) or [AssemblyKeyNameAttribute](#) attribute in source code. You can ignore the warnings.

The following example uses the [AssemblyKeyFileAttribute](#) attribute with a key file called *keyfile.snk*, which is located in the directory where the assembly is compiled.

C#

```
[assembly:AssemblyKeyFileAttribute("keyfile.snk")]
```

You can also delay sign an assembly when compiling your source file. For more information, see [Delay-sign an assembly](#).

Sign an assembly with a strong name by using the compiler

Compile your source code file or files with the `/keyfile` or `/delaysign` compiler option in C# and Visual Basic, or the `/KEYFILE` or `/DELAYSIGN` linker option in C++. After the option name, add a colon and the name of the key file. When using command-line compilers, you can copy the key file to the directory that contains your source code files.

For information on delay signing, see [Delay-sign an assembly](#).

The following example uses the C# compiler and signs the assembly *UtilityLibrary.dll* with a strong name by using the key file *sgKey.snk*.

Windows Command Prompt

```
csc /t:library UtilityLibrary.cs /keyfile:sgKey.snk
```

Enhanced strong naming

Article • 08/23/2022

A strong name signature is an identity mechanism in the .NET Framework for identifying assemblies. It is a public-key digital signature that is typically used to verify the integrity of data being passed from an originator (signer) to a recipient (verifier). This signature is used as a unique identity for an assembly and ensures that references to the assembly are not ambiguous. The assembly is signed as part of the build process and then verified when it is loaded.

Strong name signatures help prevent malicious parties from tampering with an assembly and then re-signing the assembly with the original signer's key. However, strong name keys don't contain any reliable information about the publisher, nor do they contain a certificate hierarchy. A strong name signature does not guarantee the trustworthiness of the person who signed the assembly or indicate whether that person was a legitimate owner of the key; it indicates only that the owner of the key signed the assembly. Therefore, we do not recommend using a strong name signature as a security validator for trusting third-party code. Microsoft Authenticode is the recommended way to authenticate code.

Limitations of conventional strong names

The strong naming technology used in versions before the .NET Framework 4.5 has the following shortcomings:

- Keys are constantly under attack, and improved techniques and hardware make it easier to infer a private key from a public key. To guard against attacks, larger keys are necessary. .NET Framework versions before the .NET Framework 4.5 provide the ability to sign with any size key (the default size is 1024 bits), but signing an assembly with a new key breaks all binaries that reference the older identity of the assembly. Therefore, it is extremely difficult to upgrade the size of a signing key if you want to maintain compatibility.
- Strong name signing supports only the SHA-1 algorithm. SHA-1 has recently been found to be inadequate for secure hashing applications. Therefore, a stronger algorithm (SHA-256 or greater) is necessary. It is possible that SHA-1 will lose its FIPS-compliant standing, which would present problems for those who choose to use only FIPS-compliant software and algorithms.

Advantages of enhanced strong names

The main advantages of enhanced strong names are compatibility with pre-existing strong names and the ability to claim that one identity is equivalent to another:

- Developers who have pre-existing signed assemblies can migrate their identities to the SHA-2 algorithms while maintaining compatibility with assemblies that reference the old identities.
- Developers who create new assemblies and are not concerned with pre-existing strong name signatures can use the more secure SHA-2 algorithms and sign the assemblies as they always have.

Use enhanced strong names

Strong name keys consist of a signature key and an identity key. The assembly is signed with the signature key and is identified by the identity key. Prior to .NET Framework 4.5, these two keys were identical. Starting with .NET Framework 4.5, the identity key remains the same as in earlier .NET Framework versions, but the signature key is enhanced with a stronger hash algorithm. In addition, the signature key is signed with the identity key to create a counter-signature.

The [AssemblySignatureKeyAttribute](#) attribute enables the assembly metadata to use the pre-existing public key for assembly identity, which allows old assembly references to continue to work. The [AssemblySignatureKeyAttribute](#) attribute uses the counter-signature to ensure that the owner of the new signature key is also the owner of the old identity key.

Sign with SHA-2, without key migration

Run the following commands from a command prompt to sign an assembly without migrating a strong name signature:

1. Generate the new identity key (if necessary).

```
Console  
sn -k IdentityKey.snk
```

2. Extract the identity public key, and specify that a SHA-2 algorithm should be used when signing with this key.

```
Console
```

```
sn -p IdentityKey.snk IdentityPubKey.snk sha256
```

3. Delay-sign the assembly with the identity public key file.

Console

```
csc MyAssembly.cs /keyfile:IdentityPubKey.snk /delaySign+
```

4. Re-sign the assembly with the full identity key pair.

Console

```
sn -Ra MyAssembly.exe IdentityKey.snk
```

Sign with SHA-2, with key migration

Run the following commands from a command prompt to sign an assembly with a migrated strong name signature.

1. Generate an identity and signature key pair (if necessary).

Console

```
sn -k IdentityKey.snk  
sn -k SignatureKey.snk
```

2. Extract the signature public key, and specify that a SHA-2 algorithm should be used when signing with this key.

Console

```
sn -p SignatureKey.snk SignaturePubKey.snk sha256
```

3. Extract the identity public key, which determines the hash algorithm that generates a counter-signature.

Console

```
sn -p IdentityKey.snk IdentityPubKey.snk
```

4. Generate the parameters for an [AssemblySignatureKeyAttribute](#) attribute, and attach the attribute to the assembly.

Console

```
sn -a IdentityPubKey.snk IdentityKey.snk SignaturePubKey.snk
```

This produces output similar to the following.

Output

```
Information for key migration attribute.  
(System.Reflection.AssemblySignatureKeyAttribute):  
publicKey=  
002400000c8000094000000602000002400052534131004000010001005a3a81

729d34e954a97cddce66e3ae5fec2c682e57b7442738"  
)]
```

5. Delay-sign the assembly with the identity public key.

Console

```
csc MyAssembly.cs /keyfile:IdentityPubKey.snk /delaySign+
```

6. Fully sign the assembly with the signature key pair.

Console

```
sn -Ra MyAssembly.exe SignatureKey.snk
```

How to: Reference a strong-named assembly

Article • 09/15/2021

The process for referencing types or resources in a strong-named assembly is usually transparent. You can make the reference either at compile time (early binding) or at run time.

A compile-time reference occurs when you indicate to the compiler that the assembly to be compiled explicitly references another assembly. When you use compile-time referencing, the compiler automatically gets the public key of the targeted strong-named assembly and places it in the assembly reference of the assembly being compiled.

ⓘ Note

A strong-named assembly can only use types from other strong-named assemblies. Otherwise, the security of the strong-named assembly would be compromised.

Make a compile-time reference to a strong-named assembly

At a command prompt, type the following command:

`<compiler command> /reference:<assembly name>`

In this command, *compiler command* is the compiler command for the language you are using, and *assembly name* is the name of the strong-named assembly being referenced. You can also use other compiler options, such as the `/t:library` option for creating a library assembly.

The following example creates an assembly called *myAssembly.dll* that references a strong-named assembly called *myLibAssembly.dll* from a code module called *myAssembly.cs*.

Windows Command Prompt

```
csc /t:library myAssembly.cs /reference:myLibAssembly.dll
```

Make a run-time reference to a strong-named assembly

When you make a run-time reference to a strong-named assembly, for example by using the [Assembly.Load](#) or [Assembly.GetType](#) method, you must use the display name of the referenced strong-named assembly. The syntax of a display name is as follows:

<assembly name>, <version number>, <culture>, <public key token>

For example:

Console

```
myDll, Version=1.1.0.0, Culture=en, PublicKeyToken=03689116d3a4ae33
```

In this example, `PublicKeyToken` is the hexadecimal form of the public key token. If there is no culture value, use `Culture=neutral`.

The following code example shows how to use this information with the [Assembly.Load](#) method.

C#

```
Assembly myDll =  
    Assembly.Load("myDll, Version=1.0.0.1, Culture=neutral,  
    PublicKeyToken=9b35aa32c18d4fb1");
```

You can print the hexadecimal format of the public key and public key token for a specific assembly by using the following [Strong Name \(Sn.exe\)](#) command:

`sn -Tp <assembly>`

If you have a public key file, you can use the following command instead (note the difference in case on the command-line option):

`sn -tp <public key file>`

How to: Disable the strong-name bypass feature

Article • 09/15/2021

Starting with the .NET Framework version 3.5 Service Pack 1 (SP1), strong-name signatures are not validated when an assembly is loaded into a full-trust [AppDomain](#) object, such as the default [AppDomain](#) for the `MyComputer` zone. This is referred to as the strong-name bypass feature. In a full-trust environment, demands for [StrongNameIdentityPermission](#) always succeed for signed, full-trust assemblies regardless of their signature. The only restriction is that the assembly must be fully trusted because its zone is fully trusted. Because the strong name is not a determining factor under these conditions, there is no reason for it to be validated. Bypassing the validation of strong-name signatures provides significant performance improvements.

The bypass feature applies to any full-trust assembly that is not delay-signed and that is loaded into any full-trust [AppDomain](#) from the directory specified by its [ApplicationBase](#) property.

You can override the bypass feature for all applications on a computer by setting a registry key value. You can override the setting for a single application by using an application configuration file. You cannot reinstate the bypass feature for a single application if it has been disabled by the registry key.

When you override the bypass feature, the strong name is validated only for correctness; it is not checked for a [StrongNameIdentityPermission](#). If you want to confirm a specific strong name, you have to perform that check separately.

Important

The ability to force strong-name validation depends on a registry key, as described in the following procedure. If an application is running under an account that does not have access control list (ACL) permission to access that registry key, the setting is ineffective. You must ensure that ACL rights are configured for this key so that it can be read for all assemblies.

Disable the strong-name bypass feature for all applications

- On 32-bit computers, in the system registry, create a DWORD entry with a value of 0 named `AllowStrongNameBypass` under the `HKEY_LOCAL_MACHINE\SOFTWARE\Microsoft\.NETFramework` key.
- On 64-bit computers, in the system registry, create a DWORD entry with a value of 0 named `AllowStrongNameBypass` under the `HKEY_LOCAL_MACHINE\SOFTWARE\Microsoft\.NETFramework` and `HKEY_LOCAL_MACHINE\SOFTWARE\Wow6432Node\Microsoft\.NETFramework` keys.

Disable the strong-name bypass feature for a single application

1. Open or create the application configuration file.

For more information about this file, see the Application Configuration Files section in [Configure apps](#).

2. Add the following entry:

XML

```
<configuration>
  <runtime>
    <bypassTrustedAppStrongNames enabled="false" />
  </runtime>
</configuration>
```

You can restore the bypass feature for the application by removing the configuration file setting or by setting the attribute to `true`.

ⓘ Note

You can turn strong-name validation on and off for an application only if the bypass feature is enabled for the computer. If the bypass feature has been turned off for the computer, strong names are validated for all applications and you cannot bypass validation for a single application.

Delay-sign an assembly

Article • 04/29/2022

An organization can have a closely guarded key pair that developers can't access on a daily basis. The public key is often available, but access to the private key is restricted to only a few individuals. When developing assemblies with strong names, each assembly that references the strong-named target assembly contains the token of the public key used to give the target assembly a strong name. This requires that the public key be available during the development process.

You can use delayed or partial signing at build time to reserve space in the portable executable (PE) file for the strong name signature, but defer the actual signing until some later stage, usually just before shipping the assembly.

To delay-sign an assembly:

1. Get the public key portion of the key pair from the organization that will do the eventual signing. Typically this key is in the form of an `.snk` file, which can be created using the [Strong Name tool \(Sn.exe\)](#) provided by the Windows SDK.
2. Annotate the source code for the assembly with two custom attributes from [System.Reflection](#):
 - [AssemblyKeyFileAttribute](#), which passes the name of the file containing the public key as a parameter to its constructor.
 - [AssemblyDelaySignAttribute](#), which indicates that delay signing is being used by passing `true` as a parameter to its constructor.

For example:

C#

```
[assembly:AssemblyKeyFileAttribute("myKey.snk")]
[assembly:AssemblyDelaySignAttribute(true)]
```

3. The compiler inserts the public key into the assembly manifest and reserves space in the PE file for the full strong name signature. The real public key must be stored while the assembly is built so that other assemblies that reference this assembly can obtain the key to store in their own assembly reference.
4. Because the assembly does not have a valid strong name signature, the verification of that signature must be turned off. You can do this by using the `-Vr` option with

the Strong Name tool.

The following example turns off verification for an assembly called *myAssembly.dll*.

Console

```
sn -Vr myAssembly.dll
```

To turn off verification on platforms where you can't run the Strong Name tool, such as Advanced RISC Machine (ARM) microprocessors, use the **-Vk** option to create a registry file. Import the registry file into the registry on the computer where you want to turn off verification. The following example creates a registry file for *myAssembly.dll*.

Console

```
sn -Vk myRegFile.reg myAssembly.dll
```

With either the **-Vr** or **-Vk** option, you can optionally include an *.snk* file for test key signing.

⚠ Warning

Do not rely on strong names for security. They provide a unique identity only.

ⓘ Note

If you use delay signing during development with Visual Studio on a 64-bit computer, and you compile an assembly for **Any CPU**, you might have to apply the **-Vr** option twice. (In Visual Studio, **Any CPU** is a value of the **Platform Target** build property; when you compile from the command line, it is the default.) To run your application from the command line or from File Explorer, use the 64-bit version of the [Sn.exe \(Strong Name tool\)](#) to apply the **-Vr** option to the assembly. To load the assembly into Visual Studio at design time (for example, if the assembly contains components that are used by other assemblies in your application), use the 32-bit version of the strong-name tool. This is because the just-in-time (JIT) compiler compiles the assembly to 64-bit native code when the assembly is run from the command line, and to 32-bit native code when the assembly is loaded into the design-time environment.

5. Later, usually just before shipping, you submit the assembly to your organization's signing authority for the actual strong name signing using the `-R` option with the Strong Name tool.

The following example signs an assembly called `myAssembly.dll` with a strong name using the `sgKey.snk` key pair.

Console

```
sn -R myAssembly.dll sgKey.snk
```

How to: View assembly contents

Article • 01/12/2022

You can use the [Illdasm.exe \(IL Disassembler\)](#) to view Microsoft intermediate language (MSIL) information in a file. If the file being examined is an assembly, this information can include the assembly's attributes and references to other modules and assemblies. This information can be helpful in determining whether a file is an assembly or part of an assembly and whether the file has references to other modules or assemblies.

To display the contents of an assembly using *Illdasm.exe*, enter **ildasm <assembly name>** at a command prompt. For example, the following command disassembles the *Hello.exe* assembly.

Windows Command Prompt

```
ildasm Hello.exe
```

To view assembly manifest information, double-click the **Manifest** icon in the MSIL Disassembler window.

Example

The following example starts with a basic "Hello World" program. After compiling the program, use *Illdasm.exe* to disassemble the *Hello.exe* assembly and view the assembly manifest.

C#

```
using System;

class MainApp
{
    public static void Main()
    {
        Console.WriteLine("Hello World using C#!");
    }
}
```

Running the command *ildasm.exe* on the *Hello.exe* assembly and double-clicking the **Manifest** icon in the MSIL Disassembler window produces the following output:

Output

```

// Metadata version: v4.0.30319
.assembly extern mscorel
{
    .publickeytoken = (B7 7A 5C 56 19 34 E0 89 ) //z\V.4..
    .ver 4:0:0:0
}
.assembly Hello
{
    .custom instance void
[mscorel]System.Runtime.CompilerServices.CompilationRelaxationsAttribute::ctor(int32) = ( 01 00 08 00 00 00 00 00 )
    .custom instance void
[mscorel]System.Runtime.CompilerServices.RuntimeCompatibilityAttribute::ctor() = ( 01 00 01 00 54 02 16 57 72 61 70 4E 6F 6E 45 78 //....T..WrapNonEx

63 65 70 74 69 6F 6E 54 68 72 6F 77 73 01 ) // captionThrows.
    .hash algorithm 0x00008004
    .ver 0:0:0:0
}
.module Hello.exe
// MVID: {7C2770DB-1594-438D-BAE5-98764C39CCCA}
.imagebase 0x00400000
.file alignment 0x00000200
.stackreserve 0x00100000
.subsystem 0x0003 // WINDOWS_CUI
.corflags 0x00000001 // ILOONLY
// Image base: 0x00600000

```

The following table describes each directive in the assembly manifest of the *Hello.exe* assembly used in the example:

| Directive | Description |
|-------------------------------------|--|
| .assembly extern <assembly name> | Specifies another assembly that contains items referenced by the current module (in this example, <code>mscorlib</code>). |
| .publickeytoken <token> | Specifies the token of the actual key of the referenced assembly. |
| .ver <version number> | Specifies the version number of the referenced assembly. |
| .assembly <assembly name> | Specifies the assembly name. |
| .hash algorithm <int32 value> | Specifies the hash algorithm used. |
| .ver <version number> | Specifies the version number of the assembly. |

| Directive | Description |
|---------------------|--|
| .module <file name> | Specifies the name of the modules that make up the assembly. In this example, the assembly consists of only one file. |
| .subsystem <value> | Specifies the application environment required for the program. In this example, the value 3 indicates that this executable is run from a console. |
| .corflags | Currently a reserved field in the metadata. |

An assembly manifest can contain a number of different directives, depending on the contents of the assembly. For an extensive list of the directives in the assembly manifest, see the Ecma documentation, especially "Partition II: Metadata Definition and Semantics" and "Partition III: CIL Instruction Set":

Type forwarding in the common language runtime

Article • 10/14/2022

Type forwarding allows you to move a type to another assembly without having to recompile applications that use the original assembly.

For example, suppose an application uses the `Example` class in an assembly named `Utility.dll`. The developers of `Utility.dll` might decide to refactor the assembly, and in the process they might move the `Example` class to another assembly. If the old version of `Utility.dll` is replaced by the new version of `Utility.dll` and its companion assembly, the application that uses the `Example` class fails because it cannot locate the `Example` class in the new version of `Utility.dll`.

The developers of `Utility.dll` can avoid this by forwarding requests for the `Example` class, using the `TypeForwardedToAttribute` attribute. If the attribute has been applied to the new version of `Utility.dll`, requests for the `Example` class are forwarded to the assembly that now contains the class. The existing application continues to function normally, without recompilation.

Forward a type

There are four steps to forwarding a type:

1. Move the source code for the type from the original assembly to the destination assembly.
2. In the assembly where the type used to be located, add a `TypeForwardedToAttribute` for the type that was moved. The following code shows the attribute for a type named `Example` that was moved.

C#

```
[assembly:TypeForwardedToAttribute(typeof(Example))]
```

3. Compile the assembly that now contains the type.
4. Recompile the assembly where the type used to be located, with a reference to the assembly that now contains the type. For example, if you are compiling a C# file from the command line, use the [References \(C# compiler options\)](#) option to

specify the assembly that contains the type. In C++, use the `#using` directive in the source file to specify the assembly that contains the type.

C# type forwarding example

Continuing from the contrived example description above, imagine you're developing the *Utility.dll*, and you have an `Example` class. The *Utility.csproj* is a basic class library:

```
XML

<Project Sdk="Microsoft.NET.Sdk">

    <PropertyGroup>
        <TargetFramework>net6.0</TargetFramework>
        <Nullable>enable</Nullable>
        <ImplicitUsing>true</ImplicitUsing>
    </PropertyGroup>

</Project>
```

The `Example` class provides a few properties and overrides `Object.ToString`:

```
C#

using System;

namespace Common.Objects;

public class Example
{
    public string Message { get; init; } = "Hi friends!";

    public Guid Id { get; init; } = Guid.NewGuid();

    public DateOnly Date { get; init; } =
DateOnly.FromDateTime(DateTime.Today);

    public sealed override string ToString() =>
        $"[{Id} - {Date}]: {Message}";
}
```

Now, imagine that there is a consuming project and it's represented in the *Consumer* assembly. This consuming project references the *Utility* assembly. As an example, it instantiates the `Example` object and writes it to the console in its *Program.cs* file:

```
C#
```

```
using System;
using Common.Objects;

Example example = new();

Console.WriteLine(example);
```

When the consuming app runs, it will output the state of the `Example` object. At this point, there is no type forwarding as the `Consuming.csproj` references the `Utility.csproj`. However, the developer's of the `Utility` assembly decide to remove the `Example` object as part of a refactoring. This type is moved to a newly created `Common.csproj`.

By removing this type from the `Utility` assembly, the developers are introducing a breaking change. All consuming projects will break when they update to the latest `Utility` assembly.

Instead of requiring the consuming projects to add a new reference to the `Common` assembly, you can forward the type. Since this type was removed from the `Utility` assembly, you'll need to have the `Utility.csproj` reference the `Common.csproj`:

XML

```
<Project Sdk="Microsoft.NET.Sdk">

    <PropertyGroup>
        <TargetFramework>net6.0</TargetFramework>
        <Nullable>enable</Nullable>
        <ImplicitUsing>true</ImplicitUsing>
    </PropertyGroup>

    <ItemGroup>
        <ProjectReference Include=".\\Common\\Common.csproj" />
    </ItemGroup>

</Project>
```

The preceding C# project now references the newly created `Common` assembly. This could be either a `PackageReference` or a `ProjectReference`. The `Utility` assembly needs to provide the type forwarding information. By convention type forward declarations are usually encapsulated in a single file named `TypeForwarders`, consider the following `TypeForwarders.cs` C# file in the `Utility` assembly:

C#

```
using System.Runtime.CompilerServices;
using Common.Objects;
```

```
[assembly:TypeForwardedTo(typeof(Example))]
```

The *Utility* assembly references the *Common* assembly, and it forwards the `Example` type. If you're to compile the *Utility* assembly with the type forwarding declarations and drop the *Utility.dll* into the *Consuming* bin, the consuming app will work without being compiled.

Friend assemblies

Article • 09/15/2021

A *friend assembly* is an assembly that can access another assembly's `internal` (C#) or `Friend` (Visual Basic) types and members. If you add an assembly attribute to *AssemblyA* to identify *AssemblyB* as a friend assembly, you no longer have to mark types and members in *AssemblyA* as public in order for them to be accessed by *AssemblyB*. This is especially convenient in the following scenarios:

- During unit testing, when test code runs in a separate assembly but requires access to members in the assembly being tested that are marked as `internal` in C# or `Friend` in Visual Basic.
- When you are developing a class library and additions to the library are contained in separate assemblies but require access to members in existing assemblies that are marked as `internal` in C# or `Friend` in Visual Basic.

Remarks

You can use the `InternalsVisibleToAttribute` attribute to identify one or more friend assemblies for a given assembly. The following example uses the `InternalsVisibleToAttribute` attribute in *AssemblyA* and specifies assembly *AssemblyB* as a friend assembly. This gives assembly *AssemblyB* access to all types and members in *Assembly A* that are marked as `internal` in C# or `Friend` in Visual Basic.

ⓘ Note

When you compile an assembly like *AssemblyB* that will access internal types or internal members of another assembly like *AssemblyA*, you must explicitly specify the name of the output file (`.exe` or `.dll`) by using the `-out` compiler option. This is required because the compiler has not yet generated the name for the assembly it is building at the time it is binding to external references. For more information, see [OutputAssembly \(C#\)](#) or [-out \(Visual Basic\)](#).

C#

```
using System.Runtime.CompilerServices;
using System;

[assembly: InternalsVisibleTo("AssemblyB")]
```

```

// The class is internal by default.
class FriendClass
{
    public void Test()
    {
        Console.WriteLine("Sample Class");
    }
}

// Public class that has an internal method.
public class ClassWithFriendMethod
{
    internal void Test()
    {
        Console.WriteLine("Sample Method");
    }
}

```

Only assemblies that you explicitly specify as friends can access `internal` (C#) or `Friend` (Visual Basic) types and members. For example, if *AssemblyB* is a friend of *Assembly A* and *Assembly C* references *AssemblyB*, *Assembly C* does not have access to `internal` (C#) or `Friend` (Visual Basic) types in *Assembly A*.

The compiler performs some basic validation of the friend assembly name passed to the [InternalsVisibleToAttribute](#) attribute. If *Assembly A* declares *AssemblyB* as a friend assembly, the validation rules are as follows:

- If *Assembly A* is strong named, *AssemblyB* must also be strong named. The friend assembly name that is passed to the attribute must consist of the assembly name and the public key of the strong-name key that is used to sign *AssemblyB*.

The friend assembly name that is passed to the [InternalsVisibleToAttribute](#) attribute cannot be the strong name of *AssemblyB*. Don't include the assembly version, culture, architecture, or public key token.

- If *Assembly A* is not strong named, the friend assembly name should consist of only the assembly name. For more information, see [How to: Create unsigned friend assemblies](#).
- If *AssemblyB* is strong named, you must specify the strong-name key for *AssemblyB* by using the project setting or the command-line `/keyfile` compiler option. For more information, see [How to: Create signed friend assemblies](#).

The [StrongNameIdentityPermission](#) class also provides the ability to share types, with the following differences:

- [StrongNameIdentityPermission](#) applies to an individual type, while a friend assembly applies to the whole assembly.
- If there are hundreds of types in *Assembly A* that you want to share with *AssemblyB*, you have to add [StrongNameIdentityPermission](#) to all of them. If you use a friend assembly, you only need to declare the friend relationship once.
- If you use [StrongNameIdentityPermission](#), the types you want to share have to be declared as public. If you use a friend assembly, the shared types are declared as `internal` (C#) or `Friend` (Visual Basic).

For information about how to access an assembly's `internal` (C#) or `Friend` (Visual Basic) types and methods from a module file (a file with the `.netmodule` extension), see [ModuleAssemblyName](#) (C#) or [-moduleassemblyname](#) (Visual Basic).

How to: Create unsigned friend assemblies

Article • 09/15/2021

This example shows how to use friend assemblies with assemblies that are unsigned.

Create an assembly and a friend assembly

1. Open a command prompt.
2. Create a C# or Visual Basic file named *friend_unsigned_A* that contains the following code. The code uses the `InternalsVisibleToAttribute` attribute to declare *friend_unsigned_B* as a friend assembly.

```
C#  
  
// friend_unsigned_A.cs  
// Compile with:  
// csc /target:library friend_unsigned_A.cs  
using System.Runtime.CompilerServices;  
using System;  
  
[assembly: InternalsVisibleTo("friend_unsigned_B")]  
  
// Type is internal by default.  
class Class1  
{  
    public void Test()  
    {  
        Console.WriteLine("Class1.Test");  
    }  
}  
  
// Public type with internal member.  
public class Class2  
{  
    internal void Test()  
    {  
        Console.WriteLine("Class2.Test");  
    }  
}
```

3. Compile and sign *friend_unsigned_A* by using the following command:

```
C#
```

```
csc /target:library friend_unsigned_A.cs
```

4. Create a C# or Visual Basic file named *friend_unsigned_B* that contains the following code. Because *friend_unsigned_A* specifies *friend_unsigned_B* as a friend assembly, the code in *friend_unsigned_B* can access `internal` (C#) or `Friend` (Visual Basic) types and members from *friend_unsigned_A*.

C#

```
// friend_unsigned_B.cs
// Compile with:
// csc /r:friend_unsigned_A.dll /out:friend_unsigned_B.exe
friend_unsigned_B.cs
public class Program
{
    static void Main()
    {
        // Access an internal type.
        Class1 inst1 = new Class1();
        inst1.Test();

        Class2 inst2 = new Class2();
        // Access an internal member of a public type.
        inst2.Test();

        System.Console.ReadLine();
    }
}
```

5. Compile *friend_unsigned_B* by using the following command.

C#

```
csc /r:friend_unsigned_A.dll /out:friend_unsigned_B.exe
friend_unsigned_B.cs
```

The name of the assembly that is generated by the compiler must match the friend assembly name that is passed to the `InternalsVisibleToAttribute` attribute. You must explicitly specify the name of the output assembly (`.exe` or `.dll`) by using the `-out` compiler option. For more information, see [OutputAssembly \(C# compiler options\)](#) or [-out \(Visual Basic\)](#).

6. Run the *friend_unsigned_B.exe* file.

The program outputs two strings: `Class1.Test` and `Class2.Test`.

.NET security

There are similarities between the [InternalsVisibleToAttribute](#) attribute and the [StrongNameIdentityPermission](#) class. The main difference is that [StrongNameIdentityPermission](#) can demand security permissions to run a particular section of code, whereas the [InternalsVisibleToAttribute](#) attribute controls the visibility of `internal` or `Friend` (Visual Basic) types and members.

How to: Create signed friend assemblies

Article • 09/15/2021

This example shows how to use friend assemblies with assemblies that have strong names. Both assemblies must be strong named. Although both assemblies in this example use the same keys, you could use different keys for two assemblies.

Create a signed assembly and a friend assembly

1. Open a command prompt.
2. Use the following sequence of commands with the Strong Name tool to generate a keyfile and to display its public key. For more information, see [Sn.exe \(Strong Name tool\)](#).
 - a. Generate a strong-name key for this example and store it in the file *FriendAssemblies.snk*:

```
sn -k FriendAssemblies.snk
```

- b. Extract the public key from *FriendAssemblies.snk* and put it into *FriendAssemblies.publickey*:

```
sn -p FriendAssemblies.snk FriendAssemblies.publickey
```

- c. Display the public key stored in the file *FriendAssemblies.publickey*:

```
sn -tp FriendAssemblies.publickey
```

3. Create a C# or Visual Basic file named *friend_signed_A* that contains the following code. The code uses the [InternalsVisibleToAttribute](#) attribute to declare *friend_signed_B* as a friend assembly.

The Strong Name tool generates a new public key every time it runs. Therefore, you must replace the public key in the following code with the public key you just generated, as shown in the following example.

C#

```
// friend_signed_A.cs
// Compile with:
// csc /target:library /keyfile:FriendAssemblies.snk friend_signed_A.cs
```

```
using System.Runtime.CompilerServices;

[assembly: InternalsVisibleTo("friend_signed_B,
PublicKey=002400000480000940000006020000024000052534131000400001000
100e3aedce99b7e10823920206f8e46cd5558b4ec7345bd1a5b201ffe71660625dcb8f9
a08687d881c8f65a0dcf042f81475d2e88f3e3e273c8311ee40f952db306c02fbfc5d8b
c6ee1e924e6ec8fe8c01932e0648a0d3e5695134af3bb7fab370d3012d083fa6b83179d
d3d031053f72fc1f7da8459140b0af5afc4d2804deccb6")]
class Class1
{
    public void Test()
    {
        System.Console.WriteLine("Class1.Test");
        System.Console.ReadLine();
    }
}
```

4. Compile and sign *friend_signed_A* by using the following command.

```
C#  
  
csc /target:library /keyfile:FriendAssemblies.snk friend_signed_A.cs
```

5. Create a C# or Visual Basic file named *friend_signed_B* that contains the following code. Because *friend_signed_A* specifies *friend_signed_B* as a friend assembly, the code in *friend_signed_B* can access `internal` (C#) or `Friend` (Visual Basic) types and members from *friend_signed_A*. The file contains the following code.

```
C#  
  
// friend_signed_B.cs
// Compile with:
// csc /keyfile:FriendAssemblies.snk /r:friend_signed_A.dll
// /out:friend_signed_B.exe friend_signed_B.cs
public class Program
{
    static void Main()
    {
        Class1 inst = new Class1();
        inst.Test();
    }
}
```

6. Compile and sign *friend_signed_B* by using the following command.

```
C#  
  
csc /keyfile:FriendAssemblies.snk /r:friend_signed_A.dll
```

```
/out:friend_signed_B.exe friend_signed_B.cs
```

The name of the assembly generated by the compiler must match the friend assembly name passed to the [InternalsVisibleToAttribute](#) attribute. You must explicitly specify the name of the output assembly (.exe or .dll) by using the `-out` compiler option. For more information, see [OutputAssembly \(C# compiler options\)](#) or [-out \(Visual Basic\)](#).

7. Run the `friend_signed_B.exe` file.

The program outputs the string `Class1.Test`.

.NET security

There are similarities between the [InternalsVisibleToAttribute](#) attribute and the [StrongNameIdentityPermission](#) class. The main difference is that [StrongNameIdentityPermission](#) can demand security permissions to run a particular section of code, whereas the [InternalsVisibleToAttribute](#) attribute controls the visibility of `internal` (C#) or `Friend` (Visual Basic) types and members.

How to: Determine if a file is an assembly

Article • 12/21/2022

A file is an assembly if and only if it is managed, and contains an assembly entry in its metadata. For more information on assemblies and metadata, see [Assembly manifest](#).

How to manually determine if a file is an assembly

1. Start the [Ilasm.exe \(IL Disassembler\)](#).
2. Load the file you want to test.
3. If ILDASM reports that the file is not a portable executable (PE) file, then it is not an assembly. For more information, see the topic [How to: View assembly contents](#).

How to programmatically determine if a file is an assembly

Using the AssemblyName class

1. Call the [AssemblyName.GetAssemblyName](#) method, passing the full file path and name of the file you are testing.
2. If a [BadImageFormatException](#) exception is thrown, the file is not an assembly.

This example tests a DLL to see if it is an assembly.

C#

```
using System;
using System.IO;
using System.Reflection;
using System.Runtime.InteropServices;

static class ExampleAssemblyName
{
    public static void CheckAssembly()
    {
        try
        {
```

```

        string path = Path.Combine(
            RuntimeEnvironment.GetRuntimeDirectory(),
            "System.Net.dll");

        AssemblyName testAssembly = AssemblyName.GetAssemblyName(path);
        Console.WriteLine("Yes, the file is an assembly.");
    }
    catch (FileNotFoundException)
    {
        Console.WriteLine("The file cannot be found.");
    }
    catch (BadImageFormatException)
    {
        Console.WriteLine("The file is not an assembly.");
    }
    catch (FileLoadException)
    {
        Console.WriteLine("The assembly has already been loaded.");
    }
}

/* Output:
Yes, the file is an assembly.
*/
}

```

The [GetAssemblyName](#) method loads the test file, and then releases it once the information is read.

Using the PEReader class

1. If you're targeting .NET Standard or .NET Framework, install the [System.Reflection.Metadata](#) NuGet package. (When targeting .NET Core or .NET 5+, this step isn't required because this library is included in the shared framework.)
2. Create a [System.IO.FileStream](#) instance to read data from the file you're testing.
3. Create a [System.Reflection.PortableExecutable.PEReader](#) instance, passing your file stream into the constructor.
4. Check the value of the [HasMetadata](#) property. If the value is `false`, the file is not an assembly.
5. Call the [GetMetadataReader](#) method on the PE reader instance to create a metadata reader.

6. Check the value of the [IsAssembly](#) property. If the value is `true`, the file is an assembly.

Unlike the [GetAssemblyName](#) method, the [PEReader](#) class does not throw an exception on native Portable Executable (PE) files. This enables you to avoid the extra performance cost caused by exceptions when you need to check such files. You still need to handle exceptions in case the file does not exist or is not a PE file.

This example shows how to determine if a file is an assembly using the [PEReader](#) class.

C#

```
using System;
using System.Collections.Generic;
using System.IO;
using System.Reflection.Metadata;
using System.Reflection.PortableExecutable;
using System.Runtime.InteropServices;

static class ExamplePeReader
{
    static bool IsAssembly(string path)
    {
        using var fs = new FileStream(path, FileMode.Open, FileAccess.Read,
FileShare.ReadWrite);

        // Try to read CLI metadata from the PE file.
        using var peReader = new PEReader(fs);

        if (!peReader.HasMetadata)
        {
            return false; // File does not have CLI metadata.
        }

        // Check that file has an assembly manifest.
        MetadataReader reader = peReader.GetMetadataReader();
        return reader.IsAssembly;
    }

    public static void CheckAssembly()
    {
        string path = Path.Combine(
            RuntimeEnvironment.GetRuntimeDirectory(),
            "System.Net.dll");

        try
        {
            if (IsAssembly(path))
            {
                Console.WriteLine("Yes, the file is an assembly.");
            }
            else
        }
```

```
        {
            Console.WriteLine("The file is not an assembly.");
        }
    }
    catch (BadImageFormatException)
    {
        Console.WriteLine("The file is not an executable.");
    }
    catch (FileNotFoundException)
    {
        Console.WriteLine("The file cannot be found.");
    }
}

/* Output:
Yes, the file is an assembly.
*/
}
```

How to: Load and unload assemblies

Article • 09/15/2021

The assemblies referenced by your program will automatically be loaded by the common language runtime, but it is also possible to dynamically load specific assemblies into the current application domain. For more information, see [How to: Load assemblies into an application domain](#).

In .NET Framework, there is no way to unload an individual assembly without unloading all of the application domains that contain it. Even if the assembly goes out of scope, the actual assembly file will remain loaded until all application domains that contain it are unloaded. In .NET Core, the `System.Runtime.Loader.AssemblyLoadContext` class handles the unloading of assemblies. For more information, see [How to use and debug assembly unloadability in .NET Core](#).

Load and unload assemblies

To load an assembly into an application domain, use one of the several load methods contained in the classes `AppDomain` and `Assembly`. For more information, see [How to: Load assemblies into an application domain](#). Note that .NET Core supports only a single application domain.

To unload an assembly in the .NET Framework, you must unload all of the application domains that contain it. To unload an application domain, use the `AppDomain.Unload` method. For more information, see [How to: Unload an application domain](#).

If you want to unload some assemblies but not others in a .NET Framework application, consider creating a new application domain, executing the code inside that domain, and then unloading that application domain. For more information, see [How to: Unload an application domain](#).

Walkthrough: Embed types from managed assemblies in Visual Studio

Article • 10/14/2022

If you embed type information from a strong-named managed assembly, you can loosely couple types in an application to achieve version independence. That is, your program can be written to use types from any version of a managed library without having to be recompiled for each new version.

Type embedding is frequently used with COM interop, such as an application that uses automation objects from Microsoft Office. Embedding type information enables the same build of a program to work with different versions of Microsoft Office on different computers. However, you can also use type embedding with fully managed solutions.

After you specify the public interfaces that can be embedded, you create runtime classes that implement those interfaces. A client program can embed the type information for the interfaces at design time by referencing the assembly that contains the public interfaces and setting the `Embed Interop Types` property of the reference to `True`. The client program can then load instances of the runtime objects typed as those interfaces. This is equivalent to using the command line compiler and referencing the assembly by using the [EmbedInteropTypes compiler option](#).

If you create a new version of your strong-named runtime assembly, the client program doesn't have to be recompiled. The client program continues to use whichever version of the runtime assembly is available to it, using the embedded type information for the public interfaces.

In this walkthrough, you:

1. Create a strong-named assembly with a public interface containing type information that can be embedded.
2. Create a strong-named runtime assembly that implements the public interface.
3. Create a client program that embeds the type information from the public interface and creates an instance of the class from the runtime assembly.
4. Modify and rebuild the runtime assembly.
5. Run the client program to see that it uses the new version of the runtime assembly without having to be recompiled.

ⓘ Note

Your computer might show different names or locations for some of the Visual Studio user interface elements in the following instructions. The Visual Studio edition that you have and the settings that you use determine these elements. For more information, see [Personalizing the IDE](#).

Conditions and limitations

You can embed type information from an assembly under the following conditions:

- The assembly exposes at least one public interface.
- The embedded interfaces are annotated with `ComImport` attributes and `Guid` attributes with unique GUIDs.
- The assembly is annotated with the `ImportedFromTypeLib` attribute or the `PrimaryInteropAssembly` attribute, and an assembly-level `Guid` attribute. The Visual C# and Visual Basic project templates include an assembly-level `Guid` attribute by default.

Because the primary function of type embedding is to support COM interop assemblies, the following limitations apply when you embed type information in a fully-managed solution:

- Only attributes specific to COM interop are embedded. Other attributes are ignored.
- If a type uses generic parameters, and the type of the generic parameter is an embedded type, that type cannot be used across an assembly boundary. Examples of crossing an assembly boundary include calling a method from another assembly or deriving a type from a type defined in another assembly.
- Constants are not embedded.
- The `System.Collections.Generic.Dictionary<TKey,TValue>` class does not support an embedded type as a key. You can implement your own dictionary type to support an embedded type as a key.

Create an interface

The first step is to create the type equivalence interface assembly.

1. In Visual Studio, select **File > New > Project**.
2. In the **Create a new project** dialog box, type *class library* in the **Search for templates** box. Select either the C# or Visual Basic **Class Library (.NET Framework)** template from the list, and then select **Next**.

3. In the **Configure your new project** dialog box, under **Project name**, type `TypeEquivalenceInterface`, and then select **Create**. The new project is created.
4. In **Solution Explorer**, right-click the `Class1.cs` or `Class1.vb` file, select **Rename**, and rename the file from `Class1` to `ISampleInterface`. Respond **Yes** to the prompt to also rename the class to `ISampleInterface`. This class represents the public interface for the class.
5. In **Solution Explorer**, right-click the `TypeEquivalenceInterface` project, and then select **Properties**.
6. Select **Build** on the left pane of the **Properties** screen, and set the **Output path** to a location on your computer, such as `C:\TypeEquivalenceSample`. You use the same location throughout this walkthrough.
7. Select **Build > Strong naming** on the left pane of the **Properties** screen, and then select the **Sign the assembly** check box. In the **Strong name key file**, select **Browse**.
8. Navigate to and select the `key.snk` file you created in the `TypeEquivalenceInterface` project, and then select **OK**. For more information, see [Create a public-private key pair](#).
9. Open the `ISampleInterface` class file in the code editor, and replace its contents with the following code to create the `ISampleInterface` interface:

```
C#  
  
using System;  
using System.Runtime.InteropServices;  
  
namespace TypeEquivalenceInterface  
{  
    [ComImport]  
    [Guid("8DA56996-A151-4136-B474-32784559F6DF")]  
    public interface ISampleInterface  
    {  
        void GetUserInput();  
        string UserInput { get; }  
    }  
}
```

10. On the **Tools** menu, select **Create Guid**, and in the **Create GUID** dialog box, select **Registry Format**. Select **Copy**, and then select **Exit**.

11. In the `Guid` attribute of your code, replace the sample GUID with the GUID you copied, and remove the braces (`{ }`).
12. In **Solution Explorer**, expand the **Properties** folder and select the `AssemblyInfo.cs` or `AssemblyInfo.vb` file. In the code editor, add the following attribute to the file:

```
C#  
[assembly: ImportedFromTypeLib("")]
```

13. Select **File > Save All** or press `Ctrl + Shift + S` to save the files and project.
14. In **Solution Explorer**, right-click the `TypeEquivalenceInterface` project and select **Build**. The class library DLL file is compiled and saved to the specified build output path, for example `C:\TypeEquivalenceSample`.

Create a runtime class

Next, create the type equivalence runtime class.

1. In Visual Studio, select **File > New > Project**.
2. In the **Create a new project** dialog box, type *class library* in the **Search for templates** box. Select either the C# or Visual Basic **Class Library (.NET Framework)** template from the list, and then select **Next**.
3. In the **Configure your new project** dialog box, under **Project name**, type `TypeEquivalenceRuntime`, and then select **Create**. The new project is created.
4. In **Solution Explorer**, right-click the `Class1.cs` or `Class1.vb` file, select **Rename**, and rename the file from `Class1` to `SampleClass`. Respond **Yes** to the prompt to also rename the class to `SampleClass`. This class implements the `ISampleInterface` interface.
5. In **Solution Explorer**, right-click the `TypeEquivalenceInterface` project and select **Properties**.
6. Select **Build** on the left pane of the **Properties** screen, and then set the **Output path** to the same location you used for the `TypeEquivalenceInterface` project, for example, `C:\TypeEquivalenceSample`.
7. Select **Build > Strong naming** on the left pane of the **Properties** screen, and then select the **Sign the assembly** check box. In the **Strong name key file**, select **Browse**.

8. Navigate to and select the *key.snk* file you created in the *TypeEquivalenceInterface* project, and then select **OK**. For more information, see [Create a public-private key pair](#).
9. In **Solution Explorer**, right-click the *TypeEquivalenceRuntime* project and select **Add > Reference**.
10. In the **Reference Manager** dialog, select **Browse** and browse to the output path folder. Select the *TypeEquivalenceInterface.dll* file, select **Add**, and then select **OK**.
11. In **Solution Explorer**, expand the **References** folder and select the *TypeEquivalenceInterface* reference. In the **Properties** pane, set **Specific Version** to **False** if it is not already.
12. Open the *SampleClass* class file in the code editor, and replace its contents with the following code to create the *SampleClass* class:

```
C#  
  
using System;  
using TypeEquivalenceInterface;  
  
namespace TypeEquivalenceRuntime  
{  
    public class SampleClass : ISampleInterface  
    {  
        private string p_UserInput;  
        public string UserInput { get { return p_UserInput; } }  
  
        public void GetUserInput()  
        {  
            Console.WriteLine("Please enter a value:");  
            p_UserInput = Console.ReadLine();  
        }  
    }  
}
```

13. Select **File > Save All** or press **Ctrl + Shift + S** to save the files and project.
14. In **Solution Explorer**, right-click the *TypeEquivalenceRuntime* project and select **Build**. The class library DLL file is compiled and saved to the specified build output path.

Create a client project

Finally, create a type equivalence client program that references the interface assembly.

1. In Visual Studio, select **File > New > Project**.
2. In the **Create a new project** dialog box, type *console* in the **Search for templates** box. Select either the C# or Visual Basic **Console App (.NET Framework)** template from the list, and then select **Next**.
3. In the **Configure your new project** dialog box, under **Project name**, type *TypeEquivalenceClient*, and then select **Create**. The new project is created.
4. In **Solution Explorer**, right-click the **TypeEquivalenceClient** project and select **Properties**.
5. Select **Build** on the left pane of the **Properties** screen, and then set the **Output path** to the same location you used for the **TypeEquivalenceInterface** project, for example, *C:\TypeEquivalenceSample*.
6. In **Solution Explorer**, right-click the **TypeEquivalenceClient** project and select **Add > Reference**.
7. In the **Reference Manager** dialog, if the **TypeEquivalenceInterface.dll** file is already listed, select it. If not, select **Browse**, browse to the output path folder, select the *TypeEquivalenceInterface.dll* file (not the *TypeEquivalenceRuntime.dll*), and select **Add**. Select **OK**.
8. In **Solution Explorer**, expand the **References** folder and select the **TypeEquivalenceInterface** reference. In the **Properties** pane, set **Embed Interop Types** to **True**.
9. Open the *Program.cs* or *Module1.vb* file in the code editor, and replace its contents with the following code to create the client program:

```
C#  
  
using System;  
using System.Reflection;  
using TypeEquivalenceInterface;  
  
namespace TypeEquivalenceClient  
{  
    class Program  
    {  
        static void Main(string[] args)  
        {  
            Assembly sampleAssembly =  
Assembly.Load("TypeEquivalenceRuntime");  
            ISampleInterface sampleClass =  
(ISampleInterface)sampleAssembly.CreateInstance("TypeEquivalenceRuntime")
```

```
    .SampleClass");
        sampleClass.GetUserInput();
        Console.WriteLine(sampleClass.UserInput);

        Console.WriteLine(sampleAssembly.GetName().Version.ToString());
        Console.ReadLine();
    }
}
```

10. Select **File > Save All** or press **Ctrl + Shift + S** to save the files and project.

11. Press **Ctrl + F5** to build and run the program. Note that the console output returns the assembly version 1.0.0.0.

Modify the interface

Now, modify the interface assembly, and change its version.

1. In Visual Studio, select **File > Open > Project/Solution**, and open the **TypeEquivalenceInterface** project.
2. In **Solution Explorer**, right-click the **TypeEquivalenceInterface** project and select **Properties**.
3. Select **Application** on the left pane of the **Properties** screen, and then select **Assembly Information**.
4. In the **Assembly Information** dialog box, change the **Assembly version** and **File version** values to 2.0.0.0, and then select **OK**.
5. Open the *SampleInterface.cs* or *SampleInterface.vb* file, and add the following line of code to the **ISampleInterface** interface:

```
C#
DateTime GetDate();
```

6. Select **File > Save All** or press **Ctrl + Shift + S** to save the files and project.

7. In **Solution Explorer**, right-click the **TypeEquivalenceInterface** project and select **Build**. A new version of the class library DLL file is compiled and saved to the build output path.

Modify the runtime class

Also modify the runtime class and update its version.

1. In Visual Studio, select **File > Open > Project/Solution**, and open the **TypeEquivalenceRuntime** project.
2. In **Solution Explorer**, right-click the **TypeEquivalenceRuntime** project and select **Properties**.
3. Select **Application** on the left pane of the **Properties** screen, and then select **Assembly Information**.
4. In the **Assembly Information** dialog box, change the **Assembly version** and **File version** values to **2.0.0.0**, and then select **OK**.
5. Open the *SampleClass.cs* or *SampleClass.vb* file, and add the following code to the **SampleClass** class:

```
C#  
  
public DateTime GetDate()  
{  
    return DateTime.Now;  
}
```

6. Select **File > Save All** or press **Ctrl + Shift + S** to save the files and project.
7. In **Solution Explorer**, right-click the **TypeEquivalenceRuntime** project and select **Build**. A new version of the class library DLL file is compiled and saved to the build output path.

Run the updated client program

Go to the build output folder location and run *TypeEquivalenceClient.exe*. Note that the console output now reflects the new version of the **TypeEquivalenceRuntime** assembly, **2.0.0.0**, without the program being recompiled.

How to: Inspect assembly contents using MetadataLoadContext

Article • 06/30/2022

The reflection API in .NET by default enables developers to inspect the contents of assemblies loaded into the main execution context. However, sometimes it isn't possible to load an assembly into the execution context, for example, because it was compiled for another platform or processor architecture, or it's a [reference assembly](#). The [System.Reflection.MetadataLoadContext](#) API allows you to load and inspect such assemblies. Assemblies loaded into the [MetadataLoadContext](#) are treated only as metadata, that is, you can examine types in the assembly, but you can't execute any code contained in it. Unlike the main execution context, the [MetadataLoadContext](#) doesn't automatically load dependencies from the current directory; instead it uses the custom binding logic provided by the [MetadataAssemblyResolver](#) passed to it.

Prerequisites

To use [MetadataLoadContext](#), install the [System.Reflection.MetadataLoadContext](#) NuGet package. It is supported on any .NET Standard 2.0-compliant target framework, for example, .NET Core 2.0 or .NET Framework 4.6.1.

Create MetadataAssemblyResolver for MetadataLoadContext

Creating the [MetadataLoadContext](#) requires providing the instance of the [MetadataAssemblyResolver](#). The simplest way to provide one is to use the [PathAssemblyResolver](#), which resolves assemblies from the given collection of assembly path strings. This collection, besides assemblies you want to inspect directly, should also include all needed dependencies. For example, to read the custom attribute located in an external assembly, you should include that assembly or an exception will be thrown. In most cases, you should include at least the *core assembly*, that is, the assembly containing built-in system types, such as [System.Object](#). The following code shows how to create the [PathAssemblyResolver](#) using the collection consisting of the inspected assembly and the current runtime's core assembly:

C#

```
var resolver = new PathAssemblyResolver(new string[] {
```

```
"ExampleAssembly.dll", typeof(object).Assembly.Location });
```

If you need access to all BCL types, you can include all runtime assemblies in the collection. The following code shows how to create the [PathAssemblyResolver](#) using the collection consisting of the inspected assembly and all assemblies of the current runtime:

C#

```
// Get the array of runtime assemblies.
string[] runtimeAssemblies =
Directory.GetFiles(RuntimeEnvironment.GetRuntimeDirectory(), "*.dll");

// Create the list of assembly paths consisting of runtime assemblies and
// the inspected assembly.
var paths = new List<string>(runtimeAssemblies);
paths.Add("ExampleAssembly.dll");

// Create PathAssemblyResolver that can resolve assemblies using the created
list.
var resolver = new PathAssemblyResolver(paths);
```

Create MetadataLoadContext

To create the [MetadataLoadContext](#), invoke its constructor

`MetadataLoadContext(MetadataAssemblyResolver, String)`, passing the previously created [MetadataAssemblyResolver](#) as the first parameter and the core assembly name as the second parameter. You can omit the core assembly name, in which case the constructor will attempt to use default names: "mscorlib", "System.Runtime", or "netstandard".

After you've created the context, you can load assemblies into it using methods such as [LoadFromAssemblyPath](#). You can use all reflection APIs on loaded assemblies except ones that involve code execution. The [GetCustomAttributes](#) method does involve the execution of constructors, so use the [GetCustomAttributesData](#) method instead when you need to examine custom attributes in the [MetadataLoadContext](#).

The following code sample creates [MetadataLoadContext](#), loads the assembly into it, and outputs assembly attributes into the console:

C#

```
var mlc = new MetadataLoadContext(resolver);

using (mlc)
```

```

{
    // Load assembly into MetadataLoadContext.
    Assembly assembly = mlc.LoadFromAssemblyPath("ExampleAssembly.dll");
    AssemblyName name = assembly.GetName();

    // Print assembly attribute information.
    Console.WriteLine($"{name.Name} has following attributes: ");

    foreach (CustomAttributeData attr in assembly.GetCustomAttributesData())
    {
        try
        {
            Console.WriteLine(attr.AttributeType);
        }
        catch (FileNotFoundException ex)
        {
            // We are missing the required dependency assembly.
            Console.WriteLine($"Error while getting attribute type:
{ex.Message}");
        }
    }
}

```

If you need to test types in `MetadataLoadContext` for equality or assignability, only use type objects loaded into that context. Mixing `MetadataLoadContext` types with runtime types is not supported. For example, consider a type `testedType` in `MetadataLoadContext`. If you need to test whether another type is assignable from it, don't use code like `typeof(MyType).IsAssignableFrom(testedType)`. Use code like this instead:

C#

```

Assembly matchAssembly =
mlc.LoadFromAssemblyPath(typeof(MyType).Assembly.Location);
Type matchType = assembly.GetType(typeof(MyType).FullName!)!;

if (matchType.IsAssignableFrom(testedType))
{
    Console.WriteLine($"{nameof(matchType)} is assignable from
{nameof(testedType)}");
}

```

Example

For a complete code example, see the [Inspect assembly contents using `MetadataLoadContext` sample](#).

Metadata and Self-Describing Components

Article • 03/11/2022

In the past, a software component (.exe or .dll) that was written in one language could not easily use a software component that was written in another language. COM provided a step towards solving this problem. .NET makes component interoperation even easier by allowing compilers to emit additional declarative information into all modules and assemblies. This information, called metadata, helps components to interact seamlessly.

Metadata is binary information describing your program that is stored either in a common language runtime portable executable (PE) file or in memory. When you compile your code into a PE file, metadata is inserted into one portion of the file, and your code is converted to Microsoft intermediate language (MSIL) and inserted into another portion of the file. Every type and member that is defined and referenced in a module or assembly is described within metadata. When code is executed, the runtime loads metadata into memory and references it to discover information about your code's classes, members, inheritance, and so on.

Metadata describes every type and member defined in your code in a language-neutral manner. Metadata stores the following information:

- Description of the assembly.
 - Identity (name, version, culture, public key).
 - The types that are exported.
 - Other assemblies that this assembly depends on.
 - Security permissions needed to run.
- Description of types.
 - Name, visibility, base class, and interfaces implemented.
 - Members (methods, fields, properties, events, nested types).
- Attributes.
 - Additional descriptive elements that modify types and members.

Benefits of Metadata

Metadata is the key to a simpler programming model, and eliminates the need for Interface Definition Language (IDL) files, header files, or any external method of component reference. Metadata enables .NET languages to describe themselves automatically in a language-neutral manner, unseen by both the developer and the user. Additionally, metadata is extensible through the use of attributes. Metadata provides the following major benefits:

- Self-describing files.

Common language runtime modules and assemblies are self-describing. A module's metadata contains everything needed to interact with another module. Metadata automatically provides the functionality of IDL in COM, so you can use one file for both definition and implementation. Runtime modules and assemblies do not even require registration with the operating system. As a result, the descriptions used by the runtime always reflect the actual code in your compiled file, which increases application reliability.

- Language interoperability and easier component-based design.

Metadata provides all the information required about compiled code for you to inherit a class from a PE file written in a different language. You can create an instance of any class written in any managed language (any language that targets the common language runtime) without worrying about explicit marshalling or using custom interoperability code.

- Attributes.

.NET lets you declare specific kinds of metadata, called attributes, in your compiled file. Attributes can be found throughout .NET and are used to control in more detail how your program behaves at run time. Additionally, you can emit your own custom metadata into .NET files through user-defined custom attributes. For more information, see [Attributes](#).

Metadata and the PE File Structure

Metadata is stored in one section of a .NET portable executable (PE) file, while Microsoft intermediate language (MSIL) is stored in another section of the PE file. The metadata portion of the file contains a series of table and heap data structures. The MSIL portion contains MSIL and metadata tokens that reference the metadata portion of the PE file.

You might encounter metadata tokens when you use tools such as the [MSIL Disassembler \(Ildasm.exe\)](#) to view your code's MSIL, for example.

Metadata Tables and Heaps

Each metadata table holds information about the elements of your program. For example, one metadata table describes the classes in your code, another table describes the fields, and so on. If you have ten classes in your code, the class table will have tens rows, one for each class. Metadata tables reference other tables and heaps. For example, the metadata table for classes references the table for methods.

Metadata also stores information in four heap structures: string, blob, user string, and GUID. All the strings used to name types and members are stored in the string heap. For example, a method table does not directly store the name of a particular method, but points to the method's name stored in the string heap.

Metadata Tokens

Each row of each metadata table is uniquely identified in the MSIL portion of the PE file by a metadata token. Metadata tokens are conceptually similar to pointers, persisted in MSIL, that reference a particular metadata table.

A metadata token is a four-byte number. The top byte denotes the metadata table to which a particular token refers (method, type, and so on). The remaining three bytes specify the row in the metadata table that corresponds to the programming element being described. If you define a method in C# and compile it into a PE file, the following metadata token might exist in the MSIL portion of the PE file:

`0x06000004`

The top byte (`0x06`) indicates that this is a **MethodDef** token. The lower three bytes (`000004`) tells the common language runtime to look in the fourth row of the **MethodDef** table for the information that describes this method definition.

Metadata within a PE File

When a program is compiled for the common language runtime, it is converted to a PE file that consists of three parts. The following table describes the contents of each part.

[] Expand table

| PE section | Contents of PE section |
|-------------------|---|
| PE header | The index of the PE file's main sections and the address of the entry point. The runtime uses this information to identify the file as a PE file and to determine where execution starts when loading the program into memory. |
| MSIL instructions | The Microsoft intermediate language instructions (MSIL) that make up your code. Many MSIL instructions are accompanied by metadata tokens. |
| Metadata | Metadata tables and heaps. The runtime uses this section to record information about every type and member in your code. This section also includes custom attributes and security information. |

Run-Time Use of Metadata

To better understand metadata and its role in the common language runtime, it might be helpful to construct a simple program and illustrate how metadata affects its run-time life. The following code example shows two methods inside a class called `MyApp`. The `Main` method is the program entry point, while the `Add` method simply returns the sum of two integer arguments.

```
C#
using System;
public class MyApp
{
    public static int Main()
    {
        int ValueOne = 10;
        int ValueTwo = 20;
        Console.WriteLine("The Value is: {0}", Add(ValueOne, ValueTwo));
        return 0;
    }
    public static int Add(int One, int Two)
    {
        return (One + Two);
    }
}
```

When the code runs, the runtime loads the module into memory and consults the metadata for this class. Once loaded, the runtime performs extensive analysis of the method's Microsoft intermediate language (MSIL) stream to convert it to fast native machine instructions. The runtime uses a just-in-time (JIT) compiler to convert the MSIL instructions to native machine code one method at a time as needed.

The following example shows part of the MSIL produced from the previous code's `Main` function. You can view the MSIL and metadata from any .NET application using the [MSIL Disassembler \(Ildasm.exe\)](#).

```
Console

.entrypoint
.maxstack 3
.locals ([0] int32 ValueOne,
          [1] int32 ValueTwo,
          [2] int32 V_2,
          [3] int32 V_3)
IL_0000: ldc.i4.s 10
IL_0002: stloc.0
IL_0003: ldc.i4.s 20
IL_0005: stloc.1
IL_0006: ldstr      "The Value is: {0}"
IL_000b: ldloc.0
IL_000c: ldloc.1
IL_000d: call int32 ConsoleApplication.MyApp::Add(int32,int32) /* 06000003
*/
```

The JIT compiler reads the MSIL for the whole method, analyzes it thoroughly, and generates efficient native instructions for the method. At `IL_000d`, a metadata token for the `Add` method (`/* 06000003 */`) is encountered and the runtime uses the token to consult the third row of the **MethodDef** table.

The following table shows part of the **MethodDef** table referenced by the metadata token that describes the `Add` method. While other metadata tables exist in this assembly and have their own unique values, only this table is discussed.

| Row | Relative Virtual Address (RVA) | ImplFlags | Flags | Name (Points to string heap.) | Signature (Points to blob heap.) |
|-----|--------------------------------|-----------|-----------|----------------------------------|----------------------------------|
| 1 | 0x00002050 | IL | Public | .ctor (constructor) | |
| | | Managed | ReuseSlot | | |
| | | | | SpecialName | |
| | | | | RTSpecialName | |
| | | | | .ctor | |

| Row | Relative Virtual Address (RVA) | ImplFlags | Flags | Name <small>(Points to string heap.)</small> | Signature (Points to blob heap.) |
|-----|--------------------------------|-----------|---------|---|----------------------------------|
| 2 | 0x00002058 | IL | Public | Main | String |
| | | | Managed | Static | |
| | | | | ReuseSlot | |
| 3 | 0x0000208c | IL | Public | Add | int, int, int |
| | | | Managed | Static | |
| | | | | ReuseSlot | |

Each column of the table contains important information about your code. The **RVA** column allows the runtime to calculate the starting memory address of the MSIL that defines this method. The **ImplFlags** and **Flags** columns contain bitmasks that describe the method (for example, whether the method is public or private). The **Name** column indexes the name of the method from the string heap. The **Signature** column indexes the definition of the method's signature in the blob heap.

The runtime calculates the desired offset address from the **RVA** column in the third row and returns this address to the JIT compiler, which then proceeds to the new address. The JIT compiler continues to process MSIL at the new address until it encounters another metadata token and the process is repeated.

Using metadata, the runtime has access to all the information it needs to load your code and process it into native machine instructions. In this manner, metadata enables self-describing files and, together with the common type system, cross-language inheritance.

System.Reflection.Emit.AssemblyBuilder class

Article • 01/09/2024

This article provides supplementary remarks to the reference documentation for this API.

A dynamic assembly is an assembly that is created using the Reflection Emit APIs. You can use [AssemblyBuilder](#) to generate dynamic assemblies in memory and execute their code during the same application run. A dynamic assembly can reference types defined in another dynamic or static assembly.

To get an [AssemblyBuilder](#) object, use the [AssemblyBuilder.DefineDynamicAssembly](#) method.

Dynamic assemblies can be created using one of the following access modes:

- [AssemblyBuilderAccess.Run](#)

The dynamic assembly represented by an [AssemblyBuilder](#) can be used to execute the emitted code.

- [AssemblyBuilderAccess.RunAndCollect](#)

The dynamic assembly represented by an [AssemblyBuilder](#) can be used to execute the emitted code and is automatically reclaimed by garbage collector.

The access mode must be specified by providing the appropriate [AssemblyBuilderAccess](#) value in the call to the [AssemblyBuilder.DefineDynamicAssembly](#) method when the dynamic assembly is defined and cannot be changed later. The runtime uses the access mode of a dynamic assembly to optimize the assembly's internal representation.

In .NET Framework, you can save dynamic assemblies to files. This feature is not available in .NET Core and .NET 5 and later versions. For an alternative way to generate assembly files, see [MetadataBuilder](#).

In .NET Framework, a dynamic assembly can consist of one or more dynamic modules. If a dynamic assembly contains more than one dynamic module, the assembly's manifest file name should match the module's name that is specified as the first argument to the [DefineDynamicModule](#) method. In .NET Core and .NET 5+, a dynamic assembly can only consist of one dynamic module.

Persistable dynamic assemblies in .NET Framework

In .NET Framework, dynamic assemblies and modules can be saved to files. To support this feature, the [AssemblyBuilderAccess](#) enumeration declares two additional fields: [Save](#) and [RunAndSave](#). The dynamic assembly created using one of these access modes is called a *persistable* assembly, while the regular memory-only assembly is called *transient*.

The dynamic modules in the persistable dynamic assembly are saved when the dynamic assembly is saved using the [Save](#) method. To generate an executable, the [SetEntryPoint](#) method must be called to identify the method that is the entry point to the assembly. Assemblies are saved as DLLs by default, unless the [SetEntryPoint](#) method requests the generation of a console application or a Windows-based application.

Some methods on the base [Assembly](#) class, such as [GetModules](#) and [GetLoadedModules](#), will not work correctly when called from [AssemblyBuilder](#) objects. You can load the defined dynamic assembly and call the methods on the loaded assembly. For example, to ensure that resource modules are included in the returned module list, call [GetModules](#) on the loaded [Assembly](#) object.

The signing of a dynamic assembly using [KeyPair](#) is not effective until the assembly is saved to disk. So, strong names will not work with transient dynamic assemblies.

Dynamic assemblies can reference types defined in another assembly. A transient dynamic assembly can safely reference types defined in another transient dynamic assembly, a persistable dynamic assembly, or a static assembly. However, the common language runtime does not allow a persistable dynamic module to reference a type defined in a transient dynamic module. This is because when the persisted dynamic module is loaded after being saved to disk, the runtime cannot resolve the references to types defined in the transient dynamic module.

Restrictions on emitting to remote application domains in .NET Framework

Some scenarios require a dynamic assembly to be created and executed in a remote application domain. Reflection emit does not allow a dynamic assembly to be emitted directly to a remote application domain. The solution is to emit the dynamic assembly in the current application domain, save the emitted dynamic assembly to disk, and then load the dynamic assembly into the remote application domain. The remoting and application domains are supported only in .NET Framework.

System.Reflection.Emit.MethodBuilder class

Article • 01/09/2024

This article provides supplementary remarks to the reference documentation for this API.

The [MethodBuilder](#) class is used to fully describe a method in Microsoft intermediate language (MSIL), including the name, attributes, signature, and method body. It is used in conjunction with the [TypeBuilder](#) class to create classes at runtime.

You can use reflection emit to define global methods and to define methods as type members. The APIs that define methods return [MethodBuilder](#) objects.

Global methods

A global method is defined by using the [ModuleBuilder.DefineGlobalMethod](#) method, which returns a [MethodBuilder](#) object.

Global methods must be static. If a dynamic module contains global methods, the [ModuleBuilder.CreateGlobalFunctions](#) method must be called before persisting the dynamic module or the containing dynamic assembly because the common language runtime postpones fixing up the dynamic module until all global functions have been defined.

A global native method is defined by using the [ModuleBuilder.DefinePInvokeMethod](#) method. Platform invoke (PInvoke) methods must not be declared abstract or virtual. The runtime sets the [MethodAttributes.PinvokelImpl](#) attribute for a platform invoke method.

Methods as members of types

A method is defined as a type member by using the [TypeBuilder.DefineMethod](#) method, which returns a [MethodBuilder](#) object.

The [DefineParameter](#) method is used to set the name and parameter attributes of a parameter, or of the return value. The [ParameterBuilder](#) object returned by this method represents a parameter or the return value. The [ParameterBuilder](#) object can be used to set the marshaling, to set the constant value, and to apply custom attributes.

Attributes

Members of the [MethodAttributes](#) enumeration define the precise character of a dynamic method:

- Static methods are specified using the [MethodAttributes.Static](#) attribute.
- Final methods (methods that cannot be overridden) are specified using the [MethodAttributes.Final](#) attribute.
- Virtual methods are specified using the [MethodAttributes.Virtual](#) attribute.
- Abstract methods are specified using the [MethodAttributes.Abstract](#) attribute.
- Several attributes determine method visibility. See the description of the [MethodAttributes](#) enumeration.
- Methods that implement overloaded operators must set the [MethodAttributes.SpecialName](#) attribute.
- Finalizers must set the [MethodAttributes.SpecialName](#) attribute.

Known issues

- Although [MethodBuilder](#) is derived from [MethodInfo](#), some of the abstract methods defined in the [MethodInfo](#) class are not fully implemented in [MethodBuilder](#). These [MethodBuilder](#) methods throw the [NotSupportedException](#). For example the [MethodBuilder.Invoke](#) method is not fully implemented. You can reflect on these methods by retrieving the enclosing type using the [Type.GetType](#) or [Assembly.GetType](#) methods.
- Custom modifiers are supported Starting with .NET Framework version 2.0. They are not supported in earlier versions.

System.Reflection.Emit.TypeBuilder class

Article • 01/09/2024

This article provides supplementary remarks to the reference documentation for this API.

[TypeBuilder](#) is the root class used to control the creation of dynamic classes in the runtime. It provides a set of routines that are used to define classes, add methods and fields, and create the class inside a module. A new [TypeBuilder](#) can be created from a dynamic module by calling the [ModuleBuilder.DefineType](#) method, which returns a [TypeBuilder](#) object.

Reflection emit provides the following options for defining types:

- Define a class or interface with the given name.
- Define a class or interface with the given name and attributes.
- Define a class with the given name, attributes, and base class.
- Define a class with the given name, attributes, base class, and the set of interfaces that the class implements.
- Define a class with the given name, attributes, base class, and packing size.
- Define a class with the given name, attributes, base class, and the class size as a whole.
- Define a class with the given name, attributes, base class, packing size, and the class size as a whole.

To create an array type, pointer type, or byref type for an incomplete type that is represented by a [TypeBuilder](#) object, use the [MakeArrayType](#) method, [MakePointerType](#) method, or [MakeByRefType](#) method, respectively.

Before a type is used, the [TypeBuilder.CreateType](#) method must be called. [CreateType](#) completes the creation of the type. Following the call to [CreateType](#), the caller can instantiate the type by using the [Activator.CreateInstance](#) method, and invoke members of the type by using the [Type.InvokeMember](#) method. It is an error to invoke methods that change the implementation of a type after [CreateType](#) has been called. For example, the common language runtime throws an exception if the caller tries to add new members to a type.

A class initializer is created by using the [TypeBuilder.DefineTypeInitializer](#) method. [DefineTypeInitializer](#) returns a [ConstructorBuilder](#) object.

Nested types are defined by calling one of the [TypeBuilder.DefineNestedType](#) methods.

Attributes

The [TypeBuilder](#) class uses the [TypeAttributes](#) enumeration to further specify the characteristics of the type to be created:

- Interfaces are specified using the [TypeAttributes.Interface](#) and [TypeAttributes.Abstract](#) attributes.
- Concrete classes (classes that cannot be extended) are specified using the [TypeAttributes.Sealed](#) attribute.
- Several attributes determine type visibility. See the description of the [TypeAttributes](#) enumeration.
- If [TypeAttributes.SequentialLayout](#) is specified, the class loader lays out fields in the order they are read from metadata. The class loader considers the specified packing size but ignores any specified field offsets. The metadata preserves the order in which the field definitions are emitted. Even across a merge, the metadata will not reorder the field definitions. The loader will honor the specified field offsets only if [TypeAttributes.ExplicitLayout](#) is specified.

Known issues

- Reflection emit does not verify whether a non-abstract class that implements an interface has implemented all the methods declared in the interface. However, if the class does not implement all the methods declared in an interface, the runtime does not load the class.
- Although [TypeBuilder](#) is derived from [Type](#), some of the abstract methods defined in the [Type](#) class are not fully implemented in the [TypeBuilder](#) class. Calls to these [TypeBuilder](#) methods throw a [NotSupportedException](#) exception. The desired functionality can be obtained by retrieving the created type using the [Type.GetType](#) or [Assembly.GetType](#) and reflecting on the retrieved type.

System.Reflection.Emit.DynamicMethod class

Article • 01/09/2024

This article provides supplementary remarks to the reference documentation for this API.

You can use the [DynamicMethod](#) class to generate and execute a method at run time, without having to generate a dynamic assembly and a dynamic type to contain the method. The executable code created by the just-in-time (JIT) compiler is reclaimed when the [DynamicMethod](#) object is reclaimed. Dynamic methods are the most efficient way to generate and execute small amounts of code.

A dynamic method can be anonymously hosted, or it can be logically associated with a module or with a type.

- If the dynamic method is anonymously hosted, it is located in a system-provided assembly, and therefore is isolated from other code. By default, it does not have access to any non-public data. An anonymously hosted dynamic method can have restricted ability to skip the JIT compiler's visibility checks, if it has been granted [ReflectionPermission](#) with the [ReflectionPermissionFlag.RestrictedMemberAccess](#) flag. The trust level of the assembly whose non-public members are accessed by the dynamic method must be equal to, or a subset of, the trust level of the call stack that emitted the dynamic method. For more information about anonymously hosted dynamic methods, see [Walkthrough: Emitting Code in Partial Trust Scenarios](#).
- If the dynamic method is associated with a module that you specify, the dynamic method is effectively global to that module. It can access all types in the module and all `internal` (`Friend` in Visual Basic) members of the types. You can associate a dynamic method with any module, regardless of whether you created the module, provided that a demand for [ReflectionPermission](#) with the [RestrictedMemberAccess](#) flag can be satisfied by the call stack that includes your code. If the [ReflectionPermissionFlag.MemberAccess](#) flag is included in the grant, the dynamic method can skip the JIT compiler's visibility checks and access the private data of all types declared in the module or in any other module in any assembly.

 **Note**

When you specify the module with which a dynamic method is associated, that module must not be in the system-provided assembly that is used for anonymous hosting.

- If the dynamic method is associated with a type that you specify, it has access to all members of the type, regardless of access level. In addition, JIT visibility checks can be skipped. This gives the dynamic method access to the private data of other types declared in the same module or in any other module in any assembly. You can associate a dynamic method with any type, but your code must be granted [ReflectionPermission](#) with both the [RestrictedMemberAccess](#) and [MemberAccess](#) flags.

The following table shows which types and members are accessible to an anonymously hosted dynamic method, with and without JIT visibility checks, depending on whether [ReflectionPermission](#) with the [RestrictedMemberAccess](#) flag is granted.

[+] Expand table

| Visibility checks | Without | With RestrictedMemberAccess |
|---|---|--|
| | RestrictedMemberAccess | |
| Without skipping JIT visibility checks | Public members of public types in any assembly. | Public members of public types in any assembly. |
| Skipping JIT visibility checks, with restrictions | Public members of public types in any assembly. | All members of all types, only in assemblies whose trust levels are equal to or less than the trust level of the assembly that emitted the dynamic method. |

The following table shows which types and members are accessible to a dynamic method that's associated with a module or with a type in a module.

[+] Expand table

| Skip JIT visibility checks | Associated with module | Associated with type |
|----------------------------|---|---|
| No | Public and internal members of public, internal, and private types in the module. | All members of the associated type. Public and internal members of all the other types in the module. |
| | Public members of public types in any assembly. | Public members of public types in any assembly. |

| Skip JIT visibility checks | Associated with module | Associated with type |
|----------------------------|---|---|
| Yes | All members of all types in any assembly. | All members of all types in any assembly. |

A dynamic method that is associated with a module has the permissions of that module. A dynamic method that is associated with a type has the permissions of the module containing that type.

Dynamic methods and their parameters do not have to be named, but you can specify names to assist in debugging. Custom attributes are not supported on dynamic methods or their parameters.

Although dynamic methods are `static` methods (`Shared` methods in Visual Basic), the relaxed rules for delegate binding allow a dynamic method to be bound to an object, so that it acts like an instance method when called using that delegate instance. An example that demonstrates this is provided for the [CreateDelegate\(Type, Object\)](#) method overload.

Verification

The following list summarizes the conditions under which dynamic methods can contain unverifiable code. (For example, a dynamic method is unverifiable if its [InitLocals](#) property is set to `false`.)

- A dynamic method that's associated with a security-critical assembly is also security-critical, and can skip verification. For example, an assembly without security attributes that is run as a desktop application is treated as security-critical by the runtime. If you associate a dynamic method with the assembly, the dynamic method can contain unverifiable code.
- If a dynamic method that contains unverifiable code is associated with an assembly that has level 1 transparency, the just-in-time (JIT) compiler injects a security demand. The demand succeeds only if the dynamic method is executed by fully trusted code. See [Security-Transparent Code, Level 1](#).
- If a dynamic method that contains unverifiable code is associated with an assembly that has level 2 transparency (such as mscorlib.dll), it throws an exception (injected by the JIT compiler) instead of making a security demand. See [Security-Transparent Code, Level 2](#).
- An anonymously hosted dynamic method that contains unverifiable code always throws an exception. It can never skip verification, even if it is created and

executed by fully trusted code.

The exception that's thrown for unverifiable code varies depending on the way the dynamic method is invoked. If you invoke a dynamic method by using a delegate returned from the [CreateDelegate](#) method, a [VerificationException](#) is thrown. If you invoke the dynamic method by using the [Invoke](#) method, a [TargetInvocationException](#) is thrown with an inner [VerificationException](#).

System.Reflection.PortableExecutable.DebugDirectoryEntryType enum

Article • 01/09/2024

This article provides supplementary remarks to the reference documentation for this API.

The [DebugDirectoryEntryType](#) enum describes the format of the debugging information of a [DebugDirectoryEntry](#).

See the following for the specifications related to individual enumeration members:

[] Expand table

| Member | Specification |
|---------------------|---|
| CodeView | CodeView Debug Directory Entry (type 2) ↗ |
| EmbeddedPortablePdb | Embedded Portable PDB Debug Directory Entry (type 17) ↗ |
| PdbChecksum | PDB Checksum Debug Directory Entry (type 19) ↗ |
| Reproducible | See Deterministic Debug Directory Entry (type 16) ↗ |

DebugDirectoryEntryType.Reproducible

The tool that produced the deterministic PE/COFF file guarantees that the entire content of the file is based solely on documented inputs given to the tool (such as source files, resource files, compiler options, etc.) rather than ambient environment variables (such as the current time, the operating system, the bitness of the process running the tool, etc.).

The value of the `TimeDateStamp` field in the COFF File Header of a deterministic PE/COFF file does not indicate the date and time when the file was produced and should not be interpreted that way. Instead, the value of the field is derived from a hash of the file content. The algorithm to calculate this value is an implementation detail of the tool that produced the file.

The debug directory entry of type [Reproducible](#) must have all fields except for [DebugDirectoryEntry.Type](#) zeroed.

Dependency loading in .NET

Article • 08/30/2022

Every .NET application has dependencies. Even the simple `hello world` app has dependencies on portions of the .NET class libraries.

Understanding the default assembly loading logic in .NET can help you troubleshoot typical deployment issues.

In some applications, dependencies are dynamically determined at run time. In these situations, it's critical to understand how managed assemblies and unmanaged dependencies are loaded.

AssemblyLoadContext

The [AssemblyLoadContext](#) API is central to the .NET loading design. The [Understanding AssemblyLoadContext](#) article provides a conceptual overview of the design.

Loading details

The loading algorithm details are covered briefly in several articles:

- [Managed assembly loading algorithm](#)
- [Satellite assembly loading algorithm](#)
- [Unmanaged \(native\) library loading algorithm](#)
- [Default probing](#)

Create an app with plugins

The tutorial [Create a .NET application with plugins](#) describes how to create a custom `AssemblyLoadContext`. It uses an `AssemblyDependencyResolver` to resolve the dependencies of the plugin. The tutorial correctly isolates the plugin's dependencies from the hosting application.

Assembly unloadability

The [How to use and debug assembly unloadability in .NET](#) article is a step-by-step tutorial. It shows how to load a .NET application, execute it, and then unload it. The article also provides debugging tips.

Collect detailed assembly loading information

The [Collect detailed assembly loading information](#) article describes how to collect detailed information about managed assembly loading in the runtime. It uses the `dotnet-trace` tool to capture assembly loader events in a trace of a running process.

About System.Runtime.Loader.AssemblyLoadContext

Article • 08/30/2022

The [AssemblyLoadContext](#) class was introduced in .NET Core and is not available in .NET Framework. This article supplements the [AssemblyLoadContext](#) API documentation with conceptual information.

This article is relevant to developers implementing dynamic loading, especially dynamic-loading framework developers.

What is the AssemblyLoadContext?

Every .NET 5+ and .NET Core application implicitly uses [AssemblyLoadContext](#). It's the runtime's provider for locating and loading dependencies. Whenever a dependency is loaded, an [AssemblyLoadContext](#) instance is invoked to locate it.

- AssemblyLoadContext provides a service of locating, loading, and caching managed assemblies and other dependencies.
- To support dynamic code loading and unloading, it creates an isolated context for loading code and its dependencies in their own [AssemblyLoadContext](#) instance.

Versioning rules

A single [AssemblyLoadContext](#) instance is limited to loading exactly one version of an [Assembly](#) per [simple assembly name](#). When an assembly reference is resolved against an [AssemblyLoadContext](#) instance that already has an assembly of that name loaded, the requested version is compared to the loaded version. The resolution will succeed only if the loaded version is equal or higher to the requested version.

When do you need multiple AssemblyLoadContext instances?

The restriction that a single [AssemblyLoadContext](#) instance can load only one version of an assembly can become a problem when loading code modules dynamically. Each module is independently compiled, and the modules may depend on different versions

of an [Assembly](#). This is often a problem when different modules depend on different versions of a commonly used library.

To support dynamically loading code, the [AssemblyLoadContext](#) API provides for loading conflicting versions of an [Assembly](#) in the same application. Each [AssemblyLoadContext](#) instance provides a unique dictionary that maps each [AssemblyName.Name](#) to a specific [Assembly](#) instance.

It also provides a convenient mechanism for grouping dependencies related to a code module for later unload.

The [AssemblyLoadContext.Default](#) instance

The [AssemblyLoadContext.Default](#) instance is automatically populated by the runtime at startup. It uses [default probing](#) to locate and find all static dependencies.

It solves the most common dependency loading scenarios.

Dynamic dependencies

[AssemblyLoadContext](#) has various events and virtual functions that can be overridden.

The [AssemblyLoadContext.Default](#) instance only supports overriding the events.

The articles [Managed assembly loading algorithm](#), [Satellite assembly loading algorithm](#), and [Unmanaged \(native\) library loading algorithm](#) refer to all the available events and virtual functions. The articles show each event and function's relative position in the loading algorithms. This article doesn't reproduce that information.

This section covers the general principles for the relevant events and functions.

- **Be repeatable.** A query for a specific dependency must always result in the same response. The same loaded dependency instance must be returned. This requirement is fundamental for cache consistency. For managed assemblies in particular, we're creating an [Assembly](#) cache. The cache key is a simple assembly name, [AssemblyName.Name](#).
- **Typically don't throw.** It's expected that these functions return `null` rather than throw when unable to find the requested dependency. Throwing will prematurely end the search and propagate an exception to the caller. Throwing should be restricted to unexpected errors like a corrupted assembly or an out of memory condition.

- **Avoid recursion.** Be aware that these functions and handlers implement the loading rules for locating dependencies. Your implementation shouldn't call APIs that trigger recursion. Your code should typically call `AssemblyLoadContext` load functions that require a specific path or memory reference argument.
- **Load into the correct `AssemblyLoadContext`.** The choice of where to load dependencies is application-specific. The choice is implemented by these events and functions. When your code calls `AssemblyLoadContext` load-by-path functions call them on the instance where you want the code loaded. Sometime returning `null` and letting the `AssemblyLoadContext.Default` handle the load may be the simplest option.
- **Be aware of thread races.** Loading can be triggered by multiple threads. The `AssemblyLoadContext` handles thread races by atomically adding assemblies to its cache. The race loser's instance is discarded. In your implementation logic, don't add extra logic that doesn't handle multiple threads properly.

How are dynamic dependencies isolated?

Each `AssemblyLoadContext` instance represents a unique scope for `Assembly` instances and `Type` definitions.

There's no binary isolation between these dependencies. They're only isolated by not finding each other by name.

In each `AssemblyLoadContext`:

- `AssemblyName.Name` may refer to a different `Assembly` instance.
- `Type.GetType` may return a different type instance for the same type `name`.

Shared dependencies

Dependencies can easily be shared between `AssemblyLoadContext` instances. The general model is for one `AssemblyLoadContext` to load a dependency. The other shares the dependency by using a reference to the loaded assembly.

This sharing is required of the runtime assemblies. These assemblies can only be loaded into the `AssemblyLoadContext.Default`. The same is required for frameworks like `ASP.NET`, `WPF`, or `WinForms`.

It's recommended that shared dependencies be loaded into `AssemblyLoadContext.Default`. This sharing is the common design pattern.

Sharing is implemented in the coding of the custom [AssemblyLoadContext](#) instance. [AssemblyLoadContext](#) has various events and virtual functions that can be overridden. When any of these functions return a reference to an [Assembly](#) instance that was loaded in another [AssemblyLoadContext](#) instance, the [Assembly](#) instance is shared. The standard load algorithm defers to [AssemblyLoadContext.Default](#) for loading to simplify the common sharing pattern. For more information, see [Managed assembly loading algorithm](#).

Type-conversion issues

When two [AssemblyLoadContext](#) instances contain type definitions with the same `name`, they're not the same type. They're the same type if and only if they come from the same [Assembly](#) instance.

To complicate matters, exception messages about these mismatched types can be confusing. The types are referred to in the exception messages by their simple type names. The common exception message in this case is of the form:

Object of type 'IsolatedType' cannot be converted to type 'IsolatedType'.

Debug type-conversion issues

Given a pair of mismatched types, it's important to also know:

- Each type's [Type.Assembly](#).
- Each type's [AssemblyLoadContext](#), which can be obtained via the [AssemblyLoadContext.GetLoadContext\(Assembly\)](#) function.

Given two objects `a` and `b`, evaluating the following in the debugger will be helpful:

C#

```
// In debugger look at each assembly's instance, Location, and FullName
a.GetType().Assembly
b.GetType().Assembly
// In debugger look at each AssemblyLoadContext's instance and name
System.Runtime.Loader.AssemblyLoadContext.GetLoadContext(a.GetType().Assembly)
System.Runtime.Loader.AssemblyLoadContext.GetLoadContext(b.GetType().Assembly)
```

Resolve type-conversion issues

There are two design patterns for solving these type conversion issues.

1. Use common shared types. This shared type can either be a primitive runtime type, or it can involve creating a new shared type in a shared assembly. Often the shared type is an [interface](#) defined in an application assembly. For more information, read about [how dependencies are shared](#).
2. Use marshalling techniques to convert from one type to another.

Default probing

Article • 10/11/2022

The [AssemblyLoadContext.Default](#) instance is responsible for locating an assembly's dependencies. This article describes the [AssemblyLoadContext.Default](#) instance's probing logic.

Host configured probing properties

When the runtime is started, the runtime host provides a set of named probing properties that configure [AssemblyLoadContext.Default](#) probe paths.

Each probing property is optional. If present, each property is a string value that contains a delimited list of absolute paths. The delimiter is ';' on Windows and ':' on all other platforms.

| Property Name | Description |
|-------------------------------|--|
| TRUSTED_PLATFORM_ASSEMBLIES | List of platform and application assembly file paths. |
| PLATFORM_RESOURCE_ROOTS | List of directory paths to search for satellite resource assemblies. |
| NATIVE_DLL_SEARCH_DIRECTORIES | List of directory paths to search for unmanaged (native) libraries. |
| APP_PATHS | List of directory paths to search for managed assemblies. |

How are the properties populated?

There are two main scenarios for populating the properties depending on whether the `<myapp>.deps.json` file exists.

- When the `*.deps.json` file is present, it's parsed to populate the probing properties.
- When the `*.deps.json` file isn't present, the application's directory is assumed to contain all the dependencies. The directory's contents are used to populate the probing properties.

Additionally, the `*.deps.json` files for any referenced frameworks are similarly parsed.

The environment variable `DOTNET_ADDITIONAL_DEPS` can be used to add additional dependencies. `dotnet.exe` also contains an optional `--additional-deps` parameter to set this value on application startup.

The `APP_PATHS` property is not populated by default and is omitted for most applications.

The list of all `*.deps.json` files used by the application can be accessed via
`System.AppContext.GetData("APP_CONTEXT_DEPS_FILES")`.

How do I see the probing properties from managed code?

Each property is available by calling the `AppContext.GetData(String)` function with the property name from the table above.

How do I debug the probing properties' construction?

The .NET Core runtime host will output useful trace messages when certain environment variables are enabled:

| Environment Variable | Description |
|--|--|
| <code>COREHOST_TRACE=1</code> | Enables tracing. |
| <code>COREHOST_TRACEFILE=<path></code> | Traces to a file path instead of the default <code>stderr</code> . |
| <code>COREHOST_TRACE_VERBOSITY</code> | Sets the verbosity from 1 (lowest) to 4 (highest). |

Managed assembly default probing

When probing to locate a managed assembly, the `AssemblyLoadContext.Default` looks in order at:

- Files matching the `AssemblyName.Name` in `TRUSTED_PLATFORM_ASSEMBLIES` (after removing file extensions).
- Assembly files in `APP_PATHS` with common file extensions.

Satellite (resource) assembly probing

To find a satellite assembly for a specific culture, construct a set of file paths.

For each path in `PLATFORM_RESOURCE_ROOTS` and then `APP_PATHS`, append the `CultureInfo.Name` string, a directory separator, the `AssemblyName.Name` string, and the extension '.dll'.

If any matching file exists, attempt to load and return it.

Unmanaged (native) library probing

The runtime's unmanaged library probing algorithm is identical on all platforms. However, since the actual load of the unmanaged library is performed by the underlying platform, the observed behavior can be slightly different.

1. Check if the supplied library name represents an absolute or relative path.
2. If the name represents an absolute path, use the name directly for all subsequent operations. Otherwise, use the name and create platform-defined combinations to consider. Combinations consist of platform specific prefixes (for example, `lib`) and/or suffixes (for example, `.dll`, `.dylib`, and `.so`). This is not an exhaustive list, and it doesn't represent the exact effort made on each platform. It's just an example of what is considered. For more information, see [native library loading](#).
3. The name and, if the path is relative, each combination, is then used in the following steps. The first successful load attempt immediately returns the handle to the loaded library.
 - Append it to each path supplied in the `NATIVE_DLL_SEARCH_DIRECTORIES` property and attempt to load.
 - If `DefaultDllImportSearchPathsAttribute` is either not defined on the calling assembly or p/invoke or is defined and includes `DllImportSearchPath.AssemblyDirectory`, append the name or combination to the calling assembly's directory and attempt to load.
 - Use it directly to load the library.
4. Indicate that the library failed to load.

Managed assembly loading algorithm

Article • 08/30/2022

Managed assemblies are located and loaded with an algorithm that has various stages.

All managed assemblies except satellite assemblies and `WinRT` assemblies use the same algorithm.

When are managed assemblies loaded?

The most common mechanism to trigger a managed assembly load is a static assembly reference. These references are inserted by the compiler whenever code uses a type defined in another assembly. These assemblies are loaded (`load-by-name`) as needed by the runtime. The exact timing of when the static assembly references are loaded is unspecified. It can vary between runtime versions and is influenced by optimizations like inlining.

The direct use of the following APIs will also trigger loads:

| API | Description | Active <code>AssemblyLoadContext</code> |
|--|---|--|
| AssemblyLoadContext.LoadFromAssemblyName | <code>Load-by-name</code> | The <code>this</code> instance. |
| AssemblyLoadContext.LoadFromAssemblyPath AssemblyLoadContext.LoadFromNativeImagePath | Load from path. | The <code>this</code> instance. |
| AssemblyLoadContext.LoadFromStream | Load from object. | The <code>this</code> instance. |
| Assembly.LoadFile | Load from path in a new <code>AssemblyLoadContext</code> instance | The new <code>AssemblyLoadContext</code> instance. |
| Assembly.LoadFrom | Load from path in the <code>AssemblyLoadContext.Default</code> instance. Adds an <code>AppDomain.AssemblyResolve</code> handler. The handler will load the assembly's dependencies from its directory. | The <code>AssemblyLoadContext.Default</code> instance. |
| Assembly.Load(AssemblyName) Assembly.Load(String) Assembly.LoadWithPartialName | <code>Load-by-name</code> . | Inferred from caller. Prefer <code>AssemblyLoadContext</code> methods. |
| Assembly.Load(Byte[]) Assembly.Load(Byte[], Byte[]) | Load from object in a new <code>AssemblyLoadContext</code> instance. | The new <code>AssemblyLoadContext</code> instance. |

| API | Description | Active | AssemblyLoadContext |
|--|---|---|---------------------|
| Type.GetType(String) | Load-by-name. | Inferred from caller. | |
| Type.GetType(String, Boolean) | | Prefer Type.GetType methods with an <code>assemblyResolver</code> argument. | |
| Type.GetType(String, Boolean, Boolean) | | | |
| Assembly.GetType | If type <code>name</code> describes an assembly qualified generic type, trigger a Load-by-name. | Inferred from caller. | |
| | | Prefer Type.GetType when using assembly qualified type names. | |
| Activator.CreateInstance(String, String) | Load-by-name. | Inferred from caller. | |
| Activator.CreateInstance(String, String, Object[]) | | Prefer | |
| Activator.CreateInstance(String, String, Boolean, | | Activator.CreateInstance methods taking a <code>Type</code> argument. | |
| BindingFlags, Binder, Object[], CultureInfo, | | | |
| Object[]) | | | |

Algorithm

The following algorithm describes how the runtime loads a managed assembly.

1. Determine the active [AssemblyLoadContext](#).

- For a static assembly reference, the active [AssemblyLoadContext](#) is the instance that loaded the referring assembly.
- Preferred APIs make the active [AssemblyLoadContext](#) explicit.
- Other APIs infer the active [AssemblyLoadContext](#). For these APIs, the [AssemblyLoadContext.CurrentContextualReflectionContext](#) property is used. If its value is `null`, then the inferred [AssemblyLoadContext](#) instance is used.
- See the table in the [When are managed assemblies loaded?](#) section.

2. For the Load-by-name methods, the active [AssemblyLoadContext](#) loads the assembly in the following priority order:

- Check its cache-by-name.
- Call the [AssemblyLoadContext.Load](#) function.
- Check the [AssemblyLoadContext.Default](#) instance's cache and run managed assembly default probing logic. If an assembly is newly loaded, a reference is added to the [AssemblyLoadContext.Default](#) instance's cache-by-name.
- Raise the [AssemblyLoadContext.Resolving](#) event for the active AssemblyLoadContext.
- Raise the [AppDomain.AssemblyResolve](#) event.

3. For the other types of loads, the active [AssemblyLoadContext](#) loads the assembly in the following priority order:

- Check its cache-by-name.

- Load from the specified path or raw assembly object. If an assembly is newly loaded, a reference is added to the `active AssemblyLoadContext` instance's `cache-by-name`.

4. In either case, if an assembly is newly loaded, then the `AppDomain.AssemblyLoad` event is raised.

Satellite assembly loading algorithm

Article • 11/11/2023

Satellite assemblies are used to store localized resources customized for language and culture.

Satellite assemblies use a different loading algorithm than general managed assemblies.

When are satellite assemblies loaded?

Satellite assemblies are loaded when loading a localized resource.

The basic API to load localized resources is the [System.Resources.ResourceManager](#) class. Ultimately the [ResourceManager](#) class will call the [GetSatelliteAssembly](#) method for each [CultureInfo.Name](#).

Higher-level APIs may abstract the low-level API.

Algorithm

The .NET Core resource fallback process involves the following steps:

1. Determine the `active` [AssemblyLoadContext](#) instance. In all cases, the `active` instance is the executing assembly's [AssemblyLoadContext](#).
2. The `active` instance loads a satellite assembly for the requested culture in the following priority order:
 - Check its cache.
 - If `active` is the [AssemblyLoadContext.Default](#) instance, run the [default satellite \(resource\) assembly probing](#) logic.
 - Call the [AssemblyLoadContext.Load](#) function.
 - If the managed assembly corresponding to the satellite assembly was loaded from a file, check the directory of the managed assembly for a subdirectory that matches the requested [CultureInfo.Name](#) (for example, `es-MX`).

Note

On Linux and macOS, the subdirectory is case-sensitive and must either:

- Exactly match case.
 - Be in lower case.
- Raise the [AssemblyLoadContext.Resolving](#) event.
 - Raise the [AppDomain.AssemblyResolve](#) event.

3. If a satellite assembly is loaded:

- The [AppDomain.AssemblyLoad](#) event is raised.
- The assembly is searched for the requested resource. If the runtime finds the resource in the assembly, it uses it. If it doesn't find the resource, it continues the search.

 **Note**

To find a resource within the satellite assembly, the runtime searches for the resource file requested by the [ResourceManager](#) for the current [CultureInfo.Name](#). Within the resource file, it searches for the requested resource name. If either is not found, the resource is treated as not found.

4. The [ResourceManager](#) next searches the parent culture assemblies through many potential levels, each time repeating steps 2 & 3.

Each culture has only one parent, which is defined by the [CultureInfo.Parent](#) property.

The search for parent cultures stops when a culture's [Parent](#) property is [CultureInfo.InvariantCulture](#).

For the [InvariantCulture](#), we don't return to steps 2 & 3, but rather continue with step 5.

5. If the resource is still not found, the [ResourceManager](#) uses the resource for the default (fallback) culture.

Typically, the resources for the default culture are included in the main application assembly. However, you can specify [UltimateResourceFallbackLocation.Satellite](#) for the [NeutralResourcesLanguageAttribute.Location](#) property. This value indicates that the ultimate fallback location for resources is a satellite assembly rather than the main assembly.

Note

The default culture is the ultimate fallback. Therefore, we recommend that you always include an exhaustive set of resources in the default resource file. This helps prevent exceptions from being thrown. By having an exhaustive set, you provide a fallback for all resources and ensure that at least one resource is always present for the user, even if it is not culturally specific.

6. Finally,

- If the runtime doesn't find a resource file for a default (fallback) culture, a [MissingManifestResourceException](#) or [MissingSatelliteAssemblyException](#) exception is thrown.
- If the resource file is found but the requested resource isn't present, the request returns `null`.

Unmanaged (native) library loading algorithm

Article • 10/27/2021

Unmanaged libraries are located and loaded with an algorithm involving various stages.

The following algorithm describes how native libraries are loaded through `PInvoke`.

`PInvoke` load library algorithm

`PInvoke` uses the following algorithm when attempting to load an unmanaged assembly:

1. Determine the `active AssemblyLoadContext`. For an unmanaged load library, the `active AssemblyLoadContext` is the one with the assembly that defines the `PInvoke`.
2. For the `active AssemblyLoadContext`, try to find the assembly in priority order by:
 - Checking its cache.
 - Calling the current `System.Runtime.InteropServices.DllImportResolver` delegate set by the `NativeLibrary.SetDllImportResolver(Assembly, DllImportResolver)` function.
 - Calling the `AssemblyLoadContext.LoadUnmanagedDll` function on the `active AssemblyLoadContext`.
 - Checking the `AppDomain` instance's cache and running the `Unmanaged (native) library probing` logic.
 - Raising the `AssemblyLoadContext.ResolvingUnmanagedDll` event for the `active AssemblyLoadContext`.

Collect detailed assembly loading information

Article • 11/08/2021

Starting with .NET 5, the runtime can emit events through `EventPipe` with detailed information about [managed assembly loading](#) to aid in diagnosing assembly loading issues. These `events` are emitted by the `Microsoft-Windows-DotNERTRuntime` provider under the `AssemblyLoader` keyword (`0x4`).

Prerequisites

- [.NET 5 SDK](#) or later versions
- `dotnet-trace` tool

ⓘ Note

The scope of `dotnet-trace` capabilities is greater than collecting detailed assembly loading information. For more information on the usage of `dotnet-trace`, see [dotnet-trace](#).

Collect a trace with assembly loading events

You can use `dotnet-trace` to trace an existing process or to launch a child process and trace it from startup.

Trace an existing process

To enable assembly loading events in the runtime and collect a trace of them, use `dotnet-trace` with the following command:

Console

```
dotnet-trace collect --providers Microsoft-Windows-DotNERTRuntime:4 --process-id <pid>
```

This command collects a trace of the specified `<pid>`, enabling the `AssemblyLoader` events in the `Microsoft-Windows-DotNERTRuntime` provider. The result is a `.nettrace` file.

Use dotnet-trace to launch a child process and trace it from startup

Sometimes it may be useful to collect a trace of a process from its startup. For apps running .NET 5 or later, you can use `dotnet-trace` to do this.

The following command launches `hello.exe` with `arg1` and `arg2` as its command line arguments and collects a trace from its runtime startup:

Console

```
dotnet-trace collect --providers Microsoft-Windows-DotNERTRuntime:4 -- hello.exe arg1 arg2
```

You can stop collecting the trace by pressing `Enter` or `Ctrl + C`. This also closes `hello.exe`.

ⓘ Note

- Launching `hello.exe` via `dotnet-trace` redirects its input and output, and you won't be able to interact with it on the console by default. Use the `--show-child-io` switch to interact with its `stdin` and `stdout`.
- Exiting the tool via `Ctrl + C` or `SIGTERM` safely ends both the tool and the child process.
- If the child process exits before the tool, the tool exits as well and the trace should be safely viewable.

View a trace

The collected trace file can be viewed on Windows using the Events view in [PerfView](#). All the assembly loading events will be prefixed with `Microsoft-Windows-DotNERTRuntime/AssemblyLoader`.

Example (on Windows)

This example uses the [assembly loading extension points sample](#). The application attempts to load an assembly `MyLibrary` - an assembly that is not referenced by the application and thus requires handling in an assembly loading extension point to be successfully loaded.

Collect the trace

1. Navigate to the directory with the downloaded sample. Build the application with:

```
Console  
dotnet build
```

2. Launch the application with arguments indicating that it should pause, waiting for a key press. On resuming, it will attempt to load the assembly in the default `AssemblyLoadContext` - without the handling necessary for a successful load. Navigate to the output directory and run:

```
Console  
AssemblyLoading.exe /d default
```

3. Find the application's process ID.

```
Console  
dotnet-trace ps
```

The output will list the available processes. For example:

```
Console  
35832 AssemblyLoading C:\src\AssemblyLoading\bin\Debug\net5.0\AssemblyLoading.exe
```

4. Attach `dotnet-trace` to the running application.

```
Console  
dotnet-trace collect --providers Microsoft-Windows-DotNETRuntime:4 --process-id 35832
```

5. In the window running the application, press any key to let the program continue. Tracing will automatically stop once the application exits.

View the trace

Open the collected trace in [PerfView](#) and open the Events view. Filter the events list to `Microsoft-Windows-DotNETRuntime/AssemblyLoader` events.

| Event Types | Filter: AssemblyLoader |
|---|------------------------|
| Microsoft-Windows-DotNETRuntime/AssemblyLoader/AppDomainAssemblyResolveHandlerInvoked | |
| Microsoft-Windows-DotNETRuntime/AssemblyLoader/AssemblyLoadContextResolvingHandlerInvoked | |
| Microsoft-Windows-DotNETRuntime/AssemblyLoader/KnownPathProbed | |
| Microsoft-Windows-DotNETRuntime/AssemblyLoader/ResolutionAttempted | |
| Microsoft-Windows-DotNETRuntime/AssemblyLoader/Start | |
| Microsoft-Windows-DotNETRuntime/AssemblyLoader/Stop | |

All assembly loads that occurred in the application after tracing started will be shown. To inspect the load operation for the assembly of interest for this example - `MyLibrary`, we can do some more filtering.

Assembly loads

Filter the view to the `Start` and `Stop` events under `Microsoft-Windows-DotNETRuntime/AssemblyLoader` using the event list on the left. Add the columns `AssemblyName`, `ActivityID`, and `Success` to the view. Filter to events containing `MyLibrary`.

| Text Filter: | MyLibrary | Columns To Display: | Cols | AssemblyName ActivityID Success * |
|--|---|---------------------|---------|-----------------------------------|
| Histogram: | | | | |
| Event Name | AssemblyName | ActivityID | Success | |
| Microsoft-Windows-DotNETRuntime/AssemblyLoader/Start | MyLibrary, Culture=neutral, PublicKeyToken=null | //1/2/ | | |
| Microsoft-Windows-DotNETRuntime/AssemblyLoader/Stop | MyLibrary, Culture=neutral, PublicKeyToken=null | //1/2/ | False | |

| Event Name | AssemblyName | ActivityID | Success |
|----------------------|---|------------|---------|
| AssemblyLoader/Start | MyLibrary, Culture=neutral, PublicKeyToken=null | //1/2/ | |
| AssemblyLoader/Stop | MyLibrary, Culture=neutral, PublicKeyToken=null | //1/2/ | False |

You should see one `Start`/`Stop` pair with `Success=False` on the `Stop` event, indicating the load operation failed. Note that the two events have the same activity ID. The activity ID can be used to filter all the other assembly loader events to just the ones corresponding to this load operation.

Breakdown of attempt to load

For a more detailed breakdown of the load operation, filter the view to the `ResolutionAttempted` events under `Microsoft-Windows-DotNETRuntime/AssemblyLoader` using the event list on the left. Add the columns `AssemblyName`, `Stage`, and `Result` to the view. Filter to events with the activity ID from the `Start`/`Stop` pair.

| Text Filter: | //1/2/ | Columns To Display: | Cols | AssemblyName Stage Result * |
|--|---|-----------------------------------|------------------|-----------------------------|
| Histogram: | | | | |
| Event Name | AssemblyName | Stage | Result | |
| Microsoft-Windows-DotNETRuntime/AssemblyLoader/ResolutionAttempted | MyLibrary, Culture=neutral, PublicKeyToken=null | FindInLoadContext | AssemblyNotFound | |
| Microsoft-Windows-DotNETRuntime/AssemblyLoader/ResolutionAttempted | MyLibrary, Culture=neutral, PublicKeyToken=null | ApplicationAssemblies | AssemblyNotFound | |
| Microsoft-Windows-DotNETRuntime/AssemblyLoader/ResolutionAttempted | MyLibrary, Culture=neutral, PublicKeyToken=null | AssemblyLoadContextResolvingEvent | AssemblyNotFound | |
| Microsoft-Windows-DotNETRuntime/AssemblyLoader/ResolutionAttempted | MyLibrary, Culture=neutral, PublicKeyToken=null | AppDomainAssemblyResolveEvent | AssemblyNotFound | |

| Event Name | AssemblyName | Stage | Result |
|------------------------------------|---|-----------------------------------|------------------|
| AssemblyLoader/ResolutionAttempted | MyLibrary, Culture=neutral, PublicKeyToken=null | FindInLoadContext | AssemblyNotFound |
| AssemblyLoader/ResolutionAttempted | MyLibrary, Culture=neutral, PublicKeyToken=null | ApplicationAssemblies | AssemblyNotFound |
| AssemblyLoader/ResolutionAttempted | MyLibrary, Culture=neutral, PublicKeyToken=null | AssemblyLoadContextResolvingEvent | AssemblyNotFound |
| AssemblyLoader/ResolutionAttempted | MyLibrary, Culture=neutral, PublicKeyToken=null | AppDomainAssemblyResolveEvent | AssemblyNotFound |

The events above indicate that the assembly loader attempted to resolve the assembly by looking in the current load context, running the default probing logic for managed application assemblies, invoking handlers for the `AssemblyLoadContext.Resolving` event, and invoking handlers for the `AppDomain.AssemblyResolve`. For all of these steps, the assembly was not found.

Extension points

To see which extension points were invoked, filter the view to the `AssemblyLoadContextResolvingHandlerInvoked` and `AppDomainAssemblyResolveHandlerInvoked` under `Microsoft-Windows-DotNETRuntime/AssemblyLoader` using the event list on the left. Add the columns `AssemblyName` and `HandlerName` to the view. Filter to events with the activity ID from the `Start`/`Stop` pair.

| Text Filter: | //1/2/ | Columns To Display: | Cols | AssemblyName HandlerName * |
|---|---|--------------------------------|------|----------------------------|
| Histogram: | | | | |
| Event Name | AssemblyName | HandlerName | | |
| Microsoft-Windows-DotNETRuntime/AssemblyLoader/AssemblyLoadContextResolvingHandlerInvoked | MyLibrary, Culture=neutral, PublicKeyToken=null | OnAssemblyLoadContextResolving | | |
| Microsoft-Windows-DotNETRuntime/AssemblyLoader/AppDomainAssemblyResolveHandlerInvoked | MyLibrary, Culture=neutral, PublicKeyToken=null | OnAppDomainAssemblyResolve | | |

| Event Name | AssemblyName | HandlerName |
|---|---|--------------------------------|
| AssemblyLoader/AssemblyLoadContextResolvingHandlerInvoked | MyLibrary, Culture=neutral, PublicKeyToken=null | OnAssemblyLoadContextResolving |
| AssemblyLoader/AppDomainAssemblyResolveHandlerInvoked | MyLibrary, Culture=neutral, PublicKeyToken=null | OnAppDomainAssemblyResolve |

The events above indicate that a handler named `OnAssemblyLoadContextResolving` was invoked for the `AssemblyLoadContext.Resolving` event and a handler named `OnAppDomainAssemblyResolve` was invoked for the `AppDomain.AssemblyResolve` event.

Collect another trace

Run the application with arguments such that its handler for the `AssemblyLoadContext.Resolving` event will load the `MyLibrary` assembly.

| Console | | | | |
|--|--|--|--|--|
| AssemblyLoading /d default alc-resolving | | | | |

Collect and open another `.nettrace` file using the [steps from above](#).

Filter to the `Start` and `Stop` events for `MyLibrary` again. You should see a `Start/Stop` pair with another `Start/Stop` between them. The inner load operation represents the load triggered by the handler for `AssemblyLoadContext.Resolving` when it called `AssemblyLoadContext.LoadFromAssemblyPath`. This time, you should see `Success=True` on the `Stop` event, indicating the load operation succeeded. The `ResultAssemblyPath` field shows the path of the resulting assembly.

| Event Name | AssemblyName | ActivityID | Success | ResultAssemblyPath |
|--|--|------------|---------|---|
| Microsoft-Windows-DotNETRuntime/AssemblyLoader/Start | MyLibrary, Culture=neutral, PublicKeyToken=null | //1/2/ | | |
| Microsoft-Windows-DotNETRuntime/AssemblyLoader/Start | MyLibrary, Version=1.0.0.0, Culture=neutral, PublicKeyToken=null | //1/2/1/ | | |
| Microsoft-Windows-DotNETRuntime/AssemblyLoader/Stop | MyLibrary, Version=1.0.0.0, Culture=neutral, PublicKeyToken=null | //1/2/1/ | True | C:\src\AssemblyLoading\bin\Debug\net5.0\MyLibrary.dll |
| Microsoft-Windows-DotNETRuntime/AssemblyLoader/Stop | MyLibrary, Culture=neutral, PublicKeyToken=null | //1/2/ | True | C:\src\AssemblyLoading\bin\Debug\net5.0\MyLibrary.dll |

| Event Name | AssemblyName | ActivityID | Success | ResultAssemblyPath |
|----------------------|--|------------|---------|---|
| AssemblyLoader/Start | MyLibrary, Culture=neutral, PublicKeyToken=null | //1/2/ | | |
| AssemblyLoader/Start | MyLibrary, Version=1.0.0.0, Culture=neutral, PublicKeyToken=null | //1/2/1/ | | |
| AssemblyLoader/Stop | MyLibrary, Version=1.0.0.0, Culture=neutral, PublicKeyToken=null | //1/2/1/ | True | C:\src\AssemblyLoading\bin\Debug\net5.0\MyLibrary.dll |
| AssemblyLoader/Stop | MyLibrary, Culture=neutral, PublicKeyToken=null | //1/2/ | True | C:\src\AssemblyLoading\bin\Debug\net5.0\MyLibrary.dll |

We can then look at the `ResolutionAttempted` events with the activity ID from the outer load to determine the step at which the assembly was successfully resolved. This time, the events will show that the `AssemblyLoadContextResolvingEvent` stage was successful. The `ResultAssemblyPath` field shows the path of the resulting assembly.

| Event Name | AssemblyName | Stage | Result | ResultAssemblyPath |
|--|----------------------------|-----------------------------------|------------------|---|
| Microsoft-Windows-DotNETRuntime/AssemblyLoader/ResolutionAttempted | MyLibrary, Culture=neutral | FindInLoadContext | AssemblyNotFound | |
| Microsoft-Windows-DotNETRuntime/AssemblyLoader/ResolutionAttempted | MyLibrary, Culture=neutral | ApplicationAssemblies | AssemblyNotFound | |
| Microsoft-Windows-DotNETRuntime/AssemblyLoader/ResolutionAttempted | MyLibrary, Culture=neutral | AssemblyLoadContextResolvingEvent | Success | C:\src\AssemblyLoading\bin\Debug\net5.0\MyLibrary.dll |

| Event Name | AssemblyName | Stage | Result | ResultAssemblyPath |
|------------------------------------|---|-----------------------------------|------------------|---|
| AssemblyLoader/ResolutionAttempted | MyLibrary, Culture=neutral, PublicKeyToken=null | FindInLoadContext | AssemblyNotFound | |
| AssemblyLoader/ResolutionAttempted | MyLibrary, Culture=neutral, PublicKeyToken=null | ApplicationAssemblies | AssemblyNotFound | |
| AssemblyLoader/ResolutionAttempted | MyLibrary, Culture=neutral, PublicKeyToken=null | AssemblyLoadContextResolvingEvent | Success | C:\src\AssemblyLoading\bin\Debug\net5.0\MyLibrary.dll |

Looking at `AssemblyLoadContextResolvingHandlerInvoked` events will show that the handler named `OnAssemblyLoadContextResolving` was invoked. The `ResultAssemblyPath` field shows the path of the assembly returned by the handler.

| Event Name | AssemblyName | HandlerName | ResultAssemblyPath |
|---|----------------------------|--------------------------------|---|
| Microsoft-Windows-DotNETRuntime/AssemblyLoader/AssemblyLoadContextResolvingHandlerInvoked | MyLibrary, Culture=neutral | OnAssemblyLoadContextResolving | C:\src\AssemblyLoading\bin\Debug\net5.0\MyLibrary.dll |

| Event Name | AssemblyName | HandlerName | ResultAssemblyPath |
|---|---|--------------------------------|---|
| AssemblyLoader/AssemblyLoadContextResolvingHandlerInvoked | MyLibrary, Culture=neutral, PublicKeyToken=null | OnAssemblyLoadContextResolving | C:\src\AssemblyLoading\bin\Debug\net5.0\MyLibrary.dll |

Note that there is no longer a `ResolutionAttempted` event with the `AppDomainAssemblyResolveEvent` stage or any `AppDomainAssemblyResolveHandlerInvoked` events, as the assembly was successfully loaded before reaching the step of the loading algorithm that raises the `AppDomain.AssemblyResolve` event.

Create a .NET Core application with plugins

Article • 02/04/2022

This tutorial shows you how to create a custom [AssemblyLoadContext](#) to load plugins. An [AssemblyDependencyResolver](#) is used to resolve the dependencies of the plugin. The tutorial correctly isolates the plugin's dependencies from the hosting application. You'll learn how to:

- Structure a project to support plugins.
- Create a custom [AssemblyLoadContext](#) to load each plugin.
- Use the [System.Runtime.Loader.AssemblyDependencyResolver](#) type to allow plugins to have dependencies.
- Author plugins that can be easily deployed by just copying the build artifacts.

Prerequisites

- Install the [.NET 5 SDK](#) or a newer version.

ⓘ Note

The sample code targets .NET 5, but all the features it uses were introduced in .NET Core 3.0 and are available in all .NET releases since then.

Create the application

The first step is to create the application:

1. Create a new folder, and in that folder run the following command:

```
.NET CLI  
dotnet new console -o AppWithPlugin
```

2. To make building the project easier, create a Visual Studio solution file in the same folder. Run the following command:

```
.NET CLI
```

```
dotnet new sln
```

- Run the following command to add the app project to the solution:

.NET CLI

```
dotnet sln add AppWithPlugin/AppWithPlugin.csproj
```

Now we can fill in the skeleton of our application. Replace the code in the *AppWithPlugin/Program.cs* file with the following code:

C#

```
using PluginBase;
using System;
using System.Collections.Generic;
using System.IO;
using System.Linq;
using System.Reflection;

namespace AppWithPlugin
{
    class Program
    {
        static void Main(string[] args)
        {
            try
            {
                if (args.Length == 1 && args[0] == "/d")
                {
                    Console.WriteLine("Waiting for any key...");
                    Console.ReadLine();
                }

                // Load commands from plugins.

                if (args.Length == 0)
                {
                    Console.WriteLine("Commands: ");
                    // Output the loaded commands.
                }
                else
                {
                    foreach (string commandName in args)
                    {
                        Console.WriteLine($"-- {commandName} --");

                        // Execute the command with the name passed as an
                        argument.
                    }
                }
            }
        }
    }
}
```

```
        Console.WriteLine();
    }
}
catch (Exception ex)
{
    Console.WriteLine(ex);
}
}
}
```

Create the plugin interfaces

The next step in building an app with plugins is defining the interface the plugins need to implement. We suggest that you make a class library that contains any types that you plan to use for communicating between your app and plugins. This division allows you to publish your plugin interface as a package without having to ship your full application.

In the root folder of the project, run `dotnet new classlib -o PluginBase`. Also, run `dotnet sln add PluginBase/PluginBase.csproj` to add the project to the solution file. Delete the `PluginBase/Class1.cs` file, and create a new file in the `PluginBase` folder named `ICommand.cs` with the following interface definition:

```
C#  
  
namespace PluginBase  
{  
    public interface ICommand  
    {  
        string Name { get; }  
        string Description { get; }  
  
        int Execute();  
    }  
}
```

This `ICommand` interface is the interface that all of the plugins will implement.

Now that the `ICommand` interface is defined, the application project can be filled in a little more. Add a reference from the `AppWithPlugin` project to the `PluginBase` project with the `dotnet add AppWithPlugin/AppWithPlugin.csproj reference PluginBase/PluginBase.csproj` command from the root folder.

Replace the `// Load commands from plugins` comment with the following code snippet to enable it to load plugins from given file paths:

```
C#  
  
string[] pluginPaths = new string[]  
{  
    // Paths to plugins to load.  
};  
  
IEnumerable< ICommand> commands = pluginPaths.SelectMany(pluginPath =>  
{  
    Assembly pluginAssembly = LoadPlugin(pluginPath);  
    return CreateCommands(pluginAssembly);  
}).ToList();
```

Then replace the `// Output the loaded commands` comment with the following code snippet:

```
C#  
  
foreach ( ICommand command in commands)  
{  
    Console.WriteLine($"{command.Name}\t - {command.Description}");  
}
```

Replace the `// Execute the command with the name passed as an argument` comment with the following snippet:

```
C#  
  
ICommand command = commands.FirstOrDefault(c => c.Name == commandName);  
if (command == null)  
{  
    Console.WriteLine("No such command is known.");  
    return;  
}  
  
command.Execute();
```

And finally, add static methods to the `Program` class named `LoadPlugin` and `CreateCommands`, as shown here:

```
C#  
  
static Assembly LoadPlugin(string relativePath)  
{
```

```

        throw new NotImplementedException();
    }

    static IEnumerable< ICommand> CreateCommands(Assembly assembly)
    {
        int count = 0;

        foreach (Type type in assembly.GetTypes())
        {
            if (typeof(ICommand).IsAssignableFrom(type))
            {
                ICommand result = Activator.CreateInstance(type) as ICommand;
                if (result != null)
                {
                    count++;
                    yield return result;
                }
            }
        }

        if (count == 0)
        {
            string availableTypes = string.Join(",",
assembly.GetTypes().Select(t => t.FullName));
            throw new ApplicationException(
                $"Can't find any type which implements ICommand in {assembly}
from {assembly.Location}.\\n" +
                $"Available types: {availableTypes}");
        }
    }
}

```

Load plugins

Now the application can correctly load and instantiate commands from loaded plugin assemblies, but it's still unable to load the plugin assemblies. Create a file named *PluginLoadContext.cs* in the *AppWithPlugin* folder with the following contents:

C#

```

using System;
using System.Reflection;
using System.Runtime.Loader;

namespace AppWithPlugin
{
    class PluginLoadContext : AssemblyLoadContext
    {
        private AssemblyDependencyResolver _resolver;

        public PluginLoadContext(string pluginPath)
        {

```

```

        _resolver = new AssemblyDependencyResolver(pluginPath);
    }

    protected override Assembly Load(AssemblyName assemblyName)
    {
        string assemblyPath =
_resolver.ResolveAssemblyToPath(assemblyName);
        if (assemblyPath != null)
        {
            return LoadFromAssemblyPath(assemblyPath);
        }

        return null;
    }

    protected override IntPtr LoadUnmanagedDll(string unmanagedDllName)
    {
        string libraryPath =
_resolver.ResolveUnmanagedDllToPath(unmanagedDllName);
        if (libraryPath != null)
        {
            return LoadUnmanagedDllFromPath(libraryPath);
        }

        return IntPtr.Zero;
    }
}

```

The `PluginLoadContext` type derives from `AssemblyLoadContext`. The `AssemblyLoadContext` type is a special type in the runtime that allows developers to isolate loaded assemblies into different groups to ensure that assembly versions don't conflict. Additionally, a custom `AssemblyLoadContext` can choose different paths to load assemblies from and override the default behavior. The `PluginLoadContext` uses an instance of the `AssemblyDependencyResolver` type introduced in .NET Core 3.0 to resolve assembly names to paths. The `AssemblyDependencyResolver` object is constructed with the path to a .NET class library. It resolves assemblies and native libraries to their relative paths based on the `.deps.json` file for the class library whose path was passed to the `AssemblyDependencyResolver` constructor. The custom `AssemblyLoadContext` enables plugins to have their own dependencies, and the `AssemblyDependencyResolver` makes it easy to correctly load the dependencies.

Now that the `AppWithPlugin` project has the `PluginLoadContext` type, update the `Program.LoadPlugin` method with the following body:

C#

```

static Assembly LoadPlugin(string relativePath)
{
    // Navigate up to the solution root
    string root = Path.GetFullPath(Path.Combine(
        Path.GetDirectoryName(
            Path.GetDirectoryName(
                Path.GetDirectoryName(
                    Path.GetDirectoryName(
                        Path.GetDirectoryName(
                            Path.GetDirectoryName(
                                Path.GetDirectoryName(
                                    Path.GetDirectoryName(
                                        Path.GetDirectoryName(
                                            Path.GetDirectoryName(
                                                Path.GetDirectoryName(
                                                    typeof(Program).Assembly.Location))))))))));
    string pluginLocation = Path.GetFullPath(Path.Combine(root,
relativePath.Replace('\\', Path.DirectorySeparatorChar)));
    Console.WriteLine($"Loading commands from: {pluginLocation}");
    PluginLoadContext loadContext = new PluginLoadContext(pluginLocation);
    return loadContext.LoadFromAssemblyName(new
AssemblyName(Path.GetFileNameWithoutExtension(pluginLocation)));
}

```

By using a different `PluginLoadContext` instance for each plugin, the plugins can have different or even conflicting dependencies without issue.

Simple plugin with no dependencies

Back in the root folder, do the following:

1. Run the following command to create a new class library project named

`HelloPlugin:`

```

.NET CLI
dotnet new classlib -o HelloPlugin

```

2. Run the following command to add the project to the `AppWithPlugin` solution:

```

.NET CLI
dotnet sln add HelloPlugin/HelloPlugin.csproj

```

3. Replace the `HelloPlugin/Class1.cs` file with a file named `HelloCommand.cs` with the following contents:

C#

```

using PluginBase;
using System;

```

```
namespace HelloPlugin
{
    public class HelloCommand : ICommand
    {
        public string Name { get => "hello"; }
        public string Description { get => "Displays hello message."; }

        public int Execute()
        {
            Console.WriteLine("Hello !!!");
            return 0;
        }
    }
}
```

Now, open the *HelloPlugin.csproj* file. It should look similar to the following:

XML

```
<Project Sdk="Microsoft.NET.Sdk">

<PropertyGroup>
    <TargetFramework>net5.0</TargetFramework>
</PropertyGroup>

</Project>
```

In between the `<PropertyGroup>` tags, add the following element:

XML

```
<EnableDynamicLoading>true</EnableDynamicLoading>
```

The `<EnableDynamicLoading>true</EnableDynamicLoading>` prepares the project so that it can be used as a plugin. Among other things, this will copy all of its dependencies to the output of the project. For more details see [EnableDynamicLoading](#).

In between the `<Project>` tags, add the following elements:

XML

```
<ItemGroup>
    <ProjectReference Include="..\PluginBase\PluginBase.csproj">
        <Private>false</Private>
        <ExcludeAssets>runtime</ExcludeAssets>
```

```
</ProjectReference>  
</ItemGroup>
```

The `<Private>false</Private>` element is important. This tells MSBuild to not copy `PluginBase.dll` to the output directory for `HelloPlugin`. If the `PluginBase.dll` assembly is present in the output directory, `PluginLoadContext` will find the assembly there and load it when it loads the `HelloPlugin.dll` assembly. At this point, the `HelloPlugin.HelloCommand` type will implement the `ICommand` interface from the `PluginBase.dll` in the output directory of the `HelloPlugin` project, not the `ICommand` interface that is loaded into the default load context. Since the runtime sees these two types as different types from different assemblies, the `AppWithPlugin.Program.CreateCommands` method won't find the commands. As a result, the `<Private>false</Private>` metadata is required for the reference to the assembly containing the plugin interfaces.

Similarly, the `<ExcludeAssets>runtime</ExcludeAssets>` element is also important if the `PluginBase` references other packages. This setting has the same effect as `<Private>false</Private>` but works on package references that the `PluginBase` project or one of its dependencies may include.

Now that the `HelloPlugin` project is complete, you should update the `AppWithPlugin` project to know where the `HelloPlugin` plugin can be found. After the `// Paths to plugins to load` comment, add `["@HelloPlugin\bin\Debug\net5.0\HelloPlugin.dll"]` (this path could be different based on the .NET Core version you use) as an element of the `pluginPaths` array.

Plugin with library dependencies

Almost all plugins are more complex than a simple "Hello World", and many plugins have dependencies on other libraries. The `JsonPlugin` and `OldJsonPlugin` projects in the sample show two examples of plugins with NuGet package dependencies on `Newtonsoft.Json`. Because of this, all plugin projects should add `<EnableDynamicLoading>true</EnableDynamicLoading>` to the project properties so that they copy all of their dependencies to the output of `dotnet build`. Publishing the class library with `dotnet publish` will also copy all of its dependencies to the publish output.

Other examples in the sample

The complete source code for this tutorial can be found in [the dotnet/samples repository](#). The completed sample includes a few other examples of

`AssemblyDependencyResolver` behavior. For example, the `AssemblyDependencyResolver` object can also resolve native libraries as well as localized satellite assemblies included in NuGet packages. The `UVPlugin` and `FrenchPlugin` in the samples repository demonstrate these scenarios.

Reference a plugin interface from a NuGet package

Let's say that there is an app A that has a plugin interface defined in the NuGet package named `A.PluginBase`. How do you reference the package correctly in your plugin project? For project references, using the `<Private>false</Private>` metadata on the `ProjectReference` element in the project file prevented the dll from being copied to the output.

To correctly reference the `A.PluginBase` package, you want to change the `<PackageReference>` element in the project file to the following:

XML

```
<PackageReference Include="A.PluginBase" Version="1.0.0">
    <ExcludeAssets>runtime</ExcludeAssets>
</PackageReference>
```

This prevents the `A.PluginBase` assemblies from being copied to the output directory of your plugin and ensures that your plugin will use A's version of `A.PluginBase`.

Plugin target framework recommendations

Because plugin dependency loading uses the `.deps.json` file, there is a gotcha related to the plugin's target framework. Specifically, your plugins should target a runtime, such as .NET 5, instead of a version of .NET Standard. The `.deps.json` file is generated based on which framework the project targets, and since many .NET Standard-compatible packages ship reference assemblies for building against .NET Standard and implementation assemblies for specific runtimes, the `.deps.json` may not correctly see implementation assemblies, or it may grab the .NET Standard version of an assembly instead of the .NET Core version you expect.

Plugin framework references

Currently, plugins can't introduce new frameworks into the process. For example, you can't load a plugin that uses the `Microsoft.AspNetCore.App` framework into an application that only uses the root `Microsoft.NETCore.App` framework. The host application must declare references to all frameworks needed by plugins.

How to use and debug assembly unloadability in .NET

Article • 11/13/2023

.NET (Core) introduced the ability to load and later unload a set of assemblies. In .NET Framework, custom app domains were used for this purpose, but .NET (Core) only supports a single default app domain.

Unloadability is supported through [AssemblyLoadContext](#). You can load a set of assemblies into a collectible `AssemblyLoadContext`, execute methods in them or just inspect them using reflection, and finally unload the `AssemblyLoadContext`. That unloads the assemblies loaded into the `AssemblyLoadContext`.

There's one noteworthy difference between the unloading using `AssemblyLoadContext` and using AppDomains. With AppDomains, the unloading is forced. At unload time, all threads running in the target AppDomain are aborted, managed COM objects created in the target AppDomain are destroyed, and so on. With `AssemblyLoadContext`, the unload is "cooperative". Calling the [AssemblyLoadContext.Unload](#) method just initiates the unloading. The unloading finishes after:

- No threads have methods from the assemblies loaded into the `AssemblyLoadContext` on their call stacks.
- None of the types from the assemblies loaded into the `AssemblyLoadContext`, instances of those types, and the assemblies themselves are referenced by:
 - References outside of the `AssemblyLoadContext`, except for weak references ([WeakReference](#) or [WeakReference<T>](#)).
 - Strong garbage collector (GC) handles ([GCHandleType.Normal](#) or [GCHandleType.Pinned](#)) from both inside and outside of the `AssemblyLoadContext`.

Use collectible AssemblyLoadContext

This section contains a detailed step-by-step tutorial that shows a simple way to load a .NET (Core) application into a collectible `AssemblyLoadContext`, execute its entry point, and then unload it. You can find a complete sample at <https://github.com/dotnet/samples/tree/main/core/tutorials/Unloading>.

Create a collectible AssemblyLoadContext

Derive your class from the [AssemblyLoadContext](#) and override its [AssemblyLoadContext.Load](#) method. That method resolves references to all assemblies that are dependencies of assemblies loaded into that [AssemblyLoadContext](#).

The following code is an example of the simplest custom [AssemblyLoadContext](#):

C#

```
class TestAssemblyLoadContext : AssemblyLoadContext
{
    public TestAssemblyLoadContext() : base(isCollectible: true)
    {

    }

    protected override Assembly? Load(AssemblyName name)
    {
        return null;
    }
}
```

As you can see, the `Load` method returns `null`. That means that all the dependency assemblies are loaded into the default context, and the new context contains only the assemblies explicitly loaded into it.

If you want to load some or all of the dependencies into the [AssemblyLoadContext](#) too, you can use the [AssemblyDependencyResolver](#) in the `Load` method. The [AssemblyDependencyResolver](#) resolves the assembly names to absolute assembly file paths. The resolver uses the `.deps.json` file and assembly files in the directory of the main assembly loaded into the context.

C#

```
using System.Reflection;
using System.Runtime.Loader;

namespace complex
{
    class TestAssemblyLoadContext : AssemblyLoadContext
    {
        private AssemblyDependencyResolver _resolver;

        public TestAssemblyLoadContext(string mainAssemblyToLoadPath) :
base(isCollectible: true)
        {
            _resolver = new
AssemblyDependencyResolver(mainAssemblyToLoadPath);
        }

        protected override Assembly? Load(AssemblyName name)
```

```
        {
            string? assemblyPath = _resolver.ResolveAssemblyToPath(name);
            if (assemblyPath != null)
            {
                return LoadFromAssemblyPath(assemblyPath);
            }

            return null;
        }
    }
}
```

Use a custom collectible AssemblyLoadContext

This section assumes the simpler version of the `TestAssemblyLoadContext` is being used.

You can create an instance of the custom `AssemblyLoadContext` and load an assembly into it as follows:

C#

```
var alc = new TestAssemblyLoadContext();
Assembly a = alc.LoadFromAssemblyPath(assemblyPath);
```

For each of the assemblies referenced by the loaded assembly, the `TestAssemblyLoadContext.Load` method is called so that the `TestAssemblyLoadContext` can decide where to get the assembly from. In this case, it returns `null` to indicate that it should be loaded into the default context from locations that the runtime uses to load assemblies by default.

Now that an assembly was loaded, you can execute a method from it. Run the `Main` method:

C#

```
var args = new object[1] {new string[] {"Hello"}};
_ = a.EntryPoint?.Invoke(null, args);
```

After the `Main` method returns, you can initiate unloading by either calling the `Unload` method on the custom `AssemblyLoadContext` or removing the reference you have to the `AssemblyLoadContext`:

C#

```
alc.Unload();
```

This is sufficient to unload the test assembly. Next, you'll put all of this into a separate noninlineable method to ensure that the `TestAssemblyLoadContext`, `Assembly`, and `MethodInfo` (the `Assembly.EntryPoint`) can't be kept alive by stack slot references (real- or JIT-introduced locals). That could keep the `TestAssemblyLoadContext` alive and prevent the unload.

Also, return a weak reference to the `AssemblyLoadContext` so that you can use it later to detect unload completion.

C#

```
[MethodImpl(MethodImplOptions.NoInlining)]
static void ExecuteAndUnload(string assemblyPath, out WeakReference
alcWeakRef)
{
    var alc = new TestAssemblyLoadContext();
    Assembly a = alc.LoadFromAssemblyPath(assemblyPath);

    alcWeakRef = new WeakReference(alc, trackResurrection: true);

    var args = new object[1] {new string[] {"Hello"}};
    _ = a.EntryPoint?.Invoke(null, args);

    alc.Unload();
}
```

Now you can run this function to load, execute, and unload the assembly.

C#

```
WeakReference testAlcWeakRef;
ExecuteAndUnload("absolute/path/to/your/assembly", out testAlcWeakRef);
```

However, the unload doesn't complete immediately. As previously mentioned, it relies on the garbage collector to collect all the objects from the test assembly. In many cases, it isn't necessary to wait for the unload completion. However, there are cases where it's useful to know that the unload has finished. For example, you might want to delete the assembly file that was loaded into the custom `AssemblyLoadContext` from disk. In such a case, the following code snippet can be used. It triggers garbage collection and waits for pending finalizers in a loop until the weak reference to the custom `AssemblyLoadContext` is set to `null`, indicating the target object was collected. In most cases, just one pass through the loop is required. However, for more complex cases where objects created

by the code running in the `AssemblyLoadContext` have finalizers, more passes might be needed.

C#

```
for (int i = 0; testAlcWeakRef.IsAlive && (i < 10); i++)
{
    GC.Collect();
    GC.WaitForPendingFinalizers();
}
```

The Unloading event

In some cases, it might be necessary for the code loaded into a custom `AssemblyLoadContext` to perform some cleanup when the unloading is initiated. For example, it might need to stop threads or clean up strong GC handles. The `Unloading` event can be used in such cases. You can hook a handler that performs the necessary cleanup to this event.

Troubleshoot unloadability issues

Due to the cooperative nature of the unloading, it's easy to forget about references that might be keeping the stuff in a collectible `AssemblyLoadContext` alive and preventing unload. Here's a summary of entities (some of them nonobvious) that can hold the references:

- Regular references held from outside of the collectible `AssemblyLoadContext` that are stored in a stack slot or a processor register (method locals, either explicitly created by the user code or implicitly by the just-in-time (JIT) compiler), a static variable, or a strong (pinning) GC handle, and transitively pointing to:
 - An assembly loaded into the collectible `AssemblyLoadContext`.
 - A type from such an assembly.
 - An instance of a type from such an assembly.
- Threads running code from an assembly loaded into the collectible `AssemblyLoadContext`.
- Instances of custom, noncollectible `AssemblyLoadContext` types created inside of the collectible `AssemblyLoadContext`.
- Pending `RegisteredWaitHandle` instances with callbacks set to methods in the custom `AssemblyLoadContext`.

Tip

Object references that are stored in stack slots or processor registers and that could prevent unloading of an `AssemblyLoadContext` can occur in the following situations:

- When function call results are passed directly to another function, even though there is no user-created local variable.
- When the JIT compiler keeps a reference to an object that was available at some point in a method.

Debug unloading issues

Debugging issues with unloading can be tedious. You can get into situations where you don't know what can be holding an `AssemblyLoadContext` alive, but the unload fails. The best tool to help with that is WinDbg (or LLDB on Unix) with the SOS plugin. You need to find what's keeping a `LoaderAllocator` that belongs to the specific `AssemblyLoadContext` alive. The SOS plugin lets you look at GC heap objects, their hierarchies, and roots.

To load the SOS plugin into the debugger, enter one of the following commands in the debugger command line.

In WinDbg (if it's not already loaded):

```
Console  
.loadby sos coreclr
```

In LLDB:

```
Console  
plugin load /path/to/libssosplugin.so
```

Now you'll debug an example program that has problems with unloading. The source code is available in the [Example source code](#) section. When you run it under WinDbg, the program breaks into the debugger right after attempting to check for the unload success. You can then start looking for the culprits.

 **Tip**

If you debug using LLDB on Unix, the SOS commands in the following examples don't have the ! in front of them.

Console

```
!dumpheap -type LoaderAllocator
```

This command dumps all objects with a type name containing `LoaderAllocator` that are in the GC heap. Here's an example:

Console

| Address | MT | Size |
|------------------|------------------|------|
| 000002b78000ce40 | 00007ffadc93a288 | 48 |
| 000002b78000ceb0 | 00007ffadc93a218 | 24 |

Statistics:

| MT | Count | TotalSize | Class | Name |
|--|-------|-----------|-----------------------------------|------|
| 00007ffadc93a218 | 1 | 24 | | |
| System.Reflection.LoaderAllocatorScout | | | | |
| 00007ffadc93a288 | 1 | 48 | System.Reflection.LoaderAllocator | |
| Total | 2 | objects | | |

In the "Statistics:" part, check the `MT` (`MethodTable`) that belongs to the `System.Reflection.LoaderAllocator`, which is the object you care about. Then, in the list at the beginning, find the entry with `MT` that matches that one, and get the address of the object itself. In this case, it's "000002b78000ce40".

Now that you know the address of the `LoaderAllocator` object, you can use another command to find its GC roots:

Console

```
!gcroot 0x000002b78000ce40
```

This command dumps the chain of object references that lead to the `LoaderAllocator` instance. The list starts with the root, which is the entity that keeps the `LoaderAllocator` alive and thus is the core of the problem. The root can be a stack slot, a processor register, a GC handle, or a static variable.

Here's an example of the output of the `gcroot` command:

Console

```

Thread 4ac:
  000000cf9499dd20 00007ffa7d0236bc example.Program.Main(System.String[])
[E:\unloadability\example\Program.cs @ 70]
  rbp-20: 000000cf9499dd90
    -> 000002b78000d328 System.Reflection.RuntimeMethodInfo
    -> 000002b78000d1f8 System.RuntimeType+RuntimeTypeCache
    -> 000002b78000d1d0 System.RuntimeType
    -> 000002b78000ce40 System.Reflection.LoaderAllocator

HandleTable:
  000002b7f8a81198 (strong handle)
  -> 000002b78000d948 test.Test
  -> 000002b78000ce40 System.Reflection.LoaderAllocator

  000002b7f8a815f8 (pinned handle)
  -> 000002b790001038 System.Object[]
  -> 000002b78000d390 example.TestInfo
  -> 000002b78000d328 System.Reflection.RuntimeMethodInfo
  -> 000002b78000d1f8 System.RuntimeType+RuntimeTypeCache
  -> 000002b78000d1d0 System.RuntimeType
  -> 000002b78000ce40 System.Reflection.LoaderAllocator

Found 3 roots.

```

The next step is to figure out where the root is located so you can fix it. The easiest case is when the root is a stack slot or a processor register. In that case, the `gcroot` shows the name of the function whose frame contains the root and the thread executing that function. The difficult case is when the root is a static variable or a GC handle.

In the previous example, the first root is a local of type `System.Reflection.RuntimeMethodInfo` stored in the frame of the function `example.Program.Main(System.String[])` at address `rbp-20` (`rbp` is the processor register `rbp` and `-20` is a hexadecimal offset from that register).

The second root is a normal (strong) `GCHandle` that holds a reference to an instance of the `test.Test` class.

The third root is a pinned `GCHandle`. This one is actually a static variable, but unfortunately, there's no way to tell. Statics for reference types are stored in a managed object array in internal runtime structures.

Another case that can prevent unloading of an `AssemblyLoadContext` is when a thread has a frame of a method from an assembly loaded into the `AssemblyLoadContext` on its stack. You can check that by dumping managed call stacks of all threads:

Console

```
~*e !clrstack
```

The command means "apply to all threads the `!clrstack` command". The following is the output of that command for the example. Unfortunately, LLDB on Unix doesn't have any way to apply a command to all threads, so you must manually switch threads and repeat the `clrstack` command. Ignore all threads where the debugger says "Unable to walk the managed stack".

Console

```

System.Threading.Thread.SleepInternal(Int32)
```

```
0000001fc727f260 00007ffb37ea7c2b System.Threading.Thread.Sleep(Int32)
0000001fc727f290 00007ffa865005b3 test.Program.ThreadProc()
[E:\unloadability\test\Program.cs @ 17]
0000001fc727f2c0 00007ffb37ea6a5b
System.Threading.Thread.ThreadMain_ThreadStart()
0000001fc727f2f0 00007ffadbc4cbe3
System.Threading.ExecutionContext.RunInternal(System.Threading.ExecutionCont
ext, System.Threading.ContextCallback, System.Object)
0000001fc727f568 00007ffae5fdc1e3 [GCFrame: 0000001fc727f568]
0000001fc727f7f0 00007ffae5fdc1e3 [DebuggerU2MCatchHandlerFrame:
0000001fc727f7f0]
```

As you can see, the last thread has `test.Program.ThreadProc()`. This is a function from the assembly loaded into the `AssemblyLoadContext`, and so it keeps the `AssemblyLoadContext` alive.

Example source code

The following code that contains unloadability issues is used in the previous debugging example.

Main testing program

```
C#  
  
using System;
using System.Reflection;
using System.Runtime.CompilerServices;
using System.Runtime.Loader;  
  
namespace example
{
    class TestAssemblyLoadContext : AssemblyLoadContext
    {
        public TestAssemblyLoadContext() : base(true)
        {
        }
        protected override Assembly? Load(AssemblyName name)
        {
            return null;
        }
    }

    class TestInfo
    {
        public TestInfo(MethodInfo? mi)
        {
            _entryPoint = mi;
        }
    }
}
```

```

        MethodInfo? _entryPoint;
    }

    class Program
    {
        static TestInfo? entryPoint;

        [MethodImpl(MethodImplOptions.NoInlining)]
        static int ExecuteAndUnload(string assemblyPath, out WeakReference testAlcWeakRef, out MethodInfo? testEntryPoint)
        {
            var alc = new TestAssemblyLoadContext();
            testAlcWeakRef = new WeakReference(alc);

            Assembly a = alc.LoadFromAssemblyPath(assemblyPath);
            if (a == null)
            {
                testEntryPoint = null;
                Console.WriteLine("Loading the test assembly failed");
                return -1;
            }

            var args = new object[1] {new string[] {"Hello"}};

            // Issue preventing unloading #1 - we keep MethodInfo of a
method
            // for an assembly loaded into the TestAssemblyLoadContext in a
static variable.
            entryPoint = new TestInfo(a.EntryPoint);
            testEntryPoint = a.EntryPoint;

            var oResult = a.EntryPoint?.Invoke(null, args);
            alc.Unload();
            return (oResult is int result) ? result : -1;
        }

        static void Main(string[] args)
        {
            WeakReference testAlcWeakRef;
            // Issue preventing unloading #2 - we keep MethodInfo of a
method for an assembly loaded into the TestAssemblyLoadContext in a local
variable
            MethodInfo? testEntryPoint;
            int result = ExecuteAndUnload(@"absolute/path/to/test.dll", out
testAlcWeakRef, out testEntryPoint);

            for (int i = 0; testAlcWeakRef.IsAlive && (i < 10); i++)
            {
                GC.Collect();
                GC.WaitForPendingFinalizers();
            }

            System.Diagnostics.Debugger.Break();
        }
    }
}

```

```
        Console.WriteLine($"Test completed, result={result}, entryPoint:  
{testEntryPoint} unload success: {!testAlcWeakRef.IsAlive}");  
    }  
}  
}
```

Program loaded into the TestAssemblyLoadContext

The following code represents the *test.dll* passed to the `ExecuteAndUnload` method in the main testing program.

C#

```
using System;  
using System.Runtime.InteropServices;  
using System.Threading;  
  
namespace test  
{  
    class Test  
    {  
    }  
  
    class Program  
    {  
        public static void ThreadProc()  
        {  
            // Issue preventing unloading #4 - a thread running method  
            // inside of the TestAssemblyLoadContext at the unload time  
            Thread.Sleep(Timeout.Infinite);  
        }  
  
        static GCHandle handle;  
        static int Main(string[] args)  
        {  
            // Issue preventing unloading #3 - normal GC handle  
            handle = GCHandle.Alloc(new Test());  
            Thread t = new Thread(new ThreadStart(ThreadProc));  
            t.IsBackground = true;  
            t.Start();  
            Console.WriteLine($"Hello from the test: args[0] = {args[0]}");  
  
            return 1;  
        }  
    }  
}
```

How .NET is versioned

Article • 04/27/2023

The [.NET Runtime](#) and the [.NET SDK](#) add new features at different frequencies. In general, the SDK is updated more frequently than the Runtime. This article explains the runtime and the SDK version numbers.

.NET releases a new major version every November. Even-numbered releases, such as .NET 6 or .NET 8, are long-term supported (LTS). LTS releases get free support and patches for three years. Odd-numbered releases are standard-term support. Standard-term support releases get free support and patches for 18 months.

Versioning details

The .NET Runtime has a major.minor.patch approach to versioning that follows [semantic versioning](#).

The .NET SDK, however, doesn't follow semantic versioning. The .NET SDK releases faster and its version numbers must communicate both the aligned runtime and the SDK's own minor and patch releases.

The first two positions of the .NET SDK version number match the .NET Runtime version it released with. Each version of the SDK can create applications for this runtime or any lower version.

The third position of the SDK version number communicates both the minor and patch number. The minor version is multiplied by 100. The final two digits represent the patch number. Minor version 1, patch version 2 would be represented as 102. For example, here's a possible sequence of runtime and SDK version numbers:

| Change | .NET Runtime | .NET SDK (*) | Notes |
|-----------------------|--------------|--------------|---|
| Initial release | 5.0.0 | 5.0.100 | Initial release. |
| SDK patch | 5.0.0 | 5.0.101 | Runtime didn't change with this SDK patch. SDK patch bumps last digit in SDK patch. |
| Runtime and SDK patch | 5.0.1 | 5.0.102 | Runtime patch bumps Runtime patch number. SDK patch bumps last digit in SDK patch. |
| SDK feature change | 5.0.1 | 5.0.200 | Runtime patch didn't change. New SDK feature bumps first digit in SDK patch. |

| Change | .NET Runtime | .NET SDK (*) | Notes |
|---------------|--------------|--------------|---|
| Runtime patch | 5.0.2 | 5.0.200 | Runtime patch bumps Runtime patch number. SDK doesn't change. |

From the preceding table you can see several policies:

- The Runtime and SDK share major and minor versions. The first two numbers for a given SDK and runtime should match. All the preceding examples are part of the .NET 5.0 release stream.
- The patch version of the runtime revs only when the runtime is updated. The SDK patch number doesn't update for a runtime patch.
- The patch version of the SDK updates only when the SDK is updated. It's possible that a runtime patch doesn't require an SDK patch.

NOTES:

- If the SDK has 10 feature updates before a runtime feature update, version numbers roll into the 1000 series. Version 5.0.1000 would follow version 5.0.900. This situation isn't expected to occur.
- 99 patch releases without a feature release won't occur. If a release approaches this number, it forces a feature release.

You can see more details in the initial proposal at the [dotnet/designs](#) repository.

Semantic versioning

The .NET *Runtime* roughly adheres to [Semantic Versioning \(SemVer\)](#), adopting the use of `MAJOR.MINOR.PATCH` versioning, using the various parts of the version number to describe the degree and type of change.

`MAJOR.MINOR.PATCH[-PRERELEASE-BUILDSNUMBER]`

The optional `PRERELEASE` and `BUILDSNUMBER` parts are never part of supported releases and only exist on nightly builds, local builds from source targets, and unsupported preview releases.

Understand runtime version number changes

- `MAJOR` is incremented once a year and may contain:
 - Significant changes in the product, or a new product direction.
 - API introduced breaking changes. There's a high bar to accepting breaking changes.
 - A newer `MAJOR` version of an existing dependency is adopted.

Major releases happen once a year, even-numbered versions are long-term supported (LTS) releases. The first LTS release using this versioning scheme is .NET 6. The latest non-LTS version is .NET 5.

- `MINOR` is incremented when:
 - Public API surface area is added.
 - A new behavior is added.
 - A newer `MINOR` version of an existing dependency is adopted.
 - A new dependency is introduced.
- `PATCH` is incremented when:
 - Bug fixes are made.
 - Support for a newer platform is added.
 - A newer `PATCH` version of an existing dependency is adopted.
 - Any other change doesn't fit one of the previous cases.

When there are multiple changes, the highest element affected by individual changes is incremented, and the following ones are reset to zero. For example, when `MAJOR` is incremented, `MINOR.PATCH` are reset to zero. When `MINOR` is incremented, `PATCH` is reset to zero while `MAJOR` remains the same.

Version numbers in file names

The files downloaded for .NET carry the version, for example, `dotnet-sdk-5.0.301-win10-x64.exe`.

Preview versions

Preview versions have a `-preview.[number].[build]` appended to the version number. For example, `6.0.0-preview.5.21302.13`.

Servicing versions

After a release goes out, the release branches generally stop producing daily builds and instead start producing servicing builds. Servicing versions have a `-servicing-[number]` appended to the version. For example, `5.0.1-servicing-006924`.

.NET runtime compatibility

The .NET runtime maintains a high level of compatibility between versions. .NET apps should, by and large, continue to work after upgrading to a new major .NET runtime version.

Each major .NET runtime version contains intentional, carefully vetted, and documented [breaking changes](#). The documented breaking changes aren't the only source of issues that can affect an app after upgrade. For example, a performance improvement in the .NET runtime (that's not considered a breaking change) can expose latent app threading bugs that cause the app to not work on that version. It's expected for large apps to require a few fixes after upgrading to a new .NET runtime major version.

By default, .NET apps are configured to run on a given .NET runtime major version, so recompilation is highly recommended to upgrade the app to run on a new .NET runtime major version. Then retest the app after upgrading to identify any issues.

Suppose upgrading via app recompilation isn't feasible. In that case, the .NET runtime provides [additional settings](#) to enable an app to run on a higher major .NET runtime version than the version it was compiled for. These settings don't change the risks involved in upgrading the app to a higher major .NET runtime version, and it's still required to retest the app post upgrade.

The .NET runtime supports loading libraries that target older .NET runtime versions. An app that's upgraded to a newer major .NET runtime version can reference libraries and NuGet packages that target older .NET runtime versions. It's unnecessary to simultaneously upgrade the target runtime version of all libraries and NuGet packages referenced by the app.

Select the .NET version to use

Article • 02/28/2023

This article explains the policies used by the .NET tools, SDK, and runtime for selecting versions. These policies provide a balance between running applications using the specified versions and enabling ease of upgrading both developer and end-user machines. These policies enable:

- Easy and efficient deployment of .NET, including security and reliability updates.
- Use the latest tools and commands independent of target runtime.

Version selection occurs:

- When you run an SDK command, [the SDK uses the latest installed version](#).
- When you build an assembly, [target framework monikers define build time APIs](#).
- When you run a .NET application, [target framework dependent apps roll-forward](#).
- When you publish a self-contained application, [self-contained deployments include the selected runtime](#).

The rest of this document examines those four scenarios.

The SDK uses the latest installed version

SDK commands include `dotnet new` and `dotnet run`. The .NET CLI must choose an SDK version for every `dotnet` command. It uses the latest SDK installed on the machine by default, even if:

- The project targets an earlier version of the .NET runtime.
- The latest version of the .NET SDK is a preview version.

You can take advantage of the latest SDK features and improvements while targeting earlier .NET runtime versions. You can target different runtime versions of .NET using the same SDK tools.

On rare occasions, you may need to use an earlier version of the SDK. You specify that version in a [*global.json* file](#). The "use latest" policy means you only use *global.json* to specify a .NET SDK version earlier than the latest installed version.

global.json can be placed anywhere in the file hierarchy. The CLI searches upward from the project directory for the first *global.json* it finds. You control which projects a given *global.json* applies to by its place in the file system. The .NET CLI searches for a *global.json* file iteratively navigating the path upward from the current working directory.

The first `global.json` file found specifies the version used. If that SDK version is installed, that version is used. If the SDK specified in the `global.json` isn't found, the .NET CLI uses [matching rules](#) to select a compatible SDK, or fails if none is found.

The following example shows the `global.json` syntax:

JSON

```
{  
  "sdk": {  
    "version": "5.0.0"  
  }  
}
```

The process for selecting an SDK version is:

1. `dotnet` searches for a `global.json` file iteratively reverse-navigating the path upward from the current working directory.
2. `dotnet` uses the SDK specified in the first `global.json` found.
3. `dotnet` uses the latest installed SDK if no `global.json` is found.

For more information about SDK version selection, see the [Matching rules](#) and [rollForward](#) sections of the [global.json overview](#) article.

Target Framework Monikers define build time APIs

You build your project against APIs defined in a **Target Framework Moniker** (TFM). You specify the [target framework](#) in the project file. Set the `TargetFramework` element in your project file as shown in the following example:

XML

```
<TargetFramework>net5.0</TargetFramework>
```

You may build your project against multiple TFMs. Setting multiple target frameworks is more common for libraries but can be done with applications as well. You specify a `TargetFrameworks` property (plural of `TargetFramework`). The target frameworks are semicolon-delimited as shown in the following example:

XML

```
<TargetFrameworks>net5.0;netcoreapp3.1;net47</TargetFrameworks>
```

A given SDK supports a fixed set of frameworks, capped to the target framework of the runtime it ships with. For example, the .NET 5 SDK includes the .NET 5 runtime, which is an implementation of the `net5.0` target framework. The .NET 5 SDK supports `netcoreapp2.0`, `netcoreapp2.1`, `netcoreapp3.0`, and so on, but not `net6.0` (or higher). You install the .NET 6 SDK to build for `net6.0`.

.NET Standard

.NET Standard was a way to target an API surface shared by different implementations of .NET. Starting with the release of .NET 5, which is an API standard itself, .NET Standard has little relevance, except for one scenario: .NET Standard is useful when you want to target both .NET and .NET Framework. .NET 5 implements all .NET Standard versions.

For more information, see [.NET 5 and .NET Standard](#).

Framework-dependent apps roll-forward

When you run an application from source with `dotnet run`, from a [framework-dependent deployment](#) with `dotnet myapp.dll`, or from a [framework-dependent executable](#) with `myapp.exe`, the `dotnet` executable is the **host** for the application.

The host chooses the latest patch version installed on the machine. For example, if you specified `net5.0` in your project file, and `5.0.2` is the latest .NET runtime installed, the `5.0.2` runtime is used.

If no acceptable `5.0.*` version is found, a new `5.*` version is used. For example, if you specified `net5.0` and only `5.1.0` is installed, the application runs using the `5.1.0` runtime. This behavior is referred to as "minor version roll-forward." Lower versions also won't be considered. When no acceptable runtime is installed, the application won't run.

A few usage examples demonstrate the behavior, if you target 5.0:

- ✅ 5.0 is specified. 5.0.3 is the highest patch version installed. 5.0.3 is used.
- ❌ 5.0 is specified. No 5.0.* versions are installed. 3.1.1 is the highest runtime installed. An error message is displayed.
- ✅ 5.0 is specified. No 5.0.* versions are installed. 5.1.0 is the highest runtime version installed. 5.1.0 is used.
- ❌ 3.0 is specified. No 3.x versions are installed. 5.0.0 is the highest runtime installed. An error message is displayed.

Minor version roll-forward has one side-effect that may affect end users. Consider the following scenario:

1. The application specifies that 5.0 is required.
2. When run, version 5.0.* isn't installed, however, 5.1.0 is. Version 5.1.0 will be used.
3. Later, the user installs 5.0.3 and runs the application again, 5.0.3 will now be used.

It's possible that 5.0.3 and 5.1.0 behave differently, particularly for scenarios like serializing binary data.

Control roll-forward behavior

Before overriding default roll-forward behavior, familiarize yourself with the level of [.NET runtime compatibility](#).

The roll-forward behavior for an application can be configured in four different ways:

1. Project-level setting by setting the `<RollForward>` property:

XML

```
<PropertyGroup>
  <RollForward>LatestMinor</RollForward>
</PropertyGroup>
```

2. The `*.runtimeconfig.json` file.

This file is produced when you compile your application. If the `<RollForward>` property was set in the project, it's reproduced in the `*.runtimeconfig.json` file as the `rollForward` setting. Users can edit this file to change the behavior of your application.

JSON

```
{
  "runtimeOptions": {
    "tfm": "net5.0",
    "rollForward": "LatestMinor",
    "framework": {
      "name": "Microsoft.NETCore.App",
      "version": "5.0.0"
    }
  }
}
```

3. The `dotnet` command's `--roll-forward <value>` property.

When you run an application, you can control the roll-forward behavior through the command line:

NET CLI

```
dotnet run --roll-forward LatestMinor  
dotnet myapp.dll --roll-forward LatestMinor  
myapp.exe --roll-forward LatestMinor
```

4. The `DOTNET_ROLL_FORWARD` environment variable.

Precedence

Roll forward behavior is set by the following order when your app is run, higher numbered items taking precedence over lower numbered items:

1. First the `*.runtimeconfig.json` config file is evaluated.
2. Next, the `DOTNET_ROLL_FORWARD` environment variable is considered, overriding the previous check.
3. Finally, any `--roll-forward` parameter passed to the running application overrides everything else.

Values

However you set the roll-forward setting, use one of the following values to set the behavior:

| Value | Description |
|-------------|--|
| Minor | Default if not specified. Roll-forward to the lowest higher minor version, if requested minor version is missing. If the requested minor version is present, then the <code>LatestPatch</code> policy is used. |
| Major | Roll-forward to the next available higher major version, and lowest minor version, if requested major version is missing. If the requested major version is present, then the <code>Minor</code> policy is used. |
| LatestPatch | Roll-forward to the highest patch version. This value disables minor version roll-forward. |
| LatestMinor | Roll-forward to highest minor version, even if requested minor version is present. |

| Value | Description |
|-------------|--|
| LatestMajor | Roll-forward to highest major and highest minor version, even if requested major is present. |
| Disable | Don't roll-forward, only bind to the specified version. This policy isn't recommended for general use since it disables the ability to roll-forward to the latest patches. This value is only recommended for testing. |

Self-contained deployments include the selected runtime

You can publish an application as a [self-contained distribution](#). This approach bundles the .NET runtime and libraries with your application. Self-contained deployments don't have a dependency on runtime environments. Runtime version selection occurs at publishing time, not run time.

The *restore* event that occurs when publishing selects the latest patch version of the given runtime family. For example, `dotnet publish` will select .NET 5.0.3 if it's the latest patch version in the .NET 5 runtime family. The target framework (including the latest installed security patches) is packaged with the application.

An error occurs if the minimum version specified for an application isn't satisfied. `dotnet publish` binds to the latest runtime patch version (within a given major.minor version family). `dotnet publish` doesn't support the roll-forward semantics of `dotnet run`. For more information about patches and self-contained deployments, see the article on [runtime patch selection](#) in deploying .NET applications.

Self-contained deployments may require a specific patch version. You can override the minimum runtime patch version (to higher or lower versions) in the project file, as shown in the following example:

XML

```
<PropertyGroup>
  <RuntimeFrameworkVersion>5.0.7</RuntimeFrameworkVersion>
</PropertyGroup>
```

The `RuntimeFrameworkVersion` element overrides the default version policy. For self-contained deployments, the `RuntimeFrameworkVersion` specifies the *exact* runtime framework version. For framework-dependent applications, the `RuntimeFrameworkVersion` specifies the *minimum* required runtime framework version.

.NET Runtime configuration settings

Article • 11/11/2023

.NET 5+ (including .NET Core versions) supports the use of configuration files and environment variables to configure the behavior of .NET applications.

ⓘ Note

The articles in this section concern configuration of the .NET Runtime itself. If you're migrating to .NET Core 3.1 or later and are looking for a replacement for the *app.config* file, or if you simply want a way to use custom configuration values in your .NET app, see the [Microsoft.Extensions.Configuration.ConfigurationBuilder](#) class and [Configuration in .NET](#).

Using these settings is an attractive option if:

- You don't own or control the source code for an application and therefore are unable to configure it programmatically.
- Multiple instances of your application run at the same time on a single system, and you want to configure each for optimum performance.

.NET provides the following mechanisms for configuring behavior of the .NET runtime:

- The [runtimeconfig.json file](#)
- [MSBuild properties](#)
- [Environment variables](#)

ⓘ Tip

Configuring an option by using an environment variable applies the setting to all .NET apps. Configuring an option in the *runtimeconfig.json* or project file applies the setting to that application only.

Some configuration values can also be set programmatically by calling the [AppContext.SetSwitch](#) method.

The articles in this section of the documentation are organized by category, for example, [debugging](#) and [garbage collection](#). Where applicable, configuration options are shown for *runtimeconfig.json* files, MSBuild properties, environment variables, and, for cross-reference, *app.config* files for .NET Framework projects.

runtimeconfig.json

When a project is [built](#), an `[appname].runtimeconfig.json` file is generated in the output directory. If a `runtimeconfig.template.json` file exists in the same folder as the project file, any configuration options it contains are inserted into the `[appname].runtimeconfig.json` file. If you're building the app yourself, put any configuration options in the `runtimeconfig.template.json` file. If you're just running the app, insert them directly into the `[appname].runtimeconfig.json` file.

ⓘ Note

- The `[appname].runtimeconfig.json` file will get overwritten on subsequent builds.
- If your app's `OutputType` is not `Exe` and you want configuration options to be copied from `runtimeconfig.template.json` to `[appname].runtimeconfig.json`, you must explicitly set `GenerateRuntimeConfigurationFiles` to `true` in your project file. For apps that require a `runtimeconfig.json` file, this property defaults to `true`.

Specify runtime configuration options in the `configProperties` section of the `runtimeconfig.json` or `runtimeconfig.template.json` file. This section has the form:

JSON

```
"configProperties": {  
    "config-property-name1": "config-value1",  
    "config-property-name2": "config-value2"  
}
```

Example `[appname].runtimeconfig.json` file

If you're placing the options in the output JSON file, nest them under the `runtimeOptions` property.

JSON

```
{  
    "runtimeOptions": {  
        "tfm": "netcoreapp3.1",  
        "framework": {  
            "name": "Microsoft.NETCore.App",  
            "version": "3.1.0"  
        }  
    }  
}
```

```
        },
        "configProperties": {
            "System.Globalization.UseNls": true,
            "System.Net.DisableIPv6": true,
            "System.GC.Concurrent": false,
            "System.Threading.ThreadPool.MinThreads": 4,
            "System.Threading.ThreadPool.MaxThreads": 25
        }
    }
}
```

Example `runtimeconfig.template.json` file

If you're placing the options in the template JSON file, omit the `runtimeOptions` property.

JSON

```
{
    "configProperties": {
        "System.Globalization.UseNls": true,
        "System.Net.DisableIPv6": true,
        "System.GC.Concurrent": false,
        "System.Threading.ThreadPool.MinThreads": "4",
        "System.Threading.ThreadPool.MaxThreads": "25"
    }
}
```

MSBuild properties

Some runtime configuration options can be set using MSBuild properties in the `.csproj` or `.vbproj` file of SDK-style .NET projects. MSBuild properties take precedence over options set in the `runtimeconfig.template.json` file.

For runtime configuration settings that don't have a specific MSBuild property, you can use the `RuntimeHostConfigurationOption` MSBuild item instead. Use the `runtimeconfig.json` setting name as the value of the `Include` attribute.

Here is an example SDK-style project file with MSBuild properties for configuring the behavior of the .NET runtime:

XML

```
<Project Sdk="Microsoft.NET.Sdk">

    <PropertyGroup>
```

```
<OutputType>Exe</OutputType>
<TargetFramework>netcoreapp3.1</TargetFramework>
</PropertyGroup>

<PropertyGroup>
  <ConcurrentGarbageCollection>false</ConcurrentGarbageCollection>
  <ThreadPoolMinThreads>4</ThreadPoolMinThreads>
  <ThreadPoolMaxThreads>25</ThreadPoolMaxThreads>
</PropertyGroup>

<ItemGroup>
  <RuntimeHostConfigurationOption Include="System.Globalization.UseNls"
Value="true" />
  <RuntimeHostConfigurationOption Include="System.Net.DisableIPv6"
Value="true" />
</ItemGroup>

</Project>
```

MSBuild properties for configuring the behavior of the runtime are noted in the individual articles for each area, for example, [garbage collection](#). They're also listed in the [Runtime configuration](#) section of the MSBuild properties reference for SDK-style projects.

Environment variables

Environment variables can be used to supply some runtime configuration information. Configuration knobs specified as environment variables generally have the prefix `DOTNET_`.

Note

.NET 6 standardizes on the prefix `DOTNET_` instead of `COMPlus_` for environment variables that configure .NET run-time behavior. However, the `COMPlus_` prefix will continue to work. If you're using a previous version of the .NET runtime, you should still use the `COMPlus_` prefix for environment variables.

You can define environment variables from the Windows Control Panel, at the command line, or programmatically by calling the [`Environment.SetEnvironmentVariable\(String, String\)`](#) method on both Windows and Unix-based systems.

The following examples show how to set an environment variable at the command line:

shell

```
# Windows  
set DOTNET_GCRetainVM=1  
  
# Powershell  
$env:DOTNET_GCRetainVM="1"  
  
# Unix  
export DOTNET_GCRetainVM=1
```

Runtime configuration options for compilation

Article • 11/11/2023

This article details the settings you can use to configure .NET compilation.

ⓘ Note

.NET 6 standardizes on the prefix `DOTNET_` instead of `COMPlus_` for environment variables that configure .NET run-time behavior. However, the `COMPlus_` prefix will continue to work. If you're using a previous version of the .NET runtime, you should still use the `COMPlus_` prefix for environment variables.

Tiered compilation

- Configures whether the just-in-time (JIT) compiler uses [tiered compilation](#). Tiered compilation transitions methods through two tiers:
 - The first tier generates code more quickly ([quick JIT](#)) or loads pre-compiled code ([ReadyToRun](#)).
 - The second tier generates optimized code in the background ("optimizing JIT").
- In .NET Core 3.0 and later, tiered compilation is enabled by default.
- In .NET Core 2.1 and 2.2, tiered compilation is disabled by default.
- For more information, see the [Tiered compilation guide ↗](#).

| Setting name | Values |
|-----------------------------|---|
| runtimconfig.json | <code>System.Runtime.TieredCompilation</code> <code>true</code> - enabled <code>false</code> - disabled |
| MSBuild property | <code>TieredCompilation</code> <code>true</code> - enabled <code>false</code> - disabled |
| Environment variable | <code>COMPlus_TieredCompilation</code> or <code>DOTNET_TieredCompilation</code> <code>1</code> - enabled <code>0</code> - disabled |

Examples

runtimconfig.json file:

JSON

```
{  
    "runtimeOptions": {  
        "configProperties": {  
            "System.Runtime.TieredCompilation": false  
        }  
    }  
}
```

runtimeconfig.template.json file:

JSON

```
{  
    "configProperties": {  
        "System.Runtime.TieredCompilation": false  
    }  
}
```

Project file:

XML

```
<Project Sdk="Microsoft.NET.Sdk">  
  
    <PropertyGroup>  
        <TieredCompilation>false</TieredCompilation>  
    </PropertyGroup>  
  
</Project>
```

Quick JIT

- Configures whether the JIT compiler uses *quick JIT*. For methods that don't contain loops and for which pre-compiled code is not available, quick JIT compiles them more quickly but without optimizations.
- Enabling quick JIT decreases startup time but can produce code with degraded performance characteristics. For example, the code may use more stack space, allocate more memory, and run slower.
- If quick JIT is disabled but [tiered compilation](#) is enabled, only pre-compiled code participates in tiered compilation. If a method is not pre-compiled with [ReadyToRun](#), the JIT behavior is the same as if [tiered compilation](#) were disabled.
- In .NET Core 3.0 and later, quick JIT is enabled by default.
- In .NET Core 2.1 and 2.2, quick JIT is disabled by default.

| Setting name | | Values |
|-----------------------------|---|------------------------------------|
| runtimeconfig.json | System.Runtime.TieredCompilation.QuickJit | true - enabled false - disabled |
| MSBuild property | TieredCompilationQuickJit | true - enabled false - disabled |
| Environment variable | COMPlus_TC_QuickJit or DOTNET_TC_QuickJit | 1 - enabled 0 - disabled |

Examples

runtimeconfig.json file:

JSON

```
{
  "runtimeOptions": {
    "configProperties": {
      "System.Runtime.TieredCompilation.QuickJit": false
    }
  }
}
```

runtimeconfig.template.json file:

JSON

```
{
  "configProperties": {
    "System.Runtime.TieredCompilation.QuickJit": false
  }
}
```

Project file:

XML

```
<Project Sdk="Microsoft.NET.Sdk">

  <PropertyGroup>
    <TieredCompilationQuickJit>false</TieredCompilationQuickJit>
  </PropertyGroup>

</Project>
```

Quick JIT for loops

- Configures whether the JIT compiler uses quick JIT on methods that contain loops.
- Enabling quick JIT for loops may improve startup performance. However, long-running loops can get stuck in less-optimized code for long periods.
- If [quick JIT](#) is disabled, this setting has no effect.
- If you omit this setting, quick JIT is not used for methods that contain loops. This is equivalent to setting the value to `false`.

| | Setting name | Values |
|-----------------------------|--|--|
| runtimconfig.json | <code>System.Runtime.TieredCompilation.QuickJitForLoops</code> | <code>false</code> - disabled <code>true</code> - enabled |
| MSBuild property | <code>TieredCompilationQuickJitForLoops</code> | <code>false</code> - disabled <code>true</code> - enabled |
| Environment variable | <code>COMPlus_TC_QuickJitForLoops</code> or <code>DOTNET_TC_QuickJitForLoops</code> | <code>0</code> - disabled <code>1</code> - enabled |

Examples

runtimconfig.json file:

```
JSON

{
  "runtimeOptions": {
    "configProperties": {
      "System.Runtime.TieredCompilation.QuickJitForLoops": false
    }
  }
}
```

runtimconfig.template.json file:

```
JSON

{
  "configProperties": {
    "System.Runtime.TieredCompilation.QuickJitForLoops": false
  }
}
```

```
}
```

Project file:

XML

```
<Project Sdk="Microsoft.NET.Sdk">

<PropertyGroup>

<TieredCompilationQuickJitForLoops>true</TieredCompilationQuickJitForLoops>
</PropertyGroup>

</Project>
```

ReadyToRun

- Configures whether the .NET Core runtime uses pre-compiled code for images with available ReadyToRun data. Disabling this option forces the runtime to JIT-compile framework code.
- For more information, see [Ready to Run](#).
- If you omit this setting, .NET uses ReadyToRun data when it's available. This is equivalent to setting the value to `1`.

| | Setting name | Values |
|-----------------------------|---|---|
| Environment variable | <code>COMPlus_ReadyToRun</code> or <code>DOTNET_ReadyToRun</code> | <code>1</code> - enabled <code>0</code> - disabled |

Profile-guided optimization

This setting enables dynamic or tiered profile-guided optimization (PGO) in .NET 6 and later versions.

| | Setting name | Values |
|-----------------------------|-------------------------------|--|
| Environment variable | <code>DOTNET_TieredPGO</code> | <code>1</code> - enabled <code>0</code> - disabled |
| MSBuild property | <code>TieredPGO</code> | <code>true</code> - enabled <code>false</code> - disabled |

Examples

Project file:

```
XML

<Project Sdk="Microsoft.NET.Sdk">

  <PropertyGroup>
    <TieredPGO>true</TieredPGO>
  </PropertyGroup>

</Project>
```

Runtime configuration options for debugging and profiling

Article • 12/05/2023

This article details the settings you can use to configure .NET debugging and profiling.

ⓘ Note

.NET 6 standardizes on the prefix `DOTNET_` instead of `COMPlus_` for environment variables that configure .NET run-time behavior. However, the `COMPlus_` prefix will continue to work. If you're using a previous version of the .NET runtime, you should still use the `COMPlus_` prefix for environment variables.

Enable diagnostics

- Configures whether the debugger, the profiler, and EventPipe diagnostics are enabled or disabled.
- If you omit this setting, diagnostics are enabled. This is equivalent to setting the value to `1`.

[+] Expand table

| Setting name | Values |
|--------------------------------|--|
| <code>runtimconfig.json</code> | N/A |
| Environment variable | <code>COMPlus_EnableDiagnostics</code> or <code>DOTNET_EnableDiagnostics</code> <code>1</code> - enabled <code>0</code> - disabled |

Enable profiling

- Configures whether profiling is enabled for the currently running process.
- If you omit this setting, profiling is disabled. This is equivalent to setting the value to `0`.

[+] Expand table

| | Setting name | Values |
|-----------------------------|--------------------------|--|
| runtimeconfig.json | N/A | N/A |
| Environment variable | CORECLR_ENABLE_PROFILING | <input type="radio"/> 0 - disabled <input checked="" type="radio"/> 1 - enabled |

Profiler GUID

- Specifies the GUID of the profiler to load into the currently running process.

[Expand table](#)

| | Setting name | Values |
|-----------------------------|---------------------|--------------------|
| runtimeconfig.json | N/A | N/A |
| Environment variable | CORECLR_PROFILER | <i>string-guid</i> |

Profiler location

- Specifies the path to the profiler DLL to load into the currently running process (or 32-bit or 64-bit process).
- If more than one variable is set, the bitness-specific variables take precedence. They specify which bitness of profiler to load.
- For more information, see [Finding the profiler library](#).

[Expand table](#)

| | Setting name | Values |
|-----------------------------|--------------------------|--------------------|
| Environment variable | CORECLR_PROFILER_PATH | <i>string-path</i> |
| Environment variable | CORECLR_PROFILER_PATH_32 | <i>string-path</i> |
| Environment variable | CORECLR_PROFILER_PATH_64 | <i>string-path</i> |

Export perf maps and jit dumps

- Enables or disables selective enablement of perf maps or jit dumps. These files allow third party tools, such as the Linux `perf` tool, to identify call sites for dynamically generated code and precompiled ReadyToRun (R2R) modules.

- If you omit this setting, writing perf map and jit dump files are both disabled. This is equivalent to setting the value to `0`.
- When perf maps are disabled, not all managed callsites will be properly resolved.
- Depending on the Linux kernel version, both formats are supported by the `perf` tool.
- Enabling perf maps or jit dumps causes a 10-20% overhead. To minimize performance impact, it's recommended to selectively enable either perf maps or jit dumps, but not both.

The following table compares perf maps and jit maps.

[\[+\] Expand table](#)

| Format | Description | Supported on |
|------------------|---|---|
| <i>Perf maps</i> | Emits <code>/tmp/perf-<pid>.map</code> , which contains symbolic information for dynamically generated code. Emits <code>/tmp/perfinfo-<pid>.map</code> , which includes ReadyToRun (R2R) module symbol information and is used by PerfCollect . | Perf maps are supported on all Linux kernel versions. |
| <i>Jit dumps</i> | The jit dump format supersedes perf maps and contains more detailed symbolic information. When enabled, jit dumps are output to <code>/tmp/jit-<pid>.dump</code> files. | Linux kernel versions 5.4 or higher. |

[\[+\] Expand table](#)

| | Setting name | Values |
|---------------------------------|--|--|
| <code>runtimeconfig.json</code> | N/A | N/A |
| Environment variable | <code>COMPlus_PerfMapEnabled</code> or <code>DOTNET_PerfMapEnabled</code> | <code>0</code> - disabled <code>1</code> - perf maps and jit dumps both enabled <code>2</code> - jit dumps enabled <code>3</code> - perf maps enabled |

Perf log markers

- Enables or disables the specified signal to be accepted and ignored as a marker in the perf logs.
- If you omit this setting, the specified signal is not ignored. This is equivalent to setting the value to `0`.

| Setting name | Values |
|-----------------------------|---|
| runtimeconfig.json | N/A |
| Environment variable | <code>COMPlus_PerfMapIgnoreSignal</code> or <code>DOTNET_PerfMapIgnoreSignal</code> 0 - disabled 1 - enabled |

Note

This setting is ignored if `DOTNET_PerfMapEnabled` is omitted or set to 0 (that is, disabled).

Runtime configuration options for garbage collection

Article • 11/11/2023

This page contains information about settings for the .NET runtime garbage collector (GC). If you're trying to achieve peak performance of a running app, consider using these settings. However, the defaults provide optimum performance for most applications in typical situations.

Settings are arranged into groups on this page. The settings within each group are commonly used in conjunction with each other to achieve a specific result.

Note

- These configurations are only read by the runtime when the GC is initialized (usually this means during the process startup time). If you change an environment variable when a process is already running, the change won't be reflected in that process. Settings that can be changed through APIs at run time, such as `latency level`, are omitted from this page.
- Because GC is per process, it rarely ever makes sense to set these configurations at the machine level. For example, you wouldn't want every .NET process on a machine to use server GC or the same heap hard limit.
- For number values, use decimal notation for settings in the `runtimeconfig.json` or `runtimeconfig.template.json` file and hexadecimal notation for environment variable settings. For hexadecimal values, you can specify them with or without the "0x" prefix.
- If you're using the environment variables, .NET 6 and later versions standardize on the prefix `DOTNET_` instead of `COMPlus_`. However, the `COMPlus_` prefix will continue to work. If you're using a previous version of the .NET runtime, you should still use the `COMPlus_` prefix, for example, `COMPlus_gcServer`.

Ways to specify the configuration

For different versions of the .NET runtime, there are different ways to specify the configuration values. The following table shows a summary.

| Config location | .NET versions this location applies to | Formats | How it's interpreted |
|---|--|----------|--|
| runtimeconfig.json file/ runtimeconfig.template.json file | .NET (Core) | n | n is interpreted as a decimal value. |
| Environment variable | .NET Framework, .NET (Core) | 0xn or n | n is interpreted as a hex value in either format |
| app.config file | .NET Framework | 0xn | n is interpreted as a hex value ¹ |

¹ You can specify a value without the `0x` prefix for an app.config file setting, but it's not recommended. On .NET Framework 4.8+, due to a bug, a value specified without the `0x` prefix is interpreted as hexadecimal, but on previous versions of .NET Framework, it's interpreted as decimal. To avoid having to change your config, use the `0x` prefix when specifying a value in your app.config file.

For example, to specify 12 heaps for `GCHeapCount` for a .NET Framework app named `A.exe`, add the following XML to the `A.exe.config` file.

XML

```
<?xml version="1.0" encoding="utf-8" ?>
<configuration>
    ...
    <runtime>
        <gcServer enabled="true"/>
        <GCHeapCount>0xc</GCHeapCount>
    </runtime>
</configuration>
```

For both .NET (Core) and .NET Framework, you can use environment variables.

On Windows using .NET 6 or a later version:

Windows Command Prompt

```
SET DOTNET_gcServer=1
SET DOTNET_GCHeapCount=c
```

On Windows using .NET 5 or earlier:

Windows Command Prompt

```
SET COMPlus_gcServer=1
SET COMPlus_GCHeapCount=c
```

On other operating systems:

For .NET 6 or later versions:

Bash

```
export DOTNET_gcServer=1
export DOTNET_GCHeapCount=c
```

For .NET 5 and earlier versions:

Bash

```
export COMPlus_gcServer=1
export COMPlus_GCHeapCount=c
```

If you're not using .NET Framework, you can also set the value in the *runtimeconfig.json* or *runtimeconfig.template.json* file.

runtimeconfig.json file:

JSON

```
{
  "runtimeOptions": {
    "configProperties": {
      "System.GC.Server": true,
      "System.GC.HeapCount": 12
    }
  }
}
```

runtimeconfig.template.json file:

JSON

```
{
  "configProperties": {
    "System.GC.Server": true,
    "System.GC.HeapCount": 12
  }
}
```

Flavors of garbage collection

The two main flavors of garbage collection are workstation GC and server GC. For more information about differences between the two, see [Workstation and server garbage collection](#).

The subflavors of garbage collection are background and non-concurrent.

Use the following settings to select flavors of garbage collection:

- [Workstation vs. server GC](#)
- [Background GC](#)

Workstation vs. server

- Configures whether the application uses workstation garbage collection or server garbage collection.
- Default: Workstation garbage collection. This is equivalent to setting the value to `false`.

[+] [Expand table](#)

| | Setting name | Values | Version introduced |
|--------------------------------------|--------------------------------------|--|---------------------------|
| runtimeconfig.json | <code>System.GC.Server</code> | <code>false</code> - workstation <code>true</code> - server | .NET Core 1.0 |
| MSBuild property | <code>ServerGarbageCollection</code> | <code>false</code> - workstation <code>true</code> - server | .NET Core 1.0 |
| Environment variable | <code>COMPlus_gcServer</code> | <code>0</code> - workstation <code>1</code> - server | .NET Core 1.0 |
| Environment variable | <code>DOTNET_gcServer</code> | <code>0</code> - workstation <code>1</code> - server | .NET 6 |
| app.config for .NET Framework | <code>GCServer</code> | <code>false</code> - workstation <code>true</code> - server | |

Examples

runtimeconfig.json file:

JSON

```
{  
    "runtimeOptions": {  
        "configProperties": {  
            "System.GC.Server": true  
        }  
    }  
}
```

runtimeconfig.template.json file:

JSON

```
{  
    "configProperties": {  
        "System.GC.Server": true  
    }  
}
```

Project file:

XML

```
<Project Sdk="Microsoft.NET.Sdk">  
  
    <PropertyGroup>  
        <ServerGarbageCollection>true</ServerGarbageCollection>  
    </PropertyGroup>  
  
</Project>
```

Background GC

- Configures whether background (concurrent) garbage collection is enabled.
- Default: Use background GC. This is equivalent to setting the value to `true`.
- For more information, see [Background garbage collection](#).

 Expand table

| Setting name | Values | Version introduced |
|--------------------------------------|--|--------------------|
| runtimesconfig.json | System.GC.Concurrent true - background GC false - non-concurrent GC | .NET Core 1.0 |
| MSBuild property | ConcurrentGarbageCollection true - background GC false - non-concurrent GC | .NET Core 1.0 |
| Environment variable | COMPlus_gcConcurrent 1 - background GC 0 - non-concurrent GC | .NET Core 1.0 |
| Environment variable | DOTNET_gcConcurrent 1 - background GC 0 - non-concurrent GC | .NET 6 |
| app.config for .NET Framework | gcConcurrent true - background GC false - non-concurrent GC | |

Examples

runtimesconfig.json file:

JSON

```
{
  "runtimeOptions": {
    "configProperties": {
      "System.GC.Concurrent": false
    }
  }
}
```

runtimesconfig.template.json file:

JSON

```
{
  "configProperties": {
```

```
        "System.GC.Concurrent": false  
    }  
}
```

Project file:

XML

```
<Project Sdk="Microsoft.NET.Sdk">  
  
    <PropertyGroup>  
        <ConcurrentGarbageCollection>false</ConcurrentGarbageCollection>  
    </PropertyGroup>  
  
</Project>
```

Manage resource usage

Use the following settings to manage the garbage collector's memory and processor usage:

- [Affinitize](#)
- [Affinimize mask](#)
- [Affinimize ranges](#)
- [CPU groups](#)
- [Heap count](#)
- [Heap limit](#)
- [Heap limit percent](#)
- [High memory percent](#)
- [Per-object-heap limits](#)
- [Per-object-heap limit percents](#)
- [Retain VM](#)

For more information about some of these settings, see the [Middle ground between workstation and server GC](#) blog entry.

Heap count

- Limits the number of heaps created by the garbage collector.
- Applies to server garbage collection only.
- If [GC processor affinity](#) is enabled, which is the default, the heap count setting affinizes n GC heaps/threads to the first n processors. (Use the [affinimize mask](#) or [affinimize ranges](#) settings to specify exactly which processors to affinimize.)

- If [GC processor affinity](#) is disabled, this setting limits the number of GC heaps.
- For more information, see the [GCHeapCount remarks](#).

[\[+\] Expand table](#)

| | Setting name | Values | Version introduced |
|--------------------------------------|----------------------------------|--------------------------|----------------------|
| runtimesconfig.json | <code>System.GC.HeapCount</code> | <i>decimal value</i> | .NET Core 3.0 |
| Environment variable | <code>COMPlus_GCHeapCount</code> | <i>hexadecimal value</i> | .NET Core 3.0 |
| Environment variable | <code>DOTNET_GCHeapCount</code> | <i>hexadecimal value</i> | .NET 6 |
| app.config for .NET Framework | <code>GCHeapCount</code> | <i>decimal value</i> | .NET Framework 4.6.2 |

This configuration setting doesn't have a specific MSBuild property. However, you can add a `RuntimeHostConfigurationOption` MSBuild item instead. Use the *runtimesconfig.json* setting name as the value of the `Include` attribute. For an example, see [MSBuild properties](#).

Examples

runtimesconfig.json file:

```
JSON
{
  "runtimeOptions": {
    "configProperties": {
      "System.GC.HeapCount": 16
    }
  }
}
```

runtimesconfig.template.json file:

```
JSON
{
  "configProperties": {
    "System.GC.HeapCount": 16
  }
}
```

Tip

If you're setting the option in `runtimeconfig.json`, specify a decimal value. If you're setting the option as an environment variable, specify a hexadecimal value. For example, to limit the number of heaps to 16, the values would be 16 for the JSON file and 0x10 or 10 for the environment variable.

Affinize mask

- Specifies the exact processors that garbage collector threads should use.
- If [GC processor affinity](#) is disabled, this setting is ignored.
- Applies to server garbage collection only.
- The value is a bit mask that defines the processors that are available to the process. For example, a decimal value of 1023 (or a hexadecimal value of 0x3FF or 3FF if you're using the environment variable) is 0011 1111 1111 in binary notation. This specifies that the first 10 processors are to be used. To specify the next 10 processors, that is, processors 10-19, specify a decimal value of 1047552 (or a hexadecimal value of 0xFFC00 or FFC00), which is equivalent to a binary value of 1111 1111 1100 0000 0000.

[\[+\] Expand table](#)

| | Setting name | Values | Version introduced |
|--------------------------------------|--|--------------------------|----------------------|
| runtimeconfig.json | <code>System.GC.HeapAffinizeMask</code> | <i>decimal value</i> | .NET Core 3.0 |
| Environment variable | <code>COMPlus_GCHheapAffinizeMask</code> | <i>hexadecimal value</i> | .NET Core 3.0 |
| Environment variable | <code>DOTNET_GCHheapAffinizeMask</code> | <i>hexadecimal value</i> | .NET 6 |
| app.config for .NET Framework | <code>GCHeapAffinizeMask</code> | <i>decimal value</i> | .NET Framework 4.6.2 |

This configuration setting doesn't have a specific MSBuild property. However, you can add a `RuntimeHostConfigurationOption` MSBuild item instead. Use the `runtimeconfig.json` setting name as the value of the `Include` attribute. For an example, see [MSBuild properties](#).

Examples

runtimeconfig.json file:

```
JSON

{
  "runtimeOptions": {
    "configProperties": {
      "System.GC.HeapAffinitizeMask": 1023
    }
  }
}
```

runtimeconfig.template.json file:

```
JSON

{
  "configProperties": {
    "System.GC.HeapAffinitizeMask": 1023
  }
}
```

Affinitize ranges

- Specifies the list of processors to use for garbage collector threads.
- This setting is similar to [System.GC.HeapAffinitizeMask](#), except it allows you to specify more than 64 processors.
- For Windows operating systems, prefix the processor number or range with the corresponding [CPU group](#), for example, "0:1-10,0:12,1:50-52,1:7". If you don't actually have more than 1 CPU group, you can't use this setting. You must use the [Affinitize mask](#) setting. And the numbers you specify are within that group, which means it cannot be ≥ 64 .
- For Linux operating systems, where the [CPU group](#) concept doesn't exist, you can use both this setting and the [Affinitize mask](#) setting to specify the same ranges. And instead of "0:1-10", specify "1-10" because you don't need to specify a group index.
- If [GC processor affinity](#) is disabled, this setting is ignored.
- Applies to server garbage collection only.
- For more information, see [Making CPU configuration better for GC on machines with > 64 CPUs](#) on Maoni Stephens' blog.

[] [Expand table](#)

| Setting name | Values | Version introduced |
|-----------------------------|---|--------------------|
| runtimconfig.json | System.GC.HeapAffinizeRanges Comma-separated list of processor numbers or ranges of processor numbers. Unix example: "1-10,12,50-52,70" Windows example: "0:1-10,0:12,1:50-52,1:7" | .NET Core 3.0 |
| Environment variable | COMPlus_GCHepAffinizeRanges Comma-separated list of processor numbers or ranges of processor numbers. Unix example: "1-10,12,50-52,70" Windows example: "0:1-10,0:12,1:50-52,1:7" | .NET Core 3.0 |
| Environment variable | DOTNET_GCHepAffinizeRanges Comma-separated list of processor numbers or ranges of processor numbers. Unix example: "1-10,12,50-52,70" Windows example: "0:1-10,0:12,1:50-52,1:7" | .NET 6 |

This configuration setting doesn't have a specific MSBuild property. However, you can add a `RuntimeHostConfigurationOption` MSBuild item instead. Use the `runtimconfig.json` setting name as the value of the `Include` attribute. For an example, see [MSBuild properties](#).

Examples

`runtimconfig.json` file:

```
JSON
{
  "runtimeOptions": {
    "configProperties": {
      "System.GC.HeapAffinizeRanges": "0:1-10,0:12,1:50-52,1:70"
    }
  }
}
```

```
        }
    }
}
```

runtimeconfig.template.json file:

JSON

```
{
  "configProperties": {
    "System.GC.HeapAffinimizeRanges": "0:1-10,0:12,1:50-52,1:70"
  }
}
```

CPU groups

- Configures whether the garbage collector uses [CPU groups](#) or not.

When a 64-bit Windows computer has multiple CPU groups, that is, there are more than 64 processors, enabling this element extends garbage collection across all CPU groups. The garbage collector uses all cores to create and balance heaps.

Note

This is a Windows-only concept. In older Windows versions, Windows limited a process to one CPU group. Thus, GC only used one CPU group unless you used this setting to enable multiple CPU groups. This OS limitation was lifted in Windows 11 and Server 2022. Also, starting in .NET 7, GC by default uses all CPU groups when running on Windows 11 or Server 2022.

- Applies to server garbage collection on 64-bit Windows operating systems only.
- Default: GC does not extend across CPU groups. This is equivalent to setting the value to `0`.
- For more information, see [Making CPU configuration better for GC on machines with > 64 CPUs](#) on Maoni Stephens' blog.

 Expand table

| Setting name | Values | Version introduced |
|---------------------------|--|--------------------|
| runtimeconfig.json | System.GC.CpuGroup false - disabled | .NET 5 |

| | Setting name | Values | Version introduced |
|--------------------------------------|---------------------------------|--|---------------------------|
| | | <code>true</code> - enabled | |
| Environment variable | <code>COMPlus_GCCpuGroup</code> | <code>0</code> - disabled <code>1</code> - enabled | .NET Core 1.0 |
| Environment variable | <code>DOTNET_GCCpuGroup</code> | <code>0</code> - disabled <code>1</code> - enabled | .NET 6 |
| app.config for .NET Framework | <code>GCCpuGroup</code> | <code>false</code> - disabled <code>true</code> - enabled | |

This configuration setting doesn't have a specific MSBuild property. However, you can add a `RuntimeHostConfigurationOption` MSBuild item instead. Use the `runtimeconfig.json` setting name as the value of the `Include` attribute. For an example, see [MSBuild properties](#).

ⓘ Note

To configure the common language runtime (CLR) to also distribute threads from the thread pool across all CPU groups, enable the `Thread_UseAllCpuGroups` element option. For .NET Core apps, you can enable this option by setting the value of the `DOTNET_Thread_UseAllCpuGroups` environment variable to `1`.

Affinize

- Specifies whether to *affinize* garbage collection threads with processors. To affinize a GC thread means that it can only run on its specific CPU. A heap is created for each GC thread.
- Applies to server garbage collection only.
- Default: Affinize garbage collection threads with processors. This is equivalent to setting the value to `false`.

[] Expand table

| | Setting name | Values | Version introduced |
|---------------------------|-----------------------------------|---|---------------------------|
| runtimeconfig.json | <code>System.GC.NoAffinize</code> | <code>false</code> - affinize <code>true</code> - don't affinize | .NET Core 3.0 |

| Setting name | Values | Version introduced |
|--------------------------------------|---|----------------------|
| Environment variable | <code>COMPlus_GCNoAffinitize</code> <input type="radio"/> 0 - affinitize <input checked="" type="radio"/> 1 - don't affinitize | .NET Core 3.0 |
| Environment variable | <code>DOTNET_GCNoAffinitize</code> <input type="radio"/> 0 - affinitize <input checked="" type="radio"/> 1 - don't affinitize | .NET 6 |
| app.config for .NET Framework | <code>GCNoAffinitize</code> <input type="radio"/> <code>false</code> - affinitize <input checked="" type="radio"/> <code>true</code> - don't affinitize | .NET Framework 4.6.2 |

This configuration setting doesn't have a specific MSBuild property. However, you can add a `RuntimeHostConfigurationOption` MSBuild item instead. Use the `runtimeconfig.json` setting name as the value of the `Include` attribute. For an example, see [MSBuild properties](#).

Examples

`runtimeconfig.json` file:

JSON

```
{
  "runtimeOptions": {
    "configProperties": {
      "System.GC.NoAffinitize": true
    }
  }
}
```

`runtimeconfig.template.json` file:

JSON

```
{
  "configProperties": {
    "System.GC.NoAffinitize": true
  }
}
```

Heap limit

- Specifies the maximum commit size, in bytes, for the GC heap and GC bookkeeping.
- This setting only applies to 64-bit computers.
- This setting is ignored if the [Per-object-heap limits](#) are configured.
- The default value, which only applies in certain cases, is the greater of 20 MB or 75% of the memory limit on the container. The default value applies if:
 - The process is running inside a container that has a specified memory limit.
 - `System.GC.HeapHardLimitPercent` is not set.

[] Expand table

| | Setting name | Values | Version introduced |
|-----------------------------|--------------------------------------|--------------------------|---------------------------|
| runtimesconfig.json | <code>System.GC.HeapHardLimit</code> | <i>decimal value</i> | .NET Core 3.0 |
| Environment variable | <code>COMPlus_GCHardLimit</code> | <i>hexadecimal value</i> | .NET Core 3.0 |
| Environment variable | <code>DOTNET_GCHardLimit</code> | <i>hexadecimal value</i> | .NET 6 |

This configuration setting doesn't have a specific MSBuild property. However, you can add a `RuntimeHostConfigurationOption` MSBuild item instead. Use the `runtimesconfig.json` setting name as the value of the `Include` attribute. For an example, see [MSBuild properties](#).

Examples

`runtimesconfig.json` file:

JSON

```
{
  "runtimeOptions": {
    "configProperties": {
      "System.GC.HeapHardLimit": 209715200
    }
  }
}
```

`runtimesconfig.template.json` file:

JSON

```
{  
  "configProperties": {  
    "System.GC.HeapHardLimit": 209715200  
  }  
}
```

💡 Tip

If you're setting the option in `runtimeconfig.json`, specify a decimal value. If you're setting the option as an environment variable, specify a hexadecimal value. For example, to specify a heap hard limit of 200 mebibytes (MiB), the values would be 209715200 for the JSON file and 0xC800000 or C800000 for the environment variable.

Heap limit percent

- Specifies the allowable GC heap usage as a percentage of the total physical memory.
- If `System.GC.HeapHardLimit` is also set, this setting is ignored.
- This setting only applies to 64-bit computers.
- If the process is running inside a container that has a specified memory limit, the percentage is calculated as a percentage of that memory limit.
- This setting is ignored if the [Per-object-heap limits](#) are configured.
- The default value, which only applies in certain cases, is the greater of 20 MB or 75% of the memory limit on the container. The default value applies if:
 - The process is running inside a container that has a specified memory limit.
 - `System.GC.HeapHardLimit` is not set.

[+] Expand table

| Setting name | Values | Version introduced |
|-----------------------------------|--|--------------------|
| <code>runtimeconfig.json</code> | <code>System.GC.HeapHardLimitPercent</code> <i>decimal value</i> | .NET Core 3.0 |
| <code>Environment variable</code> | <code>COMPlus_GCHardLimitPercent</code> <i>hexadecimal value</i> | .NET Core 3.0 |

| Setting name | Values | Version introduced |
|-----------------------------|---|--------------------|
| Environment variable | <code>DOTNET_GCHeapHardLimitPercent</code> hexadecimal value | .NET 6 |

This configuration setting doesn't have a specific MSBuild property. However, you can add a `RuntimeHostConfigurationOption` MSBuild item instead. Use the `runtimeconfig.json` setting name as the value of the `Include` attribute. For an example, see [MSBuild properties](#).

Examples

`runtimeconfig.json` file:

JSON

```
{
  "runtimeOptions": {
    "configProperties": {
      "System.GC.HeapHardLimitPercent": 30
    }
  }
}
```

`runtimeconfig.template.json` file:

JSON

```
{
  "configProperties": {
    "System.GC.HeapHardLimitPercent": 30
  }
}
```

Tip

If you're setting the option in `runtimeconfig.json`, specify a decimal value. If you're setting the option as an environment variable, specify a hexadecimal value. For example, to limit the heap usage to 30%, the values would be 30 for the JSON file and 0x1E or 1E for the environment variable.

Per-object-heap limits

You can specify the GC's allowable heap usage on a per-object-heap basis. The different heaps are the large object heap (LOH), small object heap (SOH), and pinned object heap (POH).

- If you specify a value for any of the `DOTNET_GCHeapHardLimitSOH`, `DOTNET_GCHeapHardLimitLOH`, or `DOTNET_GCHeapHardLimitPOH` settings, you must also specify a value for `DOTNET_GCHeapHardLimitSOH` and `DOTNET_GCHeapHardLimitLOH`. If you don't, the runtime will fail to initialize.
- The default value for `DOTNET_GCHeapHardLimitPOH` is 0. `DOTNET_GCHeapHardLimitSOH` and `DOTNET_GCHeapHardLimitLOH` don't have default values.

[+] Expand table

| | Setting name | Values | Version introduced |
|-----------------------------|---|--------------------------|---------------------------|
| runtimeconfig.json | <code>System.GC.HeapHardLimitSOH</code> | <i>decimal value</i> | .NET 5 |

| | Setting name | Values | Version introduced |
|-----------------------------|---|--------------------------|---------------------------|
| runtimeconfig.json | <code>System.GC.HeapHardLimitPOH</code> | <i>decimal value</i> | .NET 5 |
| Environment variable | <code>COMPlus_GCHeapHardLimitPOH</code> | <i>hexadecimal value</i> | .NET 5 |
| Environment variable | <code>DOTNET_GCHeapHardLimitPOH</code> | <i>hexadecimal value</i> | .NET 6 |

These configuration settings don't have specific MSBuild properties. However, you can add a `RuntimeHostConfigurationOption` MSBuild item instead. Use the `runtimeconfig.json` setting name as the value of the `Include` attribute. For an example, see [MSBuild properties](#).

💡 Tip

If you're setting the option in `runtimeconfig.json`, specify a decimal value. If you're setting the option as an environment variable, specify a hexadecimal value. For example, to specify a heap hard limit of 200 mebibytes (MiB), the values would be 209715200 for the JSON file and 0xC800000 or C800000 for the environment variable.

Per-object-heap limit percents

You can specify the GC's allowable heap usage on a per-object-heap basis. The different heaps are the large object heap (LOH), small object heap (SOH), and pinned object heap (POH).

- If you specify a value for any of the `DOTNET_GCHeapHardLimitSOHPercent`, `DOTNET_GCHeapHardLimitLOHPercent`, or `DOTNET_GCHeapHardLimitPOHPercent` settings, you must also specify a value for `DOTNET_GCHeapHardLimitSOHPercent` and `DOTNET_GCHeapHardLimitLOHPercent`. If you don't, the runtime will fail to initialize.
- These settings are ignored if `DOTNET_GCHeapHardLimitSOH`, `DOTNET_GCHeapHardLimitLOH`, and `DOTNET_GCHeapHardLimitPOH` are specified.
- A value of 1 means that GC uses 1% of total physical memory for that object heap.
- Each value must be greater than zero and less than 100. Additionally, the sum of the three percentage values must be less than 100. Otherwise, the runtime will fail to initialize.

[+] Expand table

| Setting name | Values | Version introduced |
|-----------------------------|---|--------------------|
| runtimeconfig.json | <code>System.GC.HeapHardLimitSOHPercent</code> <i>decimal value</i> | .NET 5 |
| Environment variable | <code>COMPlus_GCHeapHardLimitSOHPercent</code> <i>hexadecimal value</i> | .NET 5 |
| Environment variable | <code>DOTNET_GCHeapHardLimitSOHPercent</code> <i>hexadecimal value</i> | .NET 6 |

[+] Expand table

| | Setting name | Values | Version introduced |
|-----------------------------|-----------------------------------|--------------------------|---------------------------|
| runtimeconfig.json | System.GC.HeapHardLimitLOHPercent | <i>decimal value</i> | .NET 5 |
| Environment variable | COMPlus_GCHeapHardLimitLOHPercent | <i>hexadecimal value</i> | .NET 5 |
| Environment variable | DOTNET_GCHeapHardLimitLOHPercent | <i>hexadecimal value</i> | .NET 6 |

[+] Expand table

| | Setting name | Values | Version introduced |
|-----------------------------|-----------------------------------|--------------------------|---------------------------|
| runtimeconfig.json | System.GC.HeapHardLimitPOHPercent | <i>decimal value</i> | .NET 5 |
| Environment variable | COMPlus_GCHeapHardLimitPOHPercent | <i>hexadecimal value</i> | .NET 5 |
| Environment variable | DOTNET_GCHeapHardLimitPOHPercent | <i>hexadecimal value</i> | .NET 6 |

These configuration settings don't have specific MSBuild properties. However, you can add a `RuntimeHostConfigurationOption` MSBuild item instead. Use the *runtimeconfig.json* setting name as the value of the `Include` attribute. For an example, see [MSBuild properties](#).

💡 Tip

If you're setting the option in *runtimeconfig.json*, specify a decimal value. If you're setting the option as an environment variable, specify a hexadecimal value. For example, to limit the heap usage to 30%, the values would be 30 for the JSON file and 0x1E or 1E for the environment variable.

High memory percent

Memory load is indicated by the percentage of physical memory in use. By default, when the physical memory load reaches 90%, garbage collection becomes more aggressive about doing full, compacting garbage collections to avoid paging. When memory load is below 90%, GC favors background collections for full garbage collections, which have shorter pauses but don't reduce the total heap size by much. On

machines with a significant amount of memory (80GB or more), the default load threshold is between 90% and 97%.

The high memory load threshold can be adjusted by the `DOTNET_GCHighMemPercent` environment variable or `System.GC.HighMemoryPercent` JSON configuration setting. Consider adjusting the threshold if you want to control heap size. For example, for the dominant process on a machine with 64GB of memory, it's reasonable for GC to start reacting when there's 10% of memory available. But for smaller processes, for example, a process that only consumes 1GB of memory, GC can comfortably run with less than 10% of memory available. For these smaller processes, consider setting the threshold higher. On the other hand, if you want larger processes to have smaller heap sizes (even when there's plenty of physical memory available), lowering this threshold is an effective way for GC to react sooner to compact the heap down.

 **Note**

For processes running in a container, GC considers the physical memory based on the container limit.

 Expand table

| | Setting name | Values | Version introduced |
|-----------------------------|--|--------------------------|--|
| runtimeconfig.json | <code>System.GC.HighMemoryPercent</code> | <i>decimal value</i> | .NET 5 |
| Environment variable | <code>COMPlus_GCHighMemPercent</code> | <i>hexadecimal value</i> | .NET Core 3.0 .NET Framework 4.7.2 |
| Environment variable | <code>DOTNET_GCHighMemPercent</code> | <i>hexadecimal value</i> | .NET 6 |

This configuration setting doesn't have a specific MSBuild property. However, you can add a `RuntimeHostConfigurationOption` MSBuild item instead. Use the `runtimeconfig.json` setting name as the value of the `Include` attribute. For an example, see [MSBuild properties](#).

 **Tip**

If you're setting the option in `runtimeconfig.json`, specify a decimal value. If you're setting the option as an environment variable, specify a hexadecimal value. For

example, to set the high memory threshold to 75%, the values would be 75 for the JSON file and 0x4B or 4B for the environment variable.

Retain VM

- Configures whether segments that should be deleted are put on a standby list for future use or are released back to the operating system (OS).
- Default: Release segments back to the operating system. This is equivalent to setting the value to `false`.

[Expand table](#)

| | Setting name | Values | Version introduced |
|-----------------------------|--|--|---------------------------|
| runtimconfig.json | <code>System.GC.RetainVM</code> | <code>false</code> - release to OS <code>true</code> - put on standby | .NET Core 1.0 |
| MSBuild property | <code>RetainVMGarbageCollection</code> | <code>false</code> - release to OS <code>true</code> - put on standby | .NET Core 1.0 |
| Environment variable | <code>COMPlus_GCRetainVM</code> | <code>0</code> - release to OS <code>1</code> - put on standby | .NET Core 1.0 |
| Environment variable | <code>DOTNET_GCRetainVM</code> | <code>0</code> - release to OS <code>1</code> - put on standby | .NET 6 |

Examples

runtimconfig.json file:

JSON

```
{  
  "runtimeOptions": {  
    "configProperties": {  
      "System.GC.RetainVM": true  
    }  
  }  
}
```

`runtimconfig.template.json` file:

JSON

```
{  
    "configProperties": {  
        "System.GC.RetainVM": true  
    }  
}
```

Project file:

XML

```
<Project Sdk="Microsoft.NET.Sdk">  
  
    <PropertyGroup>  
        <RetainVMGarbageCollection>true</RetainVMGarbageCollection>  
    </PropertyGroup>  
  
</Project>
```

Large pages

- Specifies whether large pages should be used when a heap hard limit is set.
- Default: Don't use large pages when a heap hard limit is set. This is equivalent to setting the value to `0`.
- This is an experimental setting.

[Expand table](#)

| | Setting name | Values | Version introduced |
|--------------------------------|-----------------------------------|---|--------------------|
| <code>runtimconfig.json</code> | N/A | N/A | N/A |
| Environment variable | <code>COMPlus_GCLargePages</code> | <code>0</code> - disabled <code>1</code> - enabled | .NET Core 3.0 |
| Environment variable | <code>DOTNET_GCLargePages</code> | <code>0</code> - disabled <code>1</code> - enabled | .NET 6 |

Allow large objects

- Configures garbage collector support on 64-bit platforms for arrays that are greater than 2 gigabytes (GB) in total size.
- Default: GC supports arrays greater than 2-GB. This is equivalent to setting the value to 1.
- This option may become obsolete in a future version of .NET.

[\[+\] Expand table](#)

| | Setting name | Values | Version introduced |
|--------------------------------------|--|--|--------------------|
| runtimeconfig.json | N/A | N/A | N/A |
| Environment variable | <code>COMPlus_gcAllowVeryLargeObjects</code> | <input checked="" type="checkbox"/> 1 - enabled <input type="checkbox"/> 0 - disabled | .NET Core 1.0 |
| Environment variable | <code>DOTNET_gcAllowVeryLargeObjects</code> | <input checked="" type="checkbox"/> 1 - enabled <input type="checkbox"/> 0 - disabled | .NET 6 |
| app.config for .NET Framework | <code>gcAllowVeryLargeObjects</code> | <input checked="" type="checkbox"/> 1 - enabled <input type="checkbox"/> 0 - disabled | .NET Framework 4.5 |

Large object heap threshold

- Specifies the threshold size, in bytes, that causes objects to go on the large object heap (LOH).
- The default threshold is 85,000 bytes.
- The value you specify must be larger than the default threshold.
- The value might be capped by the runtime to the maximum possible size for the current configuration. You can inspect the value in use at run time through the [GC.GetConfigurationVariables\(\)](#) API.

[\[+\] Expand table](#)

| | Setting name | Values | Version introduced |
|---------------------------|-------------------------------------|----------------------|--------------------|
| runtimeconfig.json | <code>System.GC.LOHThreshold</code> | <i>decimal value</i> | .NET Core 1.0 |

| Setting name | Values | Version introduced |
|--------------------------------------|---|--------------------|
| Environment variable | <code>COMPlus_GCLOHThreshold</code> <i>hexadecimal value</i> | .NET Core 1.0 |
| Environment variable | <code>DOTNET_GCLOHThreshold</code> <i>hexadecimal value</i> | .NET 6 |
| app.config for .NET Framework | <code>GCLOHThreshold</code> <i>decimal value</i> | .NET Framework 4.8 |

This configuration setting doesn't have a specific MSBuild property. However, you can add a `RuntimeHostConfigurationOption` MSBuild item instead. Use the `runtimeconfig.json` setting name as the value of the `Include` attribute. For an example, see [MSBuild properties](#).

Examples

`runtimeconfig.json` file:

```
JSON
{
  "runtimeOptions": {
    "configProperties": {
      "System.GC.LOHTreshold": 120000
    }
  }
}
```

`runtimeconfig.template.json` file:

```
JSON
{
  "configProperties": {
    "System.GC.LOHTreshold": 120000
  }
}
```

Tip

If you're setting the option in `runtimeconfig.json`, specify a decimal value. If you're setting the option as an environment variable, specify a hexadecimal value. For

example, to set a threshold size of 120,000 bytes, the values would be 120000 for the JSON file and 0x1D4C0 or 1D4C0 for the environment variable.

Standalone GC

- Specifies the name of a GC native library that the runtime loads in place of the default GC implementation. This native library needs to reside in the same directory as the .NET runtime (**coreclr.dll** on Windows, **libcoreclr.so** on Linux).

[Expand table](#)

| | Setting name | Values | Version introduced |
|-----------------------------|-----------------------------|--------------------|--------------------|
| runtimeconfig.json | N/A | N/A | N/A |
| Environment variable | <code>COMPlus_GCName</code> | <i>string_path</i> | .NET Core 2.0 |
| Environment variable | <code>DOTNET_GCName</code> | <i>string_path</i> | .NET 6 |

Conserve memory

- Configures the garbage collector to conserve memory at the expense of more frequent garbage collections and possibly longer pause times.
- Default value is 0 - this implies no change.
- Besides the default value 0, values between 1 and 9 (inclusive) are valid. The higher the value, the more the garbage collector tries to conserve memory and thus to keep the heap small.
- If the value is non-zero, the large object heap will be compacted automatically if it has too much fragmentation.

[Expand table](#)

| | Setting name | Values | Version introduced |
|--------------------------------------|---------------------------------------|--------|--------------------|
| runtimeconfig.json | <code>System.GC.ConserveMemory</code> | 0 - 9 | .NET 6 |
| Environment variable | <code>COMPlus_GCConserveMemory</code> | 0 - 9 | .NET Framework 4.8 |
| Environment variable | <code>DOTNET_GCConserveMemory</code> | 0 - 9 | .NET 6 |
| app.config for .NET Framework | <code>GCConserveMemory</code> | 0 - 9 | .NET Framework 4.8 |

This configuration setting doesn't have a specific MSBuild property. However, you can add a `RuntimeHostConfigurationOption` MSBuild item instead. Use the `runtimeconfig.json` setting name as the value of the `Include` attribute. For an example, see [MSBuild properties](#).

Example `app.config` file:

XML

```
<configuration>
  <runtime>
    <GCConserveMemory enabled="5"/>
  </runtime>
</configuration>
```

Tip

Experiment with different numbers to see which value works best for you. Start with a value between 5 and 7.

Runtime configuration options for globalization

Article • 11/11/2023

Invariant mode

- Determines whether a .NET Core app runs in globalization-invariant mode without access to culture-specific data and behavior.
- If you omit this setting, the app runs with access to cultural data. This is equivalent to setting the value to `false`.
- For more information, see [.NET Core globalization invariant mode ↗](#).

| | Setting name | Values |
|-----------------------------|--|---|
| runtimesconfig.json | <code>System.Globalization.Invariant</code> | <code>false</code> - access to cultural data <code>true</code> - run in invariant mode |
| MSBuild property | <code>InvariantGlobalization</code> | <code>false</code> - access to cultural data <code>true</code> - run in invariant mode |
| Environment variable | <code>DOTNET_SYSTEM_GLOBALIZATION_INVARIANT</code> | <code>0</code> - access to cultural data <code>1</code> - run in invariant mode |

Examples

runtimesconfig.json file:

```
JSON

{
  "runtimeOptions": {
    "configProperties": {
      "System.Globalization.Invariant": true
    }
  }
}
```

runtimesconfig.template.json file:

```
JSON

{
  "configProperties": {
    "System.Globalization.Invariant": true
  }
}
```

```
}
```

Project file:

XML

```
<Project Sdk="Microsoft.NET.Sdk">

<PropertyGroup>
    <InvariantGlobalization>true</InvariantGlobalization>
</PropertyGroup>

</Project>
```

Era year ranges

- Determines whether range checks for calendars that support multiple eras are relaxed or whether dates that overflow an era's date range throw an [ArgumentException](#).
- If you omit this setting, range checks are relaxed. This is equivalent to setting the value to `false`.
- For more information, see [Calendars, eras, and date ranges: Relaxed range checks](#).

| Setting name | Values |
|-----------------------------|--|
| runtimeconfig.json | <code>Switch.System.Globalization.EnforceJapaneseEraYearRanges</code> <code>false</code> - relaxed range checks <code>true</code> - overflows cause an exception |
| Environment variable | N/A |

This configuration setting doesn't have a specific MSBuild property. However, you can add a `RuntimeHostConfigurationOption` MSBuild item instead. Use the `runtimeconfig.json` setting name as the value of the `Include` attribute. For an example, see [MSBuild properties](#).

Japanese date parsing

- Determines whether a string that contains either "1" or "Gannen" as the year parses successfully or whether only "1" is supported.

- If you omit this setting, strings that contain either "1" or "Gannen" as the year parse successfully. This is equivalent to setting the value to `false`.
- For more information, see [Represent dates in calendars with multiple eras](#).

| | Setting name | Values |
|-----------------------------|---|--|
| runtimeconfig.json | <code>Switch.System.Globalization.EnforceLegacyJapaneseDateParsing</code> | <code>false</code> - "Gannen" or "1" is supported <code>true</code> - only "1" is supported |
| Environment variable | N/A | N/A |

This configuration setting doesn't have a specific MSBuild property. However, you can add a `RuntimeHostConfigurationOption` MSBuild item instead. Use the `runtimeconfig.json` setting name as the value of the `Include` attribute. For an example, see [MSBuild properties](#).

Japanese year format

- Determines whether the first year of a Japanese calendar era is formatted as "Gannen" or as a number.
- If you omit this setting, the first year is formatted as "Gannen". This is equivalent to setting the value to `false`.
- For more information, see [Represent dates in calendars with multiple eras](#).

| | Setting name | Values |
|-----------------------------|---|---|
| runtimeconfig.json | <code>Switch.System.Globalization.FormatJapaneseFirstYearAsANumber</code> | <code>false</code> - format as "Gannen" <code>true</code> - format as number |
| Environment variable | N/A | N/A |

This configuration setting doesn't have a specific MSBuild property. However, you can add a `RuntimeHostConfigurationOption` MSBuild item instead. Use the `runtimeconfig.json` setting name as the value of the `Include` attribute. For an example, see [MSBuild properties](#).

NLS

- Determines whether .NET uses National Language Support (NLS) or International Components for Unicode (ICU) globalization APIs for Windows apps. .NET 5 and later versions use ICU globalization APIs by default on Windows 10 May 2019 Update and later versions.
- If you omit this setting, .NET uses ICU globalization APIs by default. This is equivalent to setting the value to `false`.
- For more information, see [Globalization APIs use ICU libraries on Windows](#).

| | Setting name | Values | Introduced |
|-----------------------------|---|---|-------------------|
| runtimesconfig.json | <code>System.Globalization.UseNls</code> | <code>false</code> - Use ICU globalization APIs <code>true</code> - Use NLS globalization APIs | .NET 5 |
| Environment variable | <code>DOTNET_SYSTEM_GLOBALIZATION_USENLS</code> | <code>false</code> - Use ICU globalization APIs <code>true</code> - Use NLS globalization APIs | .NET 5 |

This configuration setting doesn't have a specific MSBuild property. However, you can add a `RuntimeHostConfigurationOption` MSBuild item instead. Use the `runtimesconfig.json` setting name as the value of the `Include` attribute. For an example, see [MSBuild properties](#).

Predefined cultures

- Configures whether apps can create cultures other than the invariant culture when [globalization-invariant mode](#) is enabled.
- If you omit this setting, .NET restricts the creation of cultures in globalization-invariant mode. This is equivalent to setting the value to `true`.
- For more information, see [Culture creation and case mapping in globalization-invariant mode](#).

| | Setting name | Values | Introduced |
|----------------------------|--|---|-------------------|
| runtimesconfig.json | <code>System.Globalization.PredefinedCulturesOnly</code> | <code>true</code> - In globalization-invariant mode, don't allow creation of any culture except the | .NET 6 |

| Setting name | Values | Introduced |
|---|---|------------|
| | invariant culture. <code>false</code> - Allow creation of any culture. | |
| MSBuild property <code>PredefinedCulturesOnly</code> | <code>true</code> - In globalization-invariant mode, don't allow creation of any culture except the invariant culture. <code>false</code> - Allow creation of any culture. | .NET 6 |
| Environment variable <code>DOTNET_SYSTEM_GLOBALIZATION_PREDEFINED_CULTURES_ONLY</code> | <code>true</code> - In globalization-invariant mode, don't allow creation of any culture except the invariant culture. <code>false</code> - Allow creation of any culture. | .NET 6 |

Runtime configuration options for networking

Article • 11/11/2023

HTTP/2 protocol

- Configures whether support for the HTTP/2 protocol is enabled.
- Introduced in .NET Core 3.0.
- .NET Core 3.0 only: If you omit this setting, support for the HTTP/2 protocol is disabled. This is equivalent to setting the value to `false`.
- .NET Core 3.1 and .NET 5+: If you omit this setting, support for the HTTP/2 protocol is enabled. This is equivalent to setting the value to `true`.

| | Setting name | Values |
|-----------------------------|---|--|
| runtimesconfig.json | <code>System.Net.Http.SocketsHttpHandler.Http2Support</code> | <code>false</code> - disabled <code>true</code> - enabled |
| Environment variable | <code>DOTNET_SYSTEM_NET_HTTP_SOCKETSHANDLER_HTTP2SUPPORT</code> | <code>0</code> - disabled <code>1</code> - enabled |

This configuration setting doesn't have a specific MSBuild property. However, you can add a `RuntimeHostConfigurationOption` MSBuild item instead. Use the `runtimesconfig.json` setting name as the value of the `Include` attribute. For an example, see [MSBuild properties](#).

SPN creation in HttpClient (.NET 6 and later)

- Impacts generation of [service principal names](#) (SPN) for Kerberos and NTLM authentication when `Host` header is missing and target is not running on default port.
- .NET Core 2.x and 3.x do not include port in SPN.
- .NET Core 5.x does include port in SPN
- .NET 6 and later versions don't include the port, but the behavior is configurable.

| Setting name | Values |
|-----------------------------|--|
| runtimeconfig.json | <code>System.Net.Http.UsePortInSpn</code> <code>true</code> - includes port number in SPN, for example, <code>HTTP/host:port</code> <code>false</code> - does not include port in SPN, for example, <code>HTTP/host</code> |
| Environment variable | <code>DOTNET_SYSTEM_NET_HTTP_USEPORTINSPN</code> <code>1</code> - includes port number in SPN, for example, <code>HTTP/host:port</code> <code>0</code> - does not include port in SPN, for example, <code>HTTP/host</code> |

This configuration setting doesn't have a specific MSBuild property. However, you can add a `RuntimeHostConfigurationOption` MSBuild item instead. Use the *runtimeconfig.json* setting name as the value of the `Include` attribute. For an example, see [MSBuild properties](#).

UseSocketsHttpHandler (.NET Core 2.1-3.1 only)

- Configures whether `System.Net.Http.HttpClientHandler` uses `System.Net.Http.SocketsHttpHandler` or older HTTP protocol stacks (`WinHttpHandler` on Windows and `CurlHandler`, an internal class implemented on top of `libcurl`, on Linux).

! Note

You may be using high-level networking APIs instead of directly instantiating the `HttpClientHandler` class. This setting also affects which HTTP protocol stack is used by high-level networking APIs, including `HttpClient` and `HttpClientFactory`.

- If you omit this setting, `HttpClientHandler` uses `SocketsHttpHandler`. This is equivalent to setting the value to `true`.

| Setting name | Values |
|---------------------------|---|
| runtimeconfig.json | <code>System.Net.Http.UseSocketsHttpHandler</code> <code>true</code> - enables the use of <code>SocketsHttpHandler</code> <code>false</code> - enables the use of <code>WinHttpHandler</code> on Windows or <code>libcurl</code> on Linux |

| Setting name | Values |
|-----------------------------|--|
| Environment variable | <code>DOTNET_SYSTEM_NET_HTTP_USESOCKETSHTTPHANDLER</code> 1 - enables the use of SocketsHttpHandler 0 - enables the use of WinHttpHandler on Windows or libcurl on Linux |

ⓘ Note

Starting in .NET 5, the `System.Net.Http.UseSocketsHttpHandler` setting is no longer available.

Latin1 headers (.NET Core 3.1 only)

- This switch allows relaxing the HTTP header validation, enabling [SocketsHttpHandler](#) to send ISO-8859-1 (Latin-1) encoded characters in headers.
- If you omit this setting, an attempt to send a non-ASCII character will result in [HttpRequestException](#). This is equivalent to setting the value to `false`.

| Setting name | Values |
|-----------------------------|--|
| runtimeconfig.json | <code>System.Net.Http.SocketsHttpHandler.AllowLatin1Headers</code> <code>false</code> - disabled <code>true</code> - enabled |
| Environment variable | <code>DOTNET_SYSTEM_NET_HTTP_SOCKETSHTTPHANDLER_ALLOWLATIN1HEADERS</code> <code>0</code> - disabled <code>1</code> - enabled |

ⓘ Note

This option is only available in .NET Core 3.1 since version 3.1.9, and not in previous or later versions. In .NET 5 we recommend using [RequestHeaderEncodingSelector](#).

Runtime configuration options for threading

Article • 09/23/2023

This article details the settings you can use to configure threading in .NET.

! Note

.NET 6 standardizes on the prefix `DOTNET_` instead of `COMPlus_` for environment variables that configure .NET run-time behavior. However, the `COMPlus_` prefix will continue to work. If you're using a previous version of the .NET runtime, you should still use the `COMPlus_` prefix for environment variables.

Use all CPU groups on Windows

- On machines that have multiple CPU groups, this setting configures whether components such as the thread pool use all CPU groups or only the primary CPU group of the process. The setting also affects what `Environment.ProcessorCount` returns.
- When this setting is enabled, all CPU groups are used and threads are also [automatically distributed across CPU groups](#) by default.
- This setting is enabled by default on Windows 11 and later versions, and disabled by default on Windows 10 and earlier versions. For this setting to take effect when enabled, the GC must also be configured to use all CPU groups; for more information, see [GC CPU groups](#).

| | Setting name | Values |
|-----------------------------|---|--|
| runtimesconfig.json | N/A | N/A |
| Environment variable | <code>COMPlus_Thread_UseAllCpuGroups</code> or <code>DOTNET_Thread_UseAllCpuGroups</code> | <input type="radio"/> 0 - disabled <input checked="" type="radio"/> 1 - enabled |

Assign threads to CPU groups on Windows

- On machines that have multiple CPU groups and [all CPU groups are being used](#), this setting configures whether threads are automatically distributed across CPU groups.
- When this setting is enabled, new threads are assigned to a CPU group in a way that tries to fully populate a CPU group that is already in use before utilizing a new CPU group.
- This setting is enabled by default.

| | Setting name | Values |
|-----------------------------|---|--|
| runtimesconfig.json | N/A | N/A |
| Environment variable | <code>COMPlus_Thread_AssignCpuGroups</code> or <code>DOTNET_Thread_AssignCpuGroups</code> | <input type="radio"/> 0 - disabled <input checked="" type="radio"/> 1 - enabled |

Minimum threads

- Specifies the minimum number of threads for the worker thread pool.
- Corresponds to the [ThreadPool.SetMinThreads](#) method.

| | Setting name | Values |
|-----------------------------|---|--|
| runtimeconfig.json | <code>System.Threading.ThreadPool.MinThreads</code> | An integer that represents the minimum number of threads |
| MSBuild property | <code>ThreadPoolMinThreads</code> | An integer that represents the minimum number of threads |
| Environment variable | N/A | N/A |

Examples

runtimeconfig.json file:

```
JSON

{
  "runtimeOptions": {
    "configProperties": {
      "System.Threading.ThreadPool.MinThreads": 4
    }
  }
}
```

runtimeconfig.template.json file:

```
JSON

{
  "configProperties": {
    "System.Threading.ThreadPool.MinThreads": 4
  }
}
```

Project file:

```
XML

<Project Sdk="Microsoft.NET.Sdk">

  <PropertyGroup>
    <ThreadPoolMinThreads>4</ThreadPoolMinThreads>
  </PropertyGroup>

</Project>
```

Maximum threads

- Specifies the maximum number of threads for the worker thread pool.
- Corresponds to the [ThreadPool.SetMaxThreads](#) method.

| Setting name | Values |
|-----------------------------|---|
| runtimeconfig.json | <code>System.Threading.ThreadPool.MaxThreads</code> An integer that represents the maximum number of threads |
| MSBuild property | <code>ThreadPoolMaxThreads</code> An integer that represents the maximum number of threads |
| Environment variable | N/A |

Examples

runtimeconfig.json file:

JSON

```
{
  "runtimeOptions": {
    "configProperties": {
      "System.Threading.ThreadPool.MaxThreads": 20
    }
  }
}
```

runtimeconfig.template.json file:

JSON

```
{
  "configProperties": {
    "System.Threading.ThreadPool.MaxThreads": 20
  }
}
```

Project file:

XML

```
<Project Sdk="Microsoft.NET.Sdk">

  <PropertyGroup>
    <ThreadPoolMaxThreads>20</ThreadPoolMaxThreads>
  </PropertyGroup>

</Project>
```

Windows thread pool

- For projects on Windows, configures whether thread pool thread management is delegated to the Windows thread pool.
- If you omit this setting or the platform is not Windows, the .NET thread pool is used instead.

- Only applications published with Native AOT on Windows use the Windows thread pool by default, for which you can opt to use the .NET thread pool instead by disabling the config setting.
- The Windows thread pool may perform better in some cases, such as in cases where the minimum number of threads is configured to a high value, or when the Windows thread pool is already being heavily used by the app. There may also be cases where the .NET thread pool performs better, such as in heavy I/O handling on larger machines. It's advisable to check performance metrics when changing this config setting.
- Some APIs are not supported when using the Windows thread pool, such as [ThreadPool.SetMinThreads](#), [ThreadPool.SetMaxThreads](#), and [ThreadPool.BindHandle\(SafeHandle\)](#). Thread pool config settings for minimum and maximum threads are also not effective. An alternative to [ThreadPool.BindHandle\(SafeHandle\)](#) is the [ThreadPoolBoundHandle](#) class.

| Setting name | Values | Version introduced |
|-----------------------------|---|--------------------|
| runtimesconfig.json | <code>System.Threading.ThreadPool.UseWindowsThreadPool</code> <code>true</code> - enabled <code>false</code> - disabled | .NET 8 |
| MSBuild property | <code>UseWindowsThreadPool</code> <code>true</code> - enabled <code>false</code> - disabled | .NET 8 |
| Environment variable | <code>DOTNET_Threadpool_UseWindowsThreadPool</code> <code>1</code> - enabled <code>0</code> - disabled | .NET 8 |

Examples

runtimesconfig.json file:

```
JSON

{
  "runtimeOptions": {
    "configProperties": {
      "System.Threading.ThreadPool.UseWindowsThreadPool": true
    }
  }
}
```

runtimesconfig.template.json file:

```
JSON

{
  "configProperties": {
    "System.Threading.ThreadPool.UseWindowsThreadPool": true
  }
}
```

Project file:

```
XML
```

```

<Project Sdk="Microsoft.NET.Sdk">

  <PropertyGroup>
    <UseWindowsThreadPool>true</UseWindowsThreadPool>
  </PropertyGroup>

</Project>

```

Thread injection in response to blocking work items

In some cases, the thread pool detects work items that block its threads. To compensate, it injects more threads. In .NET 6+, you can use the following [runtime configuration](#) settings to configure thread injection in response to blocking work items. Currently, these settings take effect only for work items that wait for another task to complete, such as in typical [sync-over-async](#) cases.

| runtimeconfig.json setting name | Description | Version introduced |
|--|---|---------------------------|
| <code>System.Threading.ThreadPool.Blocking.ThreadsToAddWithoutDelay_ProcCountFactor</code> | After the thread count based on <code>MinThreads</code> is reached, this value (after it is multiplied by the processor count) specifies how many additional threads may be created without a delay. | .NET 6 |
| <code>System.Threading.ThreadPool.Blocking.ThreadsPerDelayStep_ProcCountFactor</code> | After the thread count based on <code>ThreadsToAddWithoutDelay</code> is reached, this value (after it is multiplied by the processor count) specifies after how many threads an additional <code>DelayStepMs</code> would be added to the delay before each new thread is created. | .NET 6 |
| <code>System.Threading.ThreadPool.Blocking.DelayStepMs</code> | After the thread count based on <code>ThreadsToAddWithoutDelay</code> is reached, this value specifies how much additional delay to add per <code>ThreadsPerDelayStep</code> threads, which would be applied before each new thread is created. | .NET 6 |
| <code>System.Threading.ThreadPool.Blocking.MaxDelayMs</code> | After the thread count based on <code>ThreadsToAddWithoutDelay</code> is reached, this value | .NET 6 |

| runtimesconfig.json setting name | Description | Version introduced |
|---|---|---------------------------|
| <code>System.Threading.ThreadPool.Blocking.IgnoreMemoryUsage</code> | specifies the max delay to use before each new thread is created. | |

How the configuration settings take effect

- After the thread count based on `MinThreads` is reached, up to `ThreadsToAddWithoutDelay` additional threads may be created without a delay.
- After that, before each additional thread is created, a delay is induced, starting with `DelayStepMs`.
- For every `ThreadsPerDelayStep` threads that are added with a delay, an additional `DelayStepMs` is added to the delay.
- The delay may not exceed `MaxDelayMs`.
- Delays are only induced before creating threads. If threads are already available, they would be released without delay to compensate for blocking work items.
- Physical memory usage and limits are also used and, beyond a threshold, the system switches to slower thread injection.

Examples

runtimesconfig.json file:

JSON

```
{
  "runtimeOptions": {
    "configProperties": {
      "System.Threading.ThreadPool.Blocking.ThreadsToAddWithoutDelay_ProcCountFactor": 5
    }
  }
}
```

runtimesconfig.template.json file:

JSON

```
{
  "configProperties": {
    "System.Threading.ThreadPool.Blocking.ThreadsToAddWithoutDelay_ProcCountFactor": 5
  }
}
```

AutoreleasePool for managed threads

This option configures whether each managed thread receives an implicit [NSAutoreleasePool](#) when running on a supported macOS platform.

| | Setting name | Values | Version introduced |
|-----------------------------|--|---------------|---------------------------|
| runtimeconfig.json | <code>System.Threading.Thread.EnableAutoreleasePool</code> | true or false | .NET 6 |
| MSBuild property | <code>AutoreleasePoolSupport</code> | true or false | .NET 6 |
| Environment variable | N/A | N/A | N/A |

Examples

runtimeconfig.json file:

JSON

```
{
  "runtimeOptions": {
    "configProperties": {
      "System.Threading.Thread.EnableAutoreleasePool": true
    }
  }
}
```

runtimeconfig.template.json file:

JSON

```
{
  "configProperties": {
    "System.Threading.Thread.EnableAutoreleasePool": true
  }
}
```

Project file:

XML

```
<Project Sdk="Microsoft.NET.Sdk">

  <PropertyGroup>
    <AutoreleasePoolSupport>true</AutoreleasePoolSupport>
  </PropertyGroup>
```

Runtime configuration options for WPF

Article • 11/11/2023

This article details the settings you can use to configure Windows Presentation Framework (WPF) in .NET.

⚠ Note

.NET 6 standardizes on the prefix `DOTNET_` instead of `COMPlus_` for environment variables that configure .NET run-time behavior. However, the `COMPlus_` prefix will continue to work. If you're using a previous version of the .NET runtime, you should still use the `COMPlus_` prefix for environment variables.

Hardware acceleration in RDP

- Configures whether hardware acceleration is used for WPF apps that are accessed through Remote Desktop Protocol (RDP). Hardware acceleration refers to the use of a computer's graphics processing unit (GPU) to speed up the rendering of graphics and visual effects in an application. This can result in improved performance and more seamless, responsive graphics.
- If you omit this setting, graphics are rendered by software instead. This is equivalent to setting the value to `false`.

| Setting name | Values | Version introduced |
|-----------------------------------|--|--------------------|
| <code>runtimconfig.json</code> | <code>Switch.System.Windows.Media.EnableHardwareAccelerationInRdp</code> <code>true</code> - enabled <code>false</code> - disabled | .NET 8 |
| <code>Environment variable</code> | N/A | N/A |

This configuration setting doesn't have a specific MSBuild property. However, you can add a `RuntimeHostConfigurationOption` MSBuild item instead. Use the `runtimconfig.json` setting name as the value of the `Include` attribute. For an example, see [MSBuild properties](#).

Troubleshoot app launch failures

Article • 04/01/2023

This article describes some common reasons and possible solutions for application launch failures. It relates to [framework-dependent applications](#), which rely on a .NET installation on your machine.

If you already know which .NET version you need, you can download it from [.NET downloads](#).

.NET installation not found

If a .NET installation isn't found, the application fails to launch with a message similar to:

```
Console

You must install .NET to run this application.

App: C:\repos\myapp\myapp.exe
Architecture: x64
Host version: 7.0.0
.NET location: Not found
```

The error message includes a link to download .NET. You can follow that link to get to the appropriate download page. You can also pick the .NET version (specified by `Host version`) from [.NET downloads](#).

On the [download page](#) for the required .NET version, find the **.NET Runtime** download that matches the architecture listed in the error message. You can then install it by downloading and running an **Installer**.

Alternatively, on the [download page](#) for the required .NET version, you can download **Binaries** for the specified architecture.

Required framework not found

If a required framework or compatible version isn't found, the application fails to launch with a message similar to:

```
Console
```

You must install or update .NET to run this application.

App: C:\repos\myapp\myapp.exe

Architecture: x64

Framework: 'Microsoft.NETCore.App', version '5.0.15' (x64)

.NET location: C:\Program Files\dotnet\

The following frameworks were found:

6.0.2 at [c:\Program Files\dotnet\shared\Microsoft.NETCore.App]

The error indicates the name, version, and architecture of the missing framework and the location at which it's expected to be installed. To run the application, you can [install a compatible runtime](#) at the specified ".NET location". If the application targets a lower version than one you have installed and you'd like to run it on a higher version, you can also [configure roll-forward behavior](#) for the application.

Install a compatible runtime

The error message includes a link to download the missing framework. You can follow this link to get to the appropriate download page.

Alternately, you can download a runtime from the [.NET downloads](#) page. There are multiple .NET runtime downloads.

The following table shows the frameworks that each runtime contains.

[+] Expand table

| Runtime download | Included frameworks |
|----------------------|---|
| ASP.NET Core Runtime | Microsoft.NETCore.App Microsoft.AspNetCore.App |
| .NET Desktop Runtime | Microsoft.NETCore.App Microsoft.WindowsDesktop.App |
| .NET Runtime | Microsoft.NETCore.App |

Select a runtime download that contains the missing framework, and then install it.

On the [download page](#) for the required .NET version, find the runtime download that matches the architecture listed in the error message. You likely want to download an [Installer](#).

Alternatively, on the [download page](#) for the required .NET version, you can download **Binaries** for the specified architecture.

In most cases, when the application that failed to launch is using such an installation, the ".NET location" in the error message points to:

```
%ProgramFiles%\dotnet
```

Other options

There are other installation and workaround options to consider.

Run the dotnet-install script

Download the [dotnet-install script](#) for your operating system. Run the script with options based on the information in the error message. The [dotnet-install script reference page](#) shows all available options.

Launch [PowerShell](#) and run:

```
PowerShell  
  
dotnet-install.ps1 -Architecture <architecture> -InstallDir <directory> -  
Runtime <runtime> -Version <version>
```

For example, the error message in the previous section would correspond to:

```
PowerShell  
  
dotnet-install.ps1 -Architecture x64 -InstallDir "C:\Program Files\dotnet\"  
-Runtime dotnet -Version 5.0.15
```

If you encounter an error stating that running scripts is disabled, you may need to set the [execution policy](#) to allow the script to run:

```
PowerShell  
  
Set-ExecutionPolicy Bypass -Scope Process
```

For more information on installation using the script, see [Install with PowerShell automation](#).

Download binaries

You can download a binary archive of .NET from the [download page](#). From the **Binaries** column of the runtime download, download the binary release matching the required architecture. Extract the downloaded archive to the ".NET location" specified in the error message.

For more information about manual installation, see [Install .NET on Windows](#)

Configure roll-forward behavior

If you already have a higher version of the required framework installed, you can make the application run on that higher version by configuring its roll-forward behavior.

When running the application, you can specify the [--roll-forward command line option](#) or set the [DOTNET_ROLL_FORWARD environment variable](#). By default, an application requires a framework that matches the same major version that the application targets, but can use a higher minor or patch version. However, application developers may have specified a different behavior. For more information, see [Framework-dependent apps roll-forward](#).

ⓘ Note

Since using this option lets the application run on a different framework version than the one for which it was designed, it may result in unintended behavior due to changes between versions of a framework.

Breaking changes

Multi-level lookup disabled for .NET 7 and later

On Windows, before .NET 7, the application could search for frameworks in multiple [install locations](#).

1. Subdirectories relative to:

- `dotnet` executable when running the application through `dotnet`.
- `DOTNET_ROOT` environment variable (if set) when running the application through its executable (`apphost`).

2. Globally registered install location (if set) in

`HKLM\SOFTWARE\dotnet\Setup\InstalledVersions\<arch>\InstallLocation`.

3. Default install location of `%ProgramFiles%\dotnet` (or `%ProgramFiles(x86)%\dotnet` for 32-bit processes on 64-bit Windows).

This multi-level lookup behavior was enabled by default but could be disabled by setting the environment variable `DOTNET_MULTILEVEL_LOOKUP=0`.

For applications targeting .NET 7 and later, multi-level lookup is completely disabled and only one location—the first location where a .NET installation is found—is searched. When an application is run through `dotnet`, frameworks are only searched for in subdirectories relative to `dotnet`. When an application is run through its executable (`apphost`), frameworks are only searched for in the first of the previously listed locations where .NET is found.

For more information, see [Multi-level lookup is disabled](#).
